A.—Printed copies of British patents can be obtained from the Comptroller of Patents, 25 Southampton Bldg., London, England, and German patents, of Kaiserliches Patentamt, Gitschinerstrasse 97/103, Berlin, S. W. 61, Germany. Photographic copies of specifications and drawings of foreign patents can be obtained from the U. S. Patent Office, Washington, D. C. The cost of copies on paper 7 by 11½ inches, single page only, is 15 cents per print. Copies on paper 11½ by 14 inches, composing single or double pages, are 25 cents per print.

MAKING MICROMETER CALIPER SCREWS

H. G.—How are the screws of micrometer calipers cut? Are they afterwards lapped or not? Are they tested for pitch, and if so by what method?

A.—The practice of the different makers of micrometer calipers differs widely. One well-known maker cuts the screws on small special screw-cutting lathes in essentially the same manner as screws are chased on the ordinary engine lathe. Another well-known maker is said to cut micrometer screws in the automatic screw machine, using special chasing dies for the purpose. Another rolls the threads with thread rolling dies. All the makers test the screws for accuracy and some of them compensate for inaccuracies by inclining the datum line on the barrel to the axis of the barrel. The datum line is inclined to the right or left, depending on whether the screw is long or short in the lead. Contributions on the subject are invited from readers.

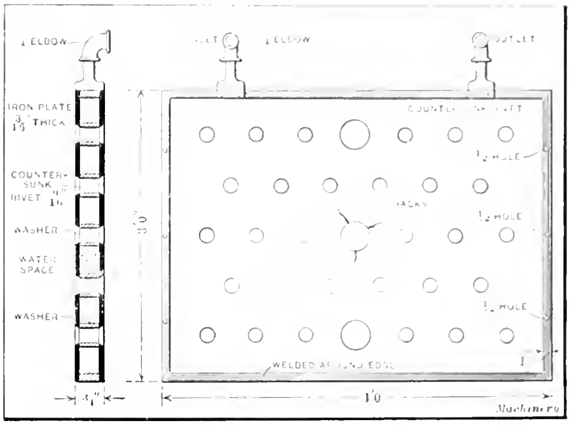
THE FOX LATHE

E. R. R.—I am running a Fox lathe. A friend asked me why it was called a Fox lathe, and I am unable to answer the question. Any information on the origin and history of this machine tool will be appreciated.

A.—The Fox lathe was first built by George H. Fox, who started in business with a partner as a machinist in Boston, Mass., in 1843. The lathe was developed some time between this date and 1859, when it was first advertised as the product of George H. Fox & Co., 45 Kingston St., Boston. The business was incorporated in 1864 as the American Machine & Tool Co., with Mr. Fox president, and this company has built it as a small side line ever since. Distinguishing features of the Fox lathe are a compound slide rest which in later years was usually surmounted by a tool turret and a screw chasing attachment, advertised by Fox as "Nason's patent screw chasing apparatus." This consists of a tool-holder clamped to a longitudinal round bar which is mounted in bearings so that it can both oscillate and slide endways. A half-nut, fixed to the bar, is brought into engagement with a short lead-screw when the operator pulls the chasing tool against the work. To change the pitch of the screw chased, it is necessary to change the lead-screw. Some improved forms of the Fox lathe have several lead-screws mounted on a revolving frame so that any one can be brought into use by turning a handle. The Fox lathe was also built many years ago by the Exeter Machine Works, Exeter, N. H. It is and always was primarily a brass-working lathe, and is widely used in the manufacture of brass valves, gas fixtures, plumbing supplies and other brass goods.

TO PREVENT RIVETS LEAKING IN STEAM PLATES

A. E. D.—We are using the oxy-acetylene welding process for welding rivets in steam plates of the form shown in the accompanying illustration with poor results and would like suggestions for overcoming the troubles. The steam plates are made of two iron plates three feet wide, four feet long laid on each side of a welded rectangular frame and are held together by rivet stays. The over-all thickness of the assembled plate is ¾ inch. The plates are 3/16 inch thick and ¾ inch space is provided between them for steam and water. The rivets are 9/16 inch diameter and are spaced at intervals of about six inches each way; washers are provided between the plates to support them when riveting. These plates are used in the manufacture of underwear, about twenty of them being piled up on a press with the goods between them. A pressure of about sixty tons is applied in a hydraulic press, and, through pipe connections provided, steam is turned on for a certain time and then shut off and cold water is circulated through the plates. The result is that the expansion and contraction stresses are very severe and the rivets soon begin to leak. We have used the oxy-acetylene apparatus for welding the rivets to the plates but the plates crack around the heads. It then becomes necessary to put in



Steam Plate for treating Textile Fabrics that leaks at the Rivets

larger rivets, some of them now being as large as two inches diameter, bnt still the plates crack around the holes. They seem to crack worse since we started riveting them than before.

A.—The expansion and contraction stresses are very severe as you say, and unless the design of the plate is changed so as to reduce the severity of these stresses, cracking of the plates and leakage around the rivets will be unavoidable. We advise making the steam plates of uniform thickness throughout, as far as possible. The rivets should be discarded in favor of hollow screwed ferrules of the same wall thickness as the plates. These ferrules may be applied the same as staybolts, being threaded on the outside and screwed through tapped holes in the plates. When they are in place they should be cut off smoothly with the face of the plates and then they may be welded with the oxy-acetylene process. In this way you will obtain a steam plate which will expand and contract without setting up as severe stresses as when thick, solid rivets are employed. Suggestions from readers are invited.

NEW ELECTRIC GENERATOR SET!

A French inventor has produced a very practical (?) device for taking the requisite exercise in the home and incidentally producing the electric energy required for lighting a small house. He has combined a so-called "exerciser" made in the form of a bicycle (without wheels) with a dynamo and storage battery so that after taking the required exercise in the morning or evening, as the case may be, enough electric energy is stored up for several lamps for domestic lighting. It is pointed out that an important factor in favor of this device is the fact that generating the electric current gives stimulus to the use of the machine, and is intended to prevent neglect of the daily exercise, which becomes a necessity, or darkness prevails. The machine is designed to provide energy for a number of lamps after an hour's pedaling. When there are several members of the family the number of lamps may be increased indefinitely!

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

GLEASON SPIRAL TYPE BEVEL GEAR GENERATOR

The machine which forms the subject of this article has been designed and built by the Gleason Works, Rochester, N. Y., for the purpose of cutting spiral bevel gears and pinions. This machine is of the generating type and is fully automatic. Fig. 1 shows the first of this type to be built, which is now in operation at the Gleason Works. Perhaps the easiest way to gain a clear idea of this machine is by comparison with the bevel gear generating machine built by the same firm for cutting straight tooth gears. The only essential difference in principle is that the new machine passes the tool through the blank in a curved path instead of in a straight path going to the cone center. The method of forming the tooth profile is the same in both cases, being the well known generating principle in which a tool representing the tooth of a crown gear is made to roll with the gear blank without slipping, cutting at the same time so as to roll out the tooth profile. The method of applying this principle in the new machine has been changed, as well as numerous details of design, some of which will be noted later. The curved tooth is obtained by building the cutter in the form of a face mill, as shown in Figs. 3 and 5, the curve being the arc of a circle whose diameter is the diameter of the mill. Fig. 3 shows the cutter as it is now being made, and Fig. 5 shows the original cutter. The average diameter of the cutter is 12 inches, and there are twenty blades, ten cutting on the outside and ten cutting on the inside, the alternate blades having shear angles in opposite directions. The cutting side of each blade is ground to the pressure angle, and the other side is given a clearance. The cutting sides and the points of the blades are finished with a grinding attachment on a relieving lathe, so that in order to sharpen them it is only necessary to grind back on the face, and the cutting edge has the correct angle all the way back, the same as on a rotary cutter.

The wedge behind each blade is used in making the necessary adjustment after sharpening. All the cutting edges on each side of the cutter must work on exactly the same radius from the center of the cutter within a fraction of a thousandth of an inch. Otherwise the profile of a gear or pinion tooth would be a series of decided flats. It is practically impossible to remove the cutter from the spindle, mount it on a grinder and sharpen the blades, and then remount it on the cutter spindle and have the blades run true. With the wedge adjustment the cutter can be sharpened on a grinder, paying only a reasonable amount of attention to having the blades true; then, when the cutter is replaced on the spindle, the blades can be trued up by means of the wedges, one blade being set to a gage to maintain the proper diameter, and the rest of the blades being set to exactly the same reading on an indicator. This method has proved to be very successful. This adjustment was not provided in the first cutter, and is not shown in Fig. 5. The cutter head fits the spindle on a taper, and is held with four cap-screws. The same cutter is used for cutting both sides of a tooth, and for both the pinion and gear. It is necessary to remove it only for sharpening, and this is not often, on account of the large number of blades in action.

The shaft shown squared for a crank in Fig. 5 is a worm-shaft. The worm-wheel with which it meshes (seen in Fig. 2) is internally threaded, and adjusts the cutter spindle lengthwise, so that the plane of the points of the cutter blades contains the cone center of the gear or pinion to be cut. The cutter is supported by a column which stands on a large cradle; and it is through this cradle that the generating motion is applied to the cutter. The cutter and work are rolled together by means of a geared drive, instead of the crown gear and segment used in the straight tooth generators. A reversing mechanism (not shown) drives this generating roll, and it is applied to the cradle by a worm and worm-wheel segment, shown under the center of the cradle in Fig. 5. The same reversing drive is carried up through the center of the machine by means of a sleeve (Fig. 2), and back along the side of the head to a worm under the rear head bearing, which meshes with a worm-wheel segment fastened to the inside of a fantail hanging down from the spindle-carrying sleeve. The connection between this sleeve and the work-carrying spindle is through the index mechanism on the outside of the fantail, which is the same as the mechanism used in earlier designs, making the machine fully automatic.

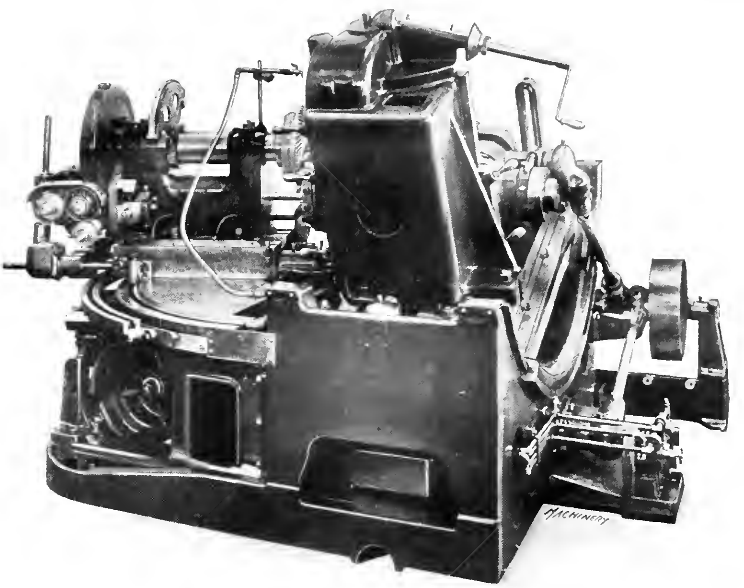

Fig. 1. Gleason Generator for machining the Spiral Type of Bevel Gears

The reversing mechanism has a fixed number of turns in each direction, and the amount of roll of the cutter-carrying cradle is controlled by a set of change gears, giving a small roll of the cradle for a pinion tooth and a large roll for a gear tooth. The relative roll between the cutter and the work is governed by a set of compound change gears on the drive going to the work-head. This ratio depends on the pitch angle of the gear or pinion that is being cut, according to the formula:

$$\frac{\text{Angle of roll of cradle}}{\text{Angle of roll of gear}} = \text{sine pitch angle of gear.}$$

A graduation in half degrees on the side of the cradle and a graduated plate with a vernier attachment on the work sleeve afford a means of testing this roll as a check. For example, in cutting the gear of a forty-nine- and thirteen-tooth combination, the pitch angle of the gear is 75 degrees 8 minutes. The compound gearing controlling the relative roll of the cutter and work must be such that taking into

consideration the constant of the fixed gears of the train, it will give:

$$\frac{\text{Angle of roll of cradle}}{\text{Angle of roll of work}} = \text{sine } 75 \text{ degrees } 8 \text{ minutes} = 0.96653.$$

To check this on the machine, assume any angle of roll of the cradle—say 30 degrees. Then the work must roll:

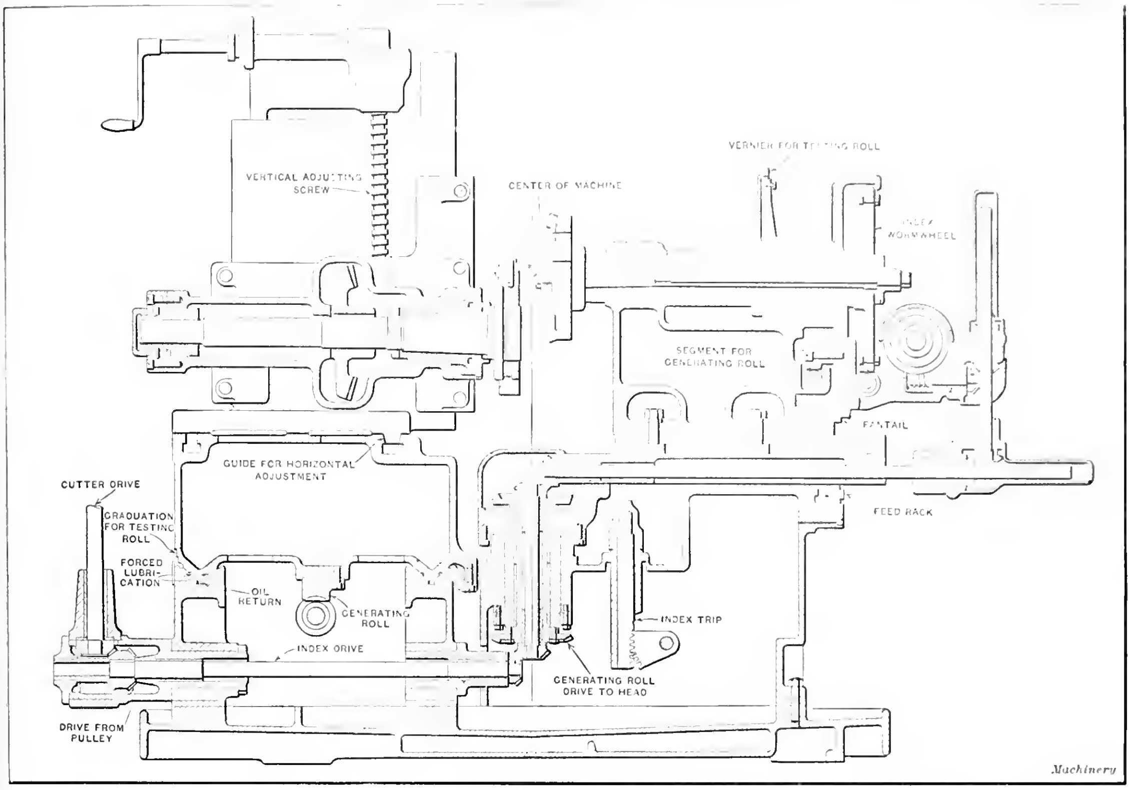

Fig. 2. Vertical Section through the Center Line of the Machine with the Work Head swung around to an Angle of 90 Degrees

$$\frac{30}{0.96653} = 31.038 \text{ degrees.}$$

By rolling the cradle through the 30 degrees and reading the roll of the work on the vernier, this result can be checked within a minute, which is quite accurate enough for producing the correct tooth profile. When the machine was built, a differential mechanism was used on the reversing drive in addition to the compound gears in order to get the relative roll of work and cutter exactly. This was found in actual use to be an unnecessary refinement and has been discarded, a single set of compound gears giving the correct roll within a minute. The reversing mechanism is timed with the feed cam. The cut takes place during the up-roll of the cutter and work. During the down-roll, the work is swung away from the cutter by the feed cam, is indexed, and returned to the cutting position. The position of the cutter with relation to the cone center of the machine can be adjusted both vertically and horizontally. The vertical adjustment is obtained by raising or lowering the cutter spindle saddle on the ways of the vertical column by means of the lifting screw shown in Fig. 2. A horizontal screw adjusts the whole vertical column transversely on the top of the cradle. For each adjustment, a scale is provided for even inches, and a graduated dial for thousandths. One side of a tooth is cut at a time and in changing from one side to the other, it is necessary to give the cutter a slight adjustment, and set the blank over to a position that gives the correct tooth thickness. In changing from a gear to a pinion it is necessary to adjust the cutter vertically so that its center is above the cone center of the machine instead of below it. This is done to give the opposite hand of spiral on the pinion from that on the gear. The same horizontal setting answers for both sides of the gear and pinion teeth so that only the vertical setting needs to be changed when a job is once started. This machine has been built primarily for finish cutting, but by changing the feed cam and throwing out the generating roll, gears can also be stocked out. The stocking cutter is the same as the

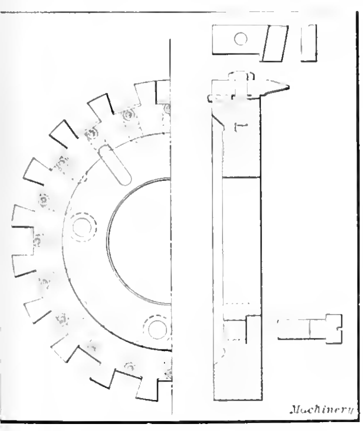

Fig. 3. Elevation and Sectional Views showing Construction of the Cutter

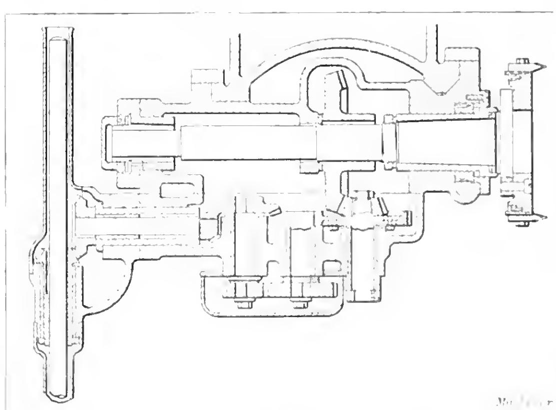

Fig. 4. Horizontal Sectional View of the Cutter-slide

finishing cutter except that there is no wedge adjustment for the blades, and the blades are ground with top rake. The stocking out is being done on a milling machine at the present time at the Gleason Works.

Fig. 1 shows the machine as it now appears. As this is the first machine built, there are several features which will be changed in the next machines. The new design of the cutter has already been described. Among other changes the universal joints in the cutter drive will be done away with, and the position of the oil pumps and piping will be changed.

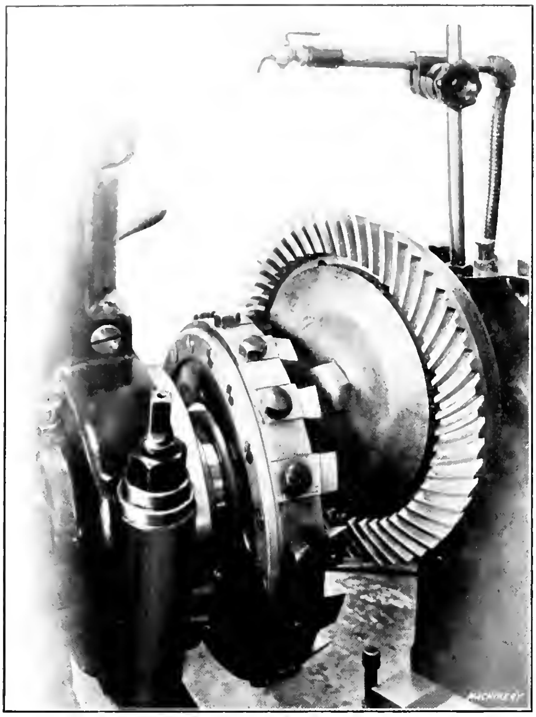

Fig. 5. Close View of the Cutter generating the Teeth in a Gear

The cutting time of spiral type gears compares very favorably with the time for cutting straight tooth gears. After stocking out a spiral gear it is necessary to cut each side of the teeth once, making two cuts around in generating. In straight tooth gears of high grade, it is usually necessary to make two generating cuts after the stocking out. Some gears and pinions at the Gleason Works have been cut with spiral teeth in the same time per set as the straight tooth gears. The average time for the spirals, however, would be a little longer than for straight tooth gears—from one to one and a quarter times as long.

Fig. 6 shows a few of the spiral bevel gears and pinions that have been cut at the Gleason Works, and Fig. 7 shows a single spiral bevel gear and pinion in mesh. Gears of a wide variety of combinations and pitches have been cut and have been subjected to severe tests by a number of automobile and axle manufacturers. In all cases the results have been very satisfactory. Trials of gear testing machines show that the pinion is capable of a wide range of adjustment with relation to the cone center of the gear, and this feature is a great advantage. It has been suggested that there is more sliding between the tooth faces of these spiral bevel gears than in the case of straight tooth gears, but this does not appear to be the case. Considering any section of a spiral gear tooth taken normal to a cone line, and a corresponding section of the pinion tooth,

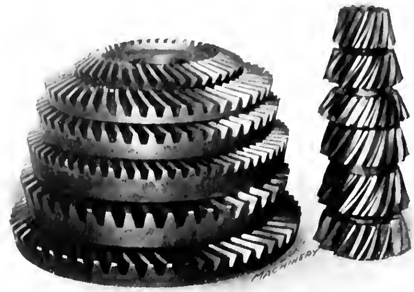

Fig. 6. Spiral Bevel Gears cut on the Gleason Generator

the shapes would be the same as corresponding sections for straight bevel teeth of the same pitch and combination, and the rolling action would be the same. Either the straight tooth or the spiral tooth may be considered as made up of an infinite number of such sections, and the fact that in the spiral tooth the sections are lined up with each other on a curve instead of on a straight line would not change the rolling contact. The angle of spiral used thus far has been such as to give a lead of about $1\frac{1}{4}$ to $1\frac{1}{2}$ the circular pitch in the width of face, and this has shown very good results in quiet running.

Fig. 7. Spiral Bevel Gear and Pinion in Mesh

The same cutter is used for both sides of the tooth, and for both pinion and gear. The outside of the cutter cuts the concave side of the tooth, and the inside cuts the convex side. The gear and pinion tooth faces in contact are thus cut on slightly different diameters of the cutter, and this results in the bearing being heavy at the center of the tooth. The amount of this difference of curvature is very slight, however, and in the average automobile gear the bearing can just be seen to fade away at each end of the tooth.

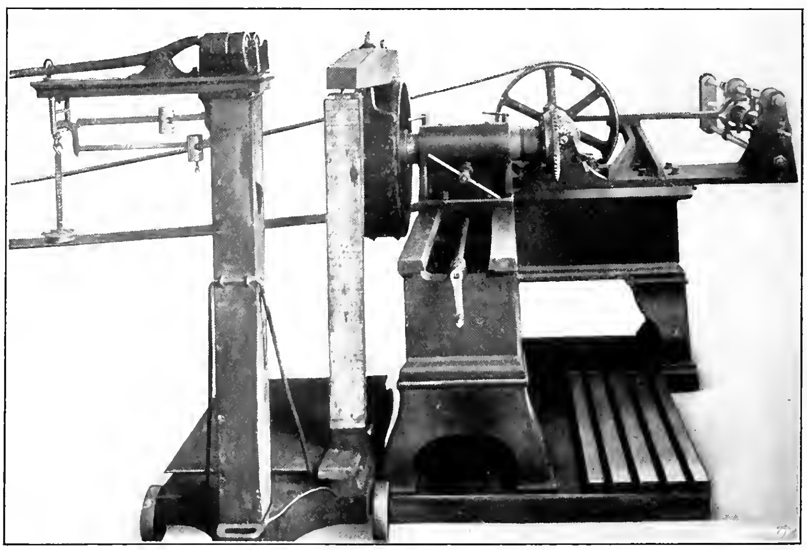

Fig. 8. Machine used for testing End Thrust of Spiral Bevel Pinions

One of the first questions that arose in connection with the use of these gears was as to the end thrust of the pinion caused by the spiral angle. The apparatus shown in Fig. 8 was used in tests made to determine the amount of this thrust. Power was applied to the pinion shaft, and the load transmitted was measured by a Prony brake on the gear shaft. The pinion shaft was free to float endwise, within certain limits, and within this range was held by a lever seen at the back on the right of the drive pulley. The other end of the lever was connected with a spring in compression (at the extreme right) so that any tendency of the pinion to thrust back brought the load on the spring. By means of a threaded handwheel the position of the spring could be adjusted endwise so as to bring the pinion back to the correct running position with each change of load on the gear. The amount of thrust could then be read by means of graduations on the spring-carrying bar, the spring having been calibrated before the tests were made.

Tests of the end thrusts were made with four pairs of bevel driving gears and pinions. The first test was made with the usual straight tooth type of bevel gear; the second and third tests were made with spiral bevel gears of different spiral angles; and the fourth test was conducted with skew bevel gears. All four pairs of gears used for these tests were cut on generating machines. For the first test the usual straight tooth gear generator was used; the gears for the second and third tests were cut on the Gleason spiral type bevel gear generator, the elements of the teeth being curved; and the gears for the fourth test were cut on a generating planer, so that the elements of the teeth are straight, but do not pass through the cone center, the tools being offset so as to pass above the center in cutting the gear and below the center in cutting the pinion. The direction of the spiral on the gears for tests No. 2 and No. 3, and of the skew for test No. 4 was the same—right-hand on the pinion. This results in a tendency to pull the pinion in toward the cone center in the forward drive, and to thrust it back against its bearings in the reverse. The straight tooth gears used for test No. 1 show a backward thrust, and the spiral and skew gears have this backward thrust combined with the pull or thrust due to the angle of the spiral or skew. The results presented in the table show the net values of these two forces—the pull due to the spiral minus the backward thrust of the straight tooth gears in the case of the forward drive; and the thrust of the spiral plus the backward thrust of straight tooth gears in the reverse drive. This accounts in a large measure for the results on the reverse being so much greater than on the forward drive.

In tests No. 2 and No. 3 the angle of the spiral is measured midway between the two ends of the tooth—this being the point at which the pressure is heaviest in this style of gear. In test No. 4 the angle of skew is measured at the large end of the tooth. If the angle of the spiral of the gears used in tests No. 2 and No. 3 were measured at the large end of the tooth, it would be greater than at the mid point, and the thrust would be less in proportion to the angle. Similarly, if the angle of skew of the gears used in test No. 4 were measured at the center of the tooth, it would be greater than at the large end, and the thrust would again be less in proportion to the angle. The method of measuring the angle, therefore, seems fair to both types of gear. The results given in the table show that the amount of end thrust or pull varies with the angle, and does not depend on whether the gears are of the spiral or skew type—the spiral type of pinion of greatest spiral angle showing the greatest thrust, the skew with a less angle showing less thrust, and the spiral

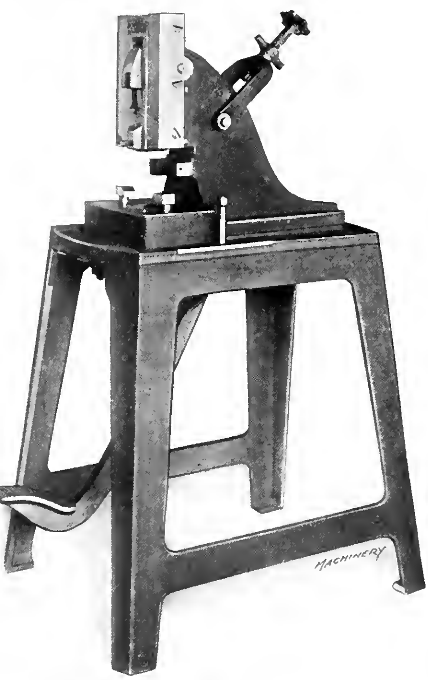
with the smallest angle showing the least thrust. The load has been given in pounds instead of in horsepower, since a given horsepower would put different loads on the teeth of pinions of different diameters. The load has been figured for the mid point of the tooth, *i. e.*, on the mean pitch radius of the pinion. The speed of the pinion in all runs reported was constant at about 260 R. P. M. A series of runs made at different speeds up to as high as 360 R. P. M. of the pinion showed the same thrust per 100 pounds of tooth load. Negative results indicate pull in toward the cone center; positive results indicate thrust away from the cone center. In each run the gear was loaded up to about 10 horsepower. Three independent sets of readings were taken in each case, and the results given are the averages of these sets of readings.

NOBLE & HUNT FOOT PRESS

Noble & Hunt, Newark, N. J., have recently developed a foot press of improved design which is shown in the accompanying illustration. This machine is intended for use in the manufacture of jewelry, metal novelties and other work of relatively small size. The features of the press are strength, extreme accuracy of the stroke and improved facilities for setting the die. It will be noticed that while the design follows the established lines of machines of this type, it is exceptionally heavy at the throat. The press is mounted on an iron stand and the slide has unusually long bearings which insure adequate support and reduce the possibility of deflection of the punch.

Ample leverage is provided. The motion from the end of the lever is transmitted to the ram by means of a link which

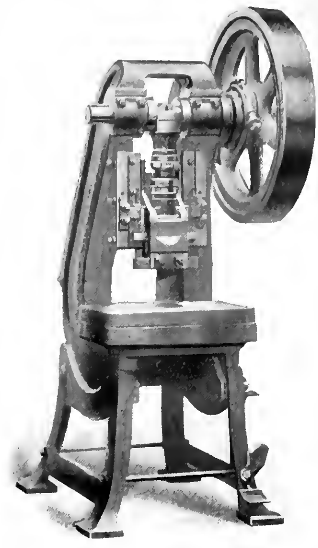


Noble & Hunt Foot Press with Improved Device for clamping the Die

is so designed that it obviates the danger of throwing the slide out of line while it is descending. This feature, in connection with the long slide bearings, increases the accuracy with which the machine operates. The usual stop or bumper is supplied at the back of the press to limit the backward stroke of the lever. The automatic clamping of the die plate is effected by means of the lever at the right-hand side of the machine. Trouble is often experienced in die setting because unequal tightening of the nuts causes the die to creep to one side, thereby throwing it out of line with the punch. With this press, the die plate is put in an approximate position and after the punch has located the die correctly on the die bed, the hand lever is thrown over, thus setting the clamps down firmly without requiring the use of a hand wrench. The lever for actuating the clamps works in conjunction with an eccentric motion. This clamping feature is one that will be readily appreciated by users of small dies. The press and stand have a total weight of 750 pounds.

WATERBURY FARREL INCLINABLE PRESSES

The Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., has recently brought out a line of inclinable open-back presses which are known as the standard Series E. These machines have an exceptionally large tool space and are of unusually heavy construction. They are adapted for a great variety of press work, the construction being such that various types of automatic feeding attachments can be readily applied. The housings are tied together at the back to increase the rigidity and the slide has bearing surfaces of ample proportions. The overhanging type of construction for the crankshaft and slide gives the maximum amount of tool space in all directions as well as permitting the attachment of the knock-out shown in the illustration.



Waterbury Farrel Series E Inclinable Open-back Presses

The crankshaft is made of high carbon machine steel, and runs in capped bearings. The Waterbury Farrel improved Johnson clutch is used, which has a particularly efficient friction. These machines can be built with back gears to meet the requirements of heavy work handled at a moderately slow speed. In addition to the floor type of machine illustrated, presses of this type are made in a small size for bench work. The machines are particularly adapted for use in the manufacture of tin boxes and similar classes of work.

WHEELOCK FLEXIBLE CUTTING LUBRICANT TUBE

Fig. 1 shows a flexible metallic tube for use in supplying the lubricant to the cutters of machine tools, which is a recent product of the Wheelock Mfg. Co., Wheelock, Vt. No

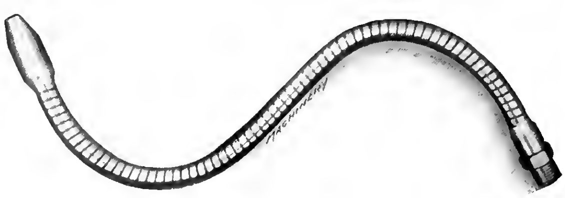


Fig. 1. Wheelock Flexible Cutting Lubricant Tube

packing of any kind is used in this tube; it consists of two steel wires which are wound together in such a way that a perfectly tight tube is produced. A cross-sectional view of the tube is shown in Fig. 2, from which the construction will be readily understood. The tube can be easily bent to any desired curve, and is sufficiently rigid to stay in the position to which it is bent. Owing to its flexibility, one end of the tube may be attached to the traveling carriage or other moving part of a machine. This feature is the chief advantage

of the Wheelock tubing over solid piping, which, if attached to such a moving part, must be provided with swinging joints or telescoping joints which are very apt to give trouble through leaking. In addition, such piping is more expensive and cumbersome.

The brass fittings used at either end of the Wheelock tubes are provided with standard pipe threads, and any special form of fittings or nozzles may be provided. This tubing is made in three sizes which have bores $\frac{1}{4}$, $\frac{3}{8}$ and $\frac{1}{2}$ inch in diameter, and the tubing may be made of any desired length.

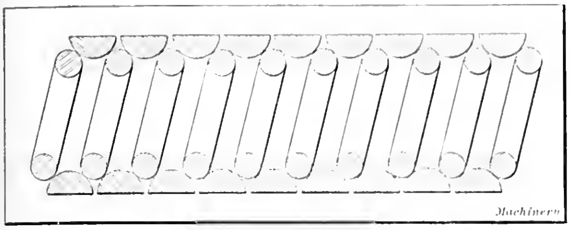

Fig. 2. Sectional View of Wheelock Lubricant Tubo showing Construction

MOTOR DRIVE FOR SPRINGFIELD SHAPER

Motor drive applied to a 15-inch crank shaper built by the Springfield Machine Tool Co., 631 Southern Ave., Springfield, Ohio, is illustrated in Fig. 1; and Fig. 2 shows the gear box which, in connection with the constant-speed motor drive, provides four changes of speed. The changes of speed may be instantly obtained. The drive is connected by means of a friction controlled by a lever, and the operator can select the desired speed and engage the power without being required to make any adjustment of the motor. This motor-drive equipment has been put on the Springfield shaper to adapt it for manual training school service, where it is used to illustrate the individual motor application.

Fig. 1. Motor Drive applied to a Springfield Shaper

The rawhide pinion through which power is delivered to the friction gear is entirely encased and a box attached to the shaper contains the starting switch, fuses, etc. The current is controlled by a push button which is shown in Fig. 1, and it will be noticed that the motor is mounted directly on the machine base. Any type of motor may be employed. Referring to the view of the gear box shown in Fig. 2, it will be seen that sliding spur gears are used which are controlled by levers shown in Fig. 1. The arrangement is such that it is impossible to engage more than one speed at a time. Both the machine and motor drive are of rigid construction and constitute an excellent equipment for either demonstrating purposes or shop work. Aside from the feature of motor drive, the shaper is the regular 15-inch Springfield crank shaper which has been on the market for a number of years.

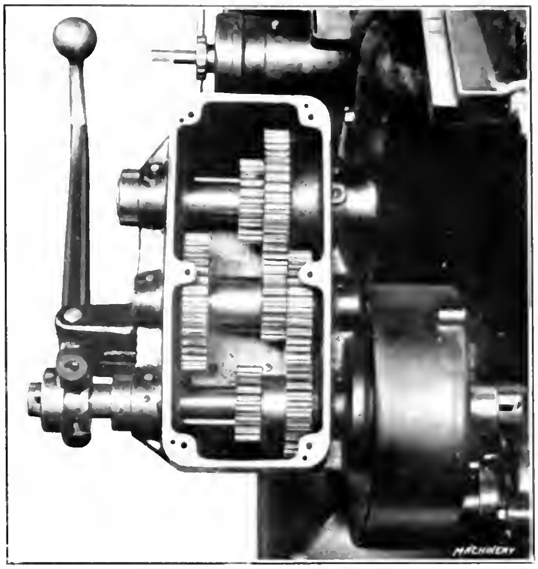

Fig. 2. Interior View of the Gear Box

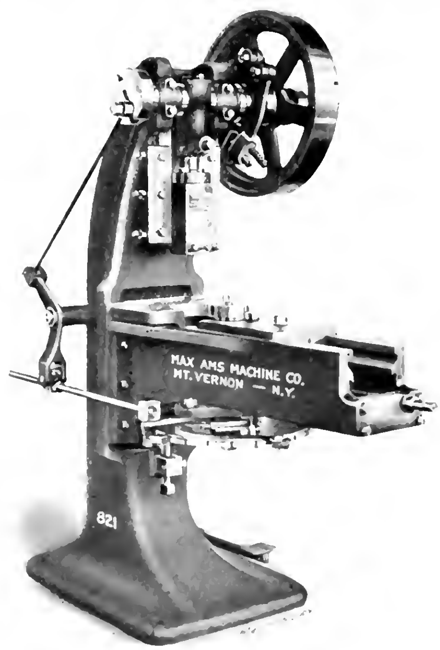
MAX AMS NOTCHING PRESS

The accompanying illustration shows a machine for notching armature disks from 4 to 30 inches in diameter, which is a recent product of the Max Ams Machine Co., Mount Vernon, N. Y. The design has been worked out along lines which adapt the machine for doing accurate work at a speed ranging from 250 to 325 revolutions per minute. A clutch is provided which grips the wheel centrally at several points. The



Max Ams Press for notching Armature Disks from 4 to 30 Inches in Diameter

indexing is obtained by an index ring that is fed and locked positively, and so arranged that wear on the teeth of the index wheel is reduced to a minimum. Other features of the machine consist of the adjustment of both the slide and the die bed by means of screws, thus providing for variations in the height of the punches and dies. The adjustment for disks of different diameters is made by a screw conveniently located at the front of the machine. When notching disks which have no keyways, a clamping arm can be used to hold the work. Depressing the treadle starts the machine and it stops automatically as soon as the disk is finished.

SPRINGFIELD 24-INCH QUICK CHANGE GEAR LATHE

For a number of years the Springfield Machine Tool Co., 631 Southern Ave., Springfield, Ohio, has been building "Ideal" rapid change gear lathes, but the change gear device has never been applied to machines of more than twenty inches swing. To meet the demand for a larger quick change gear lathe, this company has recently added the quick change gear device to its twenty-four-inch machine, the first lathe to be equipped in this way being shown in Figs. 1 and 2.

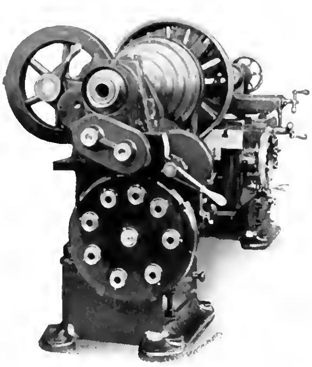


Fig. 1. End View of Springfield Lathe

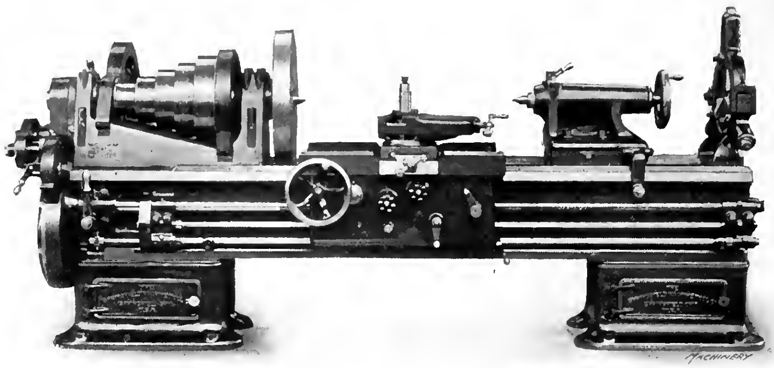

Fig. 2. Springfield 24-inch Quick Change Gear Lathe

The quick change gear device furnished on this lathe is of simple and efficient construction. Only seven gears are used when chasing right-hand threads and eight gears when chasing left-hand threads. The lead-screw is not splined. Feeds are transmitted to the apron by the regular feed-rod and the automatic stop operates in either direction. The reverse mechanism which is controlled at the apron operates both the lead-screw and feed-rod and is actuated by means of spur gears at the rear of the headstock. Particular care is taken in cutting the lead-screw and its accuracy is guaranteed.

The other features of the lathe may be briefly referred to as follows: It is equipped with a five-step cone pulley, single back gears, compound and steadyrests, large and small face-plates and a double friction counter-shaft with self-oiling bearings. The spindle is made of 60-point carbon steel, and lumen bearing metal or phosphor-bronze is used for the journal linings. The spindle journals are adjustable and ring oiled, the thrust being taken on the rear housing by means of cast-iron and hardened steel collars. The apron is of the double plate type, providing support at both the front and back of all shafts. Longitudinal and cross feeds are engaged by means of frictions and no tumbler gears are used. The tailstock is recessed and can be set over for turning a taper. Aside from the application of the quick change gear mechanism, the lathe is not new, so that a detailed description is unnecessary at this time.

RAHN-LARMON LATHE

The 16-inch engine lathe illustrated in Fig. 1 is being manufactured by the Rahn-Larmon Co., Cincinnati, Ohio. The design has been worked out with the view of meeting the requirements of modern manufacturing practice, being simple, accurate and providing ease of operation. The bed is of heavy construction and firmly braced for its entire length with box girders to provide for absorbing the vibration of the heaviest cuts. The headstock is bolted to the bed. The spindle is hollow; it is made of high carbon steel and ground perfectly cylindrical. The centers are No. 4 Morse taper hardened and ground to run accurately. The bearings are bushed with gun metal and provided with means of compensating for wear. The driving cone is of large diameter and designed to carry a wide belt; either single or double back gears, and a three, four or five step cone pulley may be used. The tailstock is of the off-set type, which allows the compound rest to be placed parallel with the bed; and the tailstock may be set over for turning tapers.

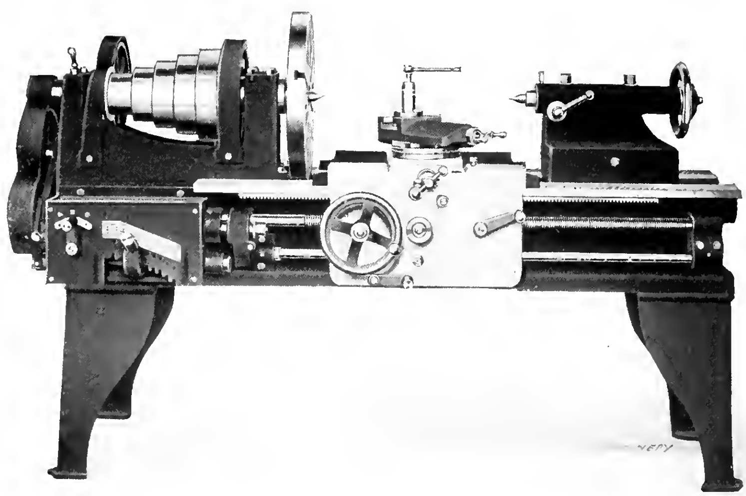

Fig. 1. Rahn-Larmon 16-inch Lathe with Quick Change Gear

The carriage is gibbed to the bed at both the front and back and is provided with a broad bearing for the compound rest. It has a long continuous bearing on the bed and can be firmly locked in place. The compound rest is provided with taper gibs for taking up wear, and the swivel section is so constructed that a long bearing for the tool rest is

provided. The apron is of simple design and all feeds are conveniently controlled. The machine shown in Fig. 1 is equipped with a quick-change gear, and a better illustration of the change gear is shown in Fig. 2. The quick-change screw cutting and feed mechanism is of very simple and substantial construction. Thirty changes of feed are obtained by shifting only two levers and these changes can

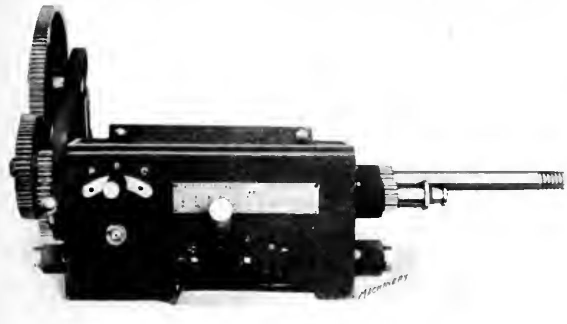

Fig. 2. Quick Change Gear Unit for Rahn-Larmon Lathe

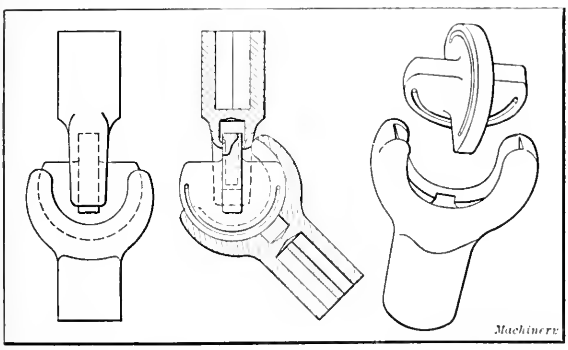
be made instantly while the lathe is running. The gears are steel, the shafts are accurately ground and all bearings are bronze bushed. The gearing at the end of the headstock is so arranged that metric or special feeds can be cut by the substitution of the proper gears. Screw chasing dials are provided which obviate the necessity of reversing the spindle when chasing threads.

Thé regular equipment of the lathe includes a countershaft, steadyrest, follow-rest, large and small faceplates, wrenches and a screw cutting dial. A taper attachment, a turret for the carriage, a turret for the bed, cabinet legs, chucks, chuck plates and special tool rests can also be obtained. In addition to the form shown in Fig. 1, the lathe is also built without the quick-change gear device.

PLANK UNIVERSAL JOINT

A universal joint of simple but strong construction is a recent product of the Plank Flexible Shaft Machine Co., 234 Ionia St., N. W., Grand Rapids, Mich. This universal joint is



Plank Universal Joint and Details of the Yoke and Center

composed of three parts—two yokes and the center. It interlocks and disengages at 45 degrees and can be disconnected at two points. The bearing surface is said to be from 300 to 400 per cent greater than that of any other universal joint now on the market and the use of screws, pins or rivets is eliminated.

The center block, as shown in the accompanying illustration, consists of one piece of chrome-nickel steel, drop-forged and machined to accurate dimensions and then heat-treated and polished. The yokes are made of high-carbon steel and they are also drop-forged before machining. The simplicity and rigidity of the construction of this universal joint make it particularly well adapted for use on automobile propeller shafts, multiple spindle drilling machines and a variety of other uses where a universal joint is required to transmit motion under severe conditions of service.

BRISTOL PNEUMATIC RECORDING TACHOMETER

In many lines of industrial work it is desirable to keep machinery running at a specified rate of rotation, and in other cases it may be necessary for stops to be made periodically. Recording tachometers are used to furnish the superintendent or manager of the plant with information concerning the way in which the machines have been operated. A case in point is the blowing engines which supply the draft to blast furnaces; these engines are driven at a predetermined number of revolutions per minute, but they are

Fig. 1. The Bristol Pneumatic Recording Tachometer

usually slowed up once every twenty-four hours when the casting is done.

The Bristol Co., Waterbury, Conn., is now manufacturing the pneumatic type of recording tachometer illustrated in Fig. 1, which has been developed to afford a means of keep-

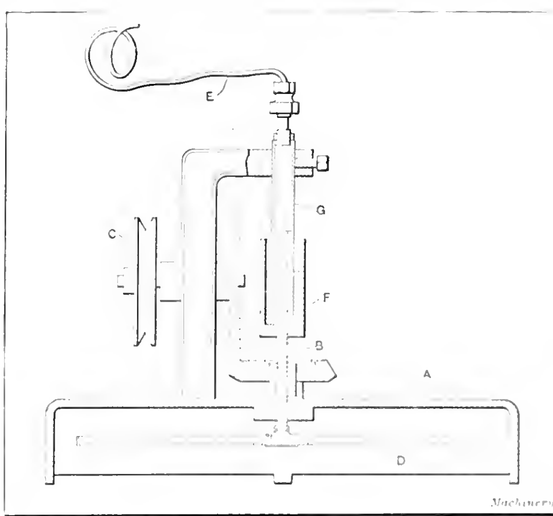


Fig. 2. Diagram showing how the Tachometer operates

ing a record of the rotative speed at which machines are operated, as outlined in the preceding paragraph. These tachometers are used extensively in connection with blast furnace blowing engines, for recording the speed of paper machines, and for similar purposes. In many cases it is not

convenient to have a self-contained recording tachometer located near the revolving shaft, and one of the important features of the new Bristol instrument is that the flexible connecting tube may be twenty-five feet in length or longer, thus allowing plenty of room between the revolving mechanism and the recording instrument. The recorder may be mounted in any convenient position, as, for instance, on a switchboard or the wall of the engine room. The pneumatic principle of operation depends on the centrifugal action of air in a revolving tube which is connected to the recording instrument through an oil sealed flexible connecting tube. Fig. 2 illustrates the construction of the revolving mechanism and shows how the tachometer operates. In this diagram *A* is the base which supports a bearing on its upper surface for the hollow shaft *B*. This shaft is rotated from the member whose angular speed is to be measured by means of the pulley *C* and bevel gears as shown in the illustration. In practice, it is generally found more convenient to drive the tachometer by means of a special form of sprocket and chain in place of the pulley *C* and a belt running over it to the shaft whose revolutions are to be counted.

At the lower end of the hollow shaft *B* there is a horizontal tube *D* which is open at the ends; the tube *D* connects with the recording instrument through the hollow shaft *B* and the flexible tube *E*. The upper end of the shaft *B* is surrounded by a casing *F*; this casing is partially filled with oil, and the free end of a second casing *G* dips into it. The casing *G* remains stationary and the flexible tube *E* leading to the recording instrument is connected with it. The recording instrument is a special low range Bristol recording vacuum gage. When the tube *D* revolves in the casing *A*, the action of centrifugal force tends to throw the air out of the ends of the tube *D*, thus creating a vacuum which actuates the gage. As the magnitude of centrifugal force is dependent upon the rate of rotation, it will be evident that the gage can be graduated to show the number of revolutions per minute.

DETRICK & HARVEY HORIZONTAL DRILLING MACHINE

The accompanying illustrations show a machine designed for heavy drilling operations with high-speed drills, which is a recent product of the Detrick & Harvey Machine Co., Baltimore, Md. The general design follows the lines of a horizontal boring and drilling machine of the traversing column type having a fixed work table, a column traversing horizontally on the runway and a saddle traveling vertically on the column.

The spindle of the machine is made of hammered high-carbon steel with a tapered front bearing 7⅞ inches in diameter, the bearing being bushed with phosphor-bronze and provided with means for compensating for wear. The thrust is taken by a dust-proof roller thrust bearing and the spindle has a standard taper socket. The main body of the spindle is 4 inches in diameter. Power is provided by a 4 to 1 variable-speed, 20-horsepower motor which is mounted at the top of the column. All driving gears are of cast steel or manganese bronze and the pinions are of high-carbon steel. The range of spindle speeds is from 60 to 240 revolutions per minute and no belts or chains are used in driving the spindle or feed mechanism. The power feed is driven from the spindle sleeve gear; and the feed mechanism is equipped with all-steel gears and clutches, with a steel pinion engaging a rack cut from solid steel on the feed quill. Four changes of feed ranging from 0.004 to 0.090 inch per revolution are provided.

The vertical movement of the saddle and the horizontal movement of the column are obtained through handwheels conveniently located within reach of the operating platform. The column is mounted on rollers to reduce friction on the runway to a minimum. Both the saddle and column may be easily changed to any required position and have gibs for taking up wear. The controller for the motor is also mounted on the operating platform, thus providing complete control of the machine from a single position. An oil jet is provided for the drill, the oil being delivered by a rotary pump driven by a small auxiliary motor. The work table is provided with a channel around all four sides, by means of which the oil is returned to the supply tank of the pump, thus eliminating all waste. The high table provided on this machine enables the spindle to be brought down within 3 inches of its surface; the vertical adjustment of the head on the column is 12 inches and horizontal adjustment of the column on the bed is 6 feet. The machine can be made in various sizes to meet the requirements of individual cases.

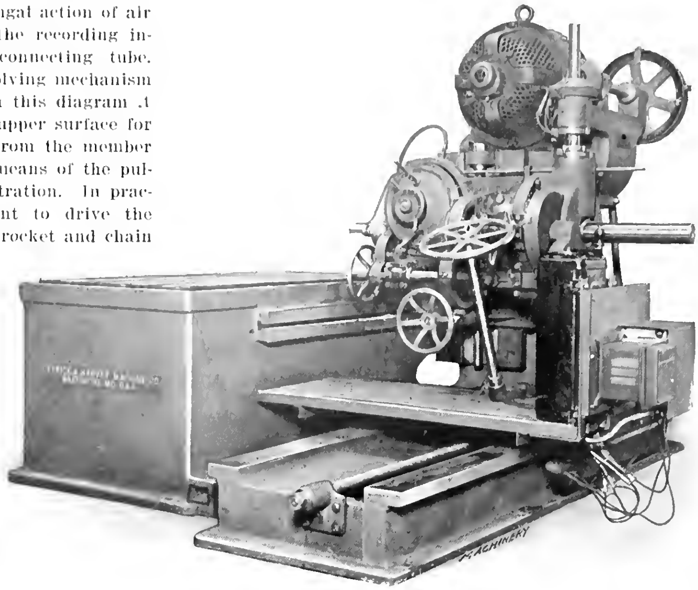

Fig. 1. Operating Side of the Detrick & Harvey Horizontal Drilling Machine

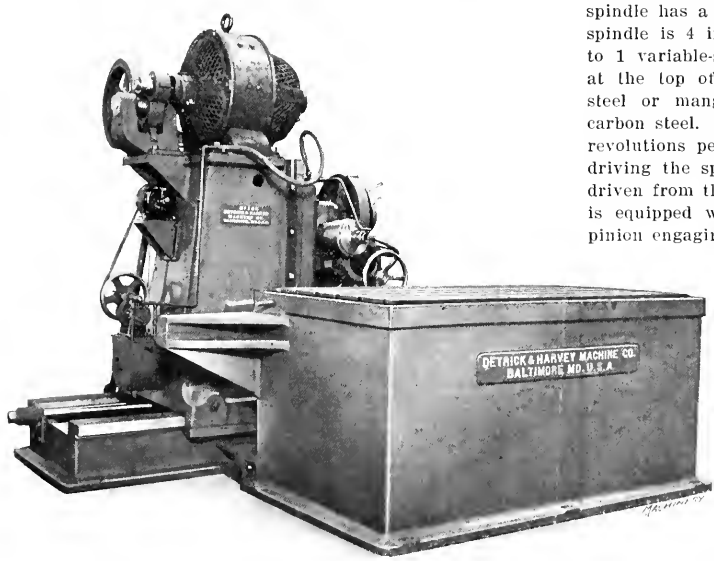

Fig. 2. Detrick & Harvey Drilling Machine showing Table, Spindle, etc.

PRATT & WHITNEY DIE-SINKING MACHINE

The duplex die-sinking machine shown in Fig. 1 has recently been developed by the Pratt & Whitney Co., Hartford, Conn., to supplement its smaller sizes of die-sinking machines. The present machine differs from the smaller sizes in that the head is made the movable member. The reason for this change in design is that the weight of the dies for which this machine will generally be used is so great that it was considered inadvisable to adopt a construction that would make it necessary to elevate the table and work. The machine has a wide range and is of unusually heavy construction. The design includes several new features, among which may be mentioned the duplex spindle construction, the method of feed control and other points which will be referred to in detail in subsequent paragraphs. These features add greatly to the efficiency of the machine and make it particularly well adapted for finishing large forging dies in an economical manner. The bearing surface on the column, on which the head is mounted, is of liberal proportions, tapered gib adjustments being provided to compensate for wear. The head is accurately counterbalanced, and is raised or lowered by a handwheel *A*, which is connected with the elevating screw *B* by means of bevel gears. A micrometer dial enables the travel to be accurately controlled, and, in addition, a positive vertical stop *C* is provided. A powerful binding device controlled through the handle *D* permits the head to be clamped at any desired point.

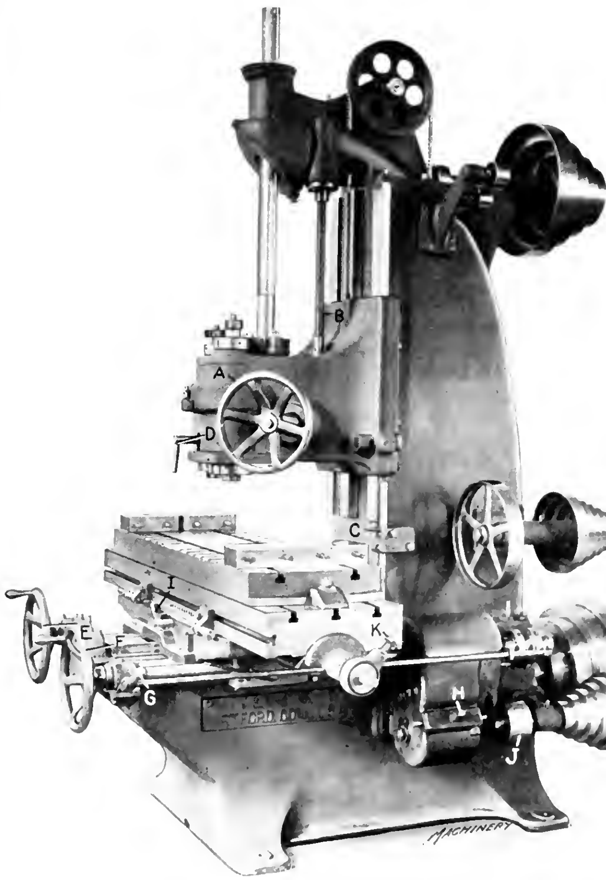

Fig. 1. Pratt & Whitney No. 4 Duplex Die-sinking Machine

It will be seen that the machine is provided with two spindles, one of which is considerably larger than the other. The value of this construction lies in the fact that on large die work it is frequently necessary to take finishing cuts with cutters of small diameter, requiring a high spindle speed. It was found that a spindle of sufficient size to stand up under the heavier cuts which are required of this machine could not be provided with a sufficient range of speeds to drive small cutters satisfactorily. With the two spindles, speeds ranging from 11 to 610 revolutions per minute are obtainable, which makes the machine equally efficient on both light and heavy cuts. The spindles are made of special steel and mounted in bronze bushed cylindrical bearings, which have conical seats in the heads and means for compensating for wear. Both the spindles are located in the same plane and are not adjustable vertically. The large spindle is provided with a tapered hole of the same dimensions as that of the spindle of the No. 3 die-sinking machine built by the Pratt & Whitney Co., and the small spindle corresponds to the spindle of the No. 2 die-sinking machine of this company's manufacture. Both spindles are provided with pull-back rods for holding the cutters securely in place. A simple but efficient spindle locking device is also provided for holding the spindles stationary while tightening the cutter chucks. Each spindle is provided with eight speeds by means of a four-step cone pulley and a two-speed countershaft. A vertical shaft driven from the cone by means of bevel gearing transmits the power directly to the larger spindle through spur gearing. The small spindle is driven through gearing from the large spindle and the drive may be engaged or disengaged at will.

Both the saddle and table are of unusually heavy construction, liberal bearing surfaces being provided, with tapered gibs for making the necessary adjustments. Either the saddle or the table may be positively clamped at any point by means of binders provided for this purpose. The table has hand transverse feed, and both hand and power longitudinal feeds. The transverse feed is controlled through the handwheel *E*, the hand longitudinal feed through the handwheel *F*, and the power longitudinal feed through the lever *G*. The handwheels on the front of the machine are widely separated with a view of enabling the operator to get near to the work when necessary. Micrometer dials are provided to enable the adjustments to be accurately gaged. The power feed is operative in either direction, the lever *G* being pushed in or pulled out, according to the direction in which the table is to travel. In order to meet the diversified requirements of the machine, a liberal range of feeds has been provided. The feed mechanism is contained in a compact unit located at the right-hand side of the machine and is so constructed that two gear ratios are obtainable by means of sliding gears which act in conjunction with the six-step feed cones to give twelve changes of feed. The sliding gears are operated by the handle *H*.

The travel of the table is controlled by means of positive stops, this method being preferable to the ordinary automatic knock-outs, due to the fact that in sinking forging dies the operator always works to a line. It can readily be seen that it would be quite impossible to provide an automatic device which would be sufficiently accurate for this purpose. The stops are carried on the side of the table, suitable locating places being provided which act in conjunction with ordinary binders to prevent the stops from slipping. Furthermore, micrometer screws are provided which make it possible to obtain very delicate adjustments. Should the operator neglect to disengage the feed, the stop will engage the abutment *I* on the saddle, thus stopping the table. The friction through which the feed is controlled will slip under these conditions, preventing damage to the machine. Ordinarily, the operator would disengage the feed a trifle before the cutter reaches the line on the work, and then bring the table up to the micrometer stop by hand. The feed friction referred to is enclosed in a case *J* and is sufficiently powerful to provide adequate feed under all working conditions. In addition to the regular feeds, the table is provided with a quick hand return. This movement is obtained by releasing the lock-bolt *K* and rotating the feed-screw by means of a crank, the end of the screw being squared for this purpose. In the operation of the regular feeds, the screw remains

stationary and the nut rotates, which makes it possible to obtain a very rapid return by rotating the screw.

The plain vise which forms a part of the regular equipment of this machine extends practically the full length of the table. The top of the vise is provided with suitable locating places for the accommodation of the jaws; and the vise is pivoted at the center, allowing it to be swung to an angle of 15 degrees in either direction from the center. The machine may also be provided with a circular vise which is mounted directly upon the table. The rotary hand feed is transmitted through a worm and worm-wheel. Fig. 2 shows the cherrying attachment set up in the operating position, and Fig. 3 shows a larger view. It will be seen that the attachment is

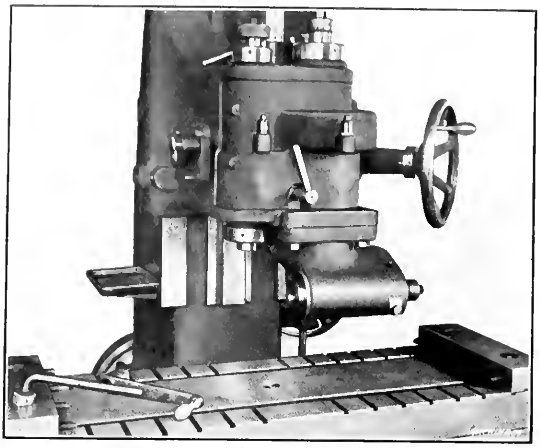

Fig. 2. Cherrying Attachment set up on Pratt & Whitney Die-sinking Machine

clamped to the under side of the head, being located by and driven from the large spindle. It may be swiveled and securely clamped in four different positions, *i. e.*, the horizontal spindle can be located in the most desirable position to operate upon the die that is being machined. The spindle of the attachment is provided with the same taper as the large spindle of the machine. Chucks for straight shank cutters are provided for use on this machine. These chucks are of rugged construction, being made of hardened steel and finished by grinding. They are made in sizes suitable for use in either the large or the small spindle.

The machine described in the preceding paragraphs is known as the No. 4 size, and its capacity is as follows: size of top of table, 18 by 72 inches; longitudinal travel, 30 inches;

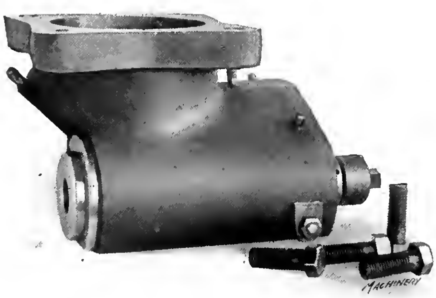

Fig. 3. Cherrying Attachment shown in Fig. 2

transverse travel, 16 inches; maximum distance from table to spindle, 28 inches; vertical movement of head, 20 inches, and maximum opening of plain vise, 52½ inches.

WATSON-STILLMAN HYDRAULIC STRAIGHTENING PRESS

The Watson-Stillman Co., 192 Fulton St., New York City, has recently added to its line the hydraulic straightening press shown in the accompanying illustrations. This machine has a capacity of 325 tons, which is sufficient for straightening steel shafts up to 10 inches in diameter; and the only limit to the length of the shaft is the extent of the foundations provided. By referring to Fig. 1, it will be seen

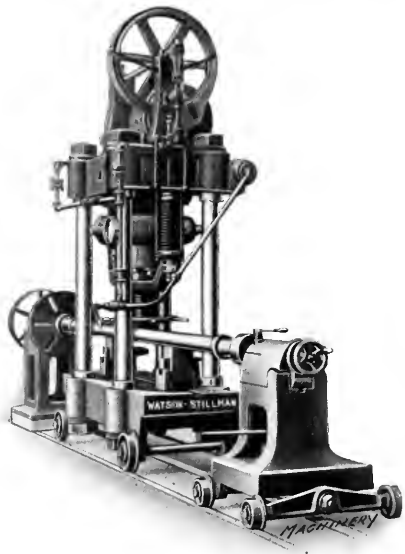

Fig. 1. Watson-Stillman Hydraulic Straightening Press in Operation

that the press is a motor-driven self-contained unit requiring no outside air or hydraulic system. There are three independent parts to the equipment—the headstock, which is stationary, and the press and tailstock, which are mounted on rollers to permit of their adjustment for straightening

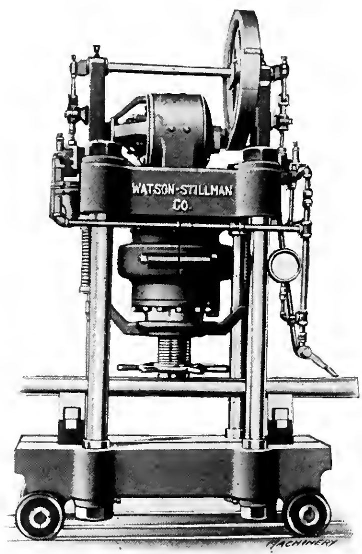

Fig. 2. Front View of the Watson-Stillman Press

shafts of various lengths. The bed rails are set flush with the floor so that when the movable parts are not in use, they can be rolled to one side, leaving the floor clear of obstructions. The head and tailstock are similar to those of a lathe except that the centers are hinged to follow the movement of the ends of the shaft while the shaft is bending.

The shaft is rotated from the headstock and the high point noted. The press is then moved to that point and the bending blocks adjusted. The ram has a maximum movement of 2 inches, and a square thread adjusting screw is mounted concentrically in it, as shown in Fig. 2. This provides for making adjustment for the different diameters of shafts

straightened in the machine, and also enables the operator to predetermine the flexure desired. In this way, all danger of over-bending is eliminated. The entire hydraulic power plant, including a five-horsepower motor, pump, reservoir, etc., is mounted on the top of the platen of the press. The floor space required is 3 feet 6 inches wide by the length of the shaft to be straightened plus six feet. The total weight of the press is 19,300 pounds.

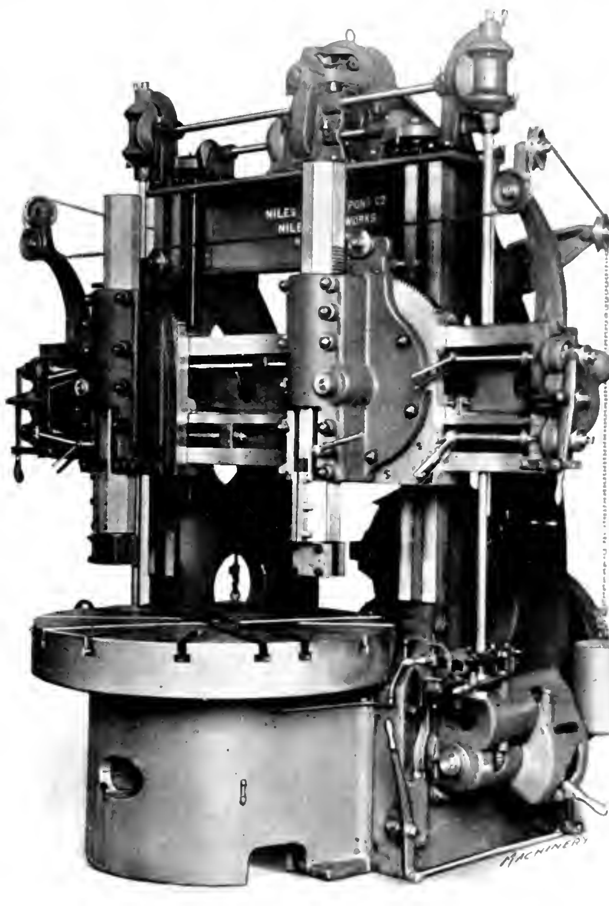
NILES BORING AND TURNING MILLS

The accompanying illustration shows the 53-inch size of a line of boring and turning mills which has recently been placed upon the market by the Niles-Bement-Pond Co., 111 Broadway, New York City. In the design of these machines, particular care has been paid to the development of features which add to the convenience of operation, thus increasing the output of the machine and operator. The levers for all changes of feed and reversal, rapid power traverse or hand adjustment of the saddles and bars, cross-rail adjustment and table control are within easy reach of the operating position. One lever disengages the feed, engages the fine and coarse feed and operates the rapid traverse in either direction. Rapid power traverse to the saddles and bars in either direction is provided and also hand adjustment of the saddles and bars by automatic releasing ratchets located at the sides of the saddles. The machine is entirely self-contained, no part extending below the floor line and no special foundation being required.

The housings are of the box girder form with broad faces which have no openings in the front of them. The cross-rail elevating screws are located between the housings. The table is strongly ribbed and supported by an annular bearing which is kept flooded with oil. The table is driven by a coarse pitch bevel gear, which is accurately cut and of wide face. The surface of the table has two pairs of parallel and eight radial T-slots. The table is maintained in strict alignment by an upper and lower bearing. The upper bearing is bored from the solid bed and fitted with an adjustable taper bushing to compensate for wear. The lower bearing is bronze bushed and there is an adjustable threaded collar on the end of the spindle to prevent lifting.

The cross-rail is of the three-track type. It has a narrow guide at the bottom with the saddle traversing screw located between the guiding surfaces. The cross-rail is of the box girder form and made of exceptional depth to enable it to resist the strains resulting from heavy cutting. It may be readily clamped to the housings in any desired position, and power adjustment is provided. The saddles have wide bearings on the cross-rail, which are accurately scraped and provided with tapered gibs to compensate for wear. A clamping bolt provides for clamping each saddle while the bar is feeding. The bars are octagon shaped steel forgings which are scraped to a bearing on four sides. Eight changes of positive feed are available; the feeds are reversible and independent for each head, both in amount and direction. The tool-holders are steel forgings provided with means for readily clamping the tools for boring, turning and facing operations. The tool-holders have straight shanks and are readily removed to provide for the insertion of special boring bars. Counterweights for each bar are attached to the same chain, but act independently of each other, and will not pull the swings over nor interfere with the movement of the saddles. The counterweight chain is placed at the rear of the bars to prevent interference with an overhead crane when moving work on or off the table of the machine. Safety friction clutches located on the vertical spline shafts insure against accidents in case the heads or bars meet with an obstruction while feeding or traversing.

Where direct current motor drive is employed, a four to one variable speed motor carried on the plate located between the housings at the rear of the machine is employed. Power is transmitted through a double run of clutch gears giving two mechanical changes of speed, which, in connection with the sixteen or more speeds in the controller, affords thirty-two or more speeds to the table. The motor is fitted with a push button control and a dynamic brake for the table. An auxiliary motor located on the top brace of the mill is furnished for elevating the cross-rail and operating the rapid power traverse for the bars and saddles. Belt drive through a single pulley or alternating current motor drive from a constant speed motor may also be employed. In this case, the drive is through a speed-box and back gear located at the rear of the mill, twelve changes of speed being provided. The speed-box is fitted with a hand operated friction clutch for starting or stopping the table, and a brake is provided that is controlled by the same hand lever which operates the clutch. Belt driven machines are built on the convertible plan and may be readily changed over for motor drive, if so required. This line of boring and turning mills is made in four sizes which have actual swings of $41\frac{1}{2}$, 54, 63 and $74\frac{1}{2}$ inches.



Fifty-three-inch Niles Boring and Turning Mill

KELSEY DRAFTING TABLE

A great deal of attention is now being paid to the development of convenient methods of controlling machinery and other factory equipments, so as to reduce the effort required of the operator and increase his efficiency. In the case of the draftsman, improved methods of control of this kind are particularly valuable, as the reduction of fatigue means that he is at his best both mentally and physically, which is particularly important in striving for the best results in drafting. The Kelsey drafting table illustrated in this connection is equipped with a special form of ruling

edge, which is more convenient to use than the regular form of T-square, thus reducing fatigue and increasing the draftsman's efficiency.

The design of the table may be briefly described as follows: a drawing-board holder, consisting of two castings mounted on a rocker shaft, has the drawing-board clamped between wooden front and back pieces by means of thumbscrews. The ruling edge or blade works independently of the edges of the board, and the way in which it is supported

Fig. 1. Kelsey Drafting Table with Blade in Operating Position

allows the draftsman to work with greater ease and rapidity than he could with an ordinary T-square. The blade is carried by a pivoted support which is almost counterbalanced by springs at either end of the table, the slight excess of weight being carried by a finger bar secured to the blade. The support is hung from a rocker shaft and so adjusted that a slight lift raises the blade a considerable distance

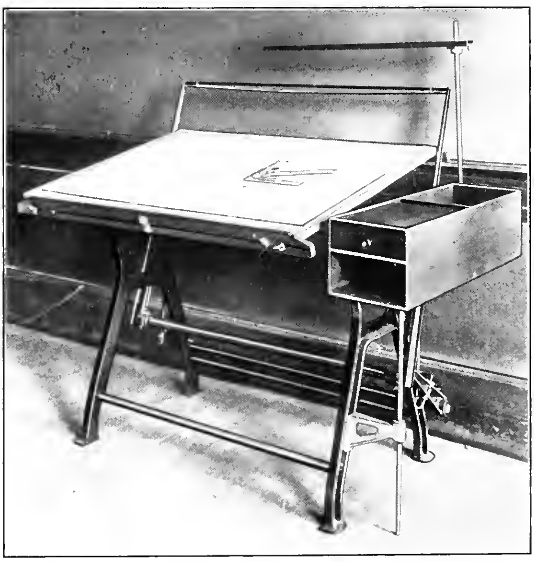


Fig. 2. Kelsey Table with Blade lifted up from the Paper

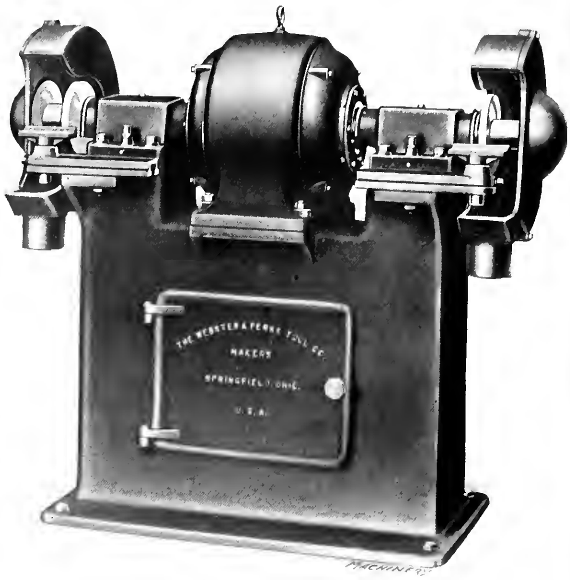
above the drawing-board, where it is held stationary until it is again wanted. This feature is particularly convenient when applying tracing cloth or changing drawings on the board. As the blade is practically balanced and can be moved into any desired position over the board by means of the finger bar, the convenience of the arrangement will be apparent. This device can be supplied as an attachment for use on any substantial table, in which case the support for the blade is mounted above the table.

The illustrations show the draftsman's universal square and protractor, which is a product of the same maker, in place on the table. This instrument affords a particularly efficient means of drawing horizontal, vertical and angular lines. The instrument is made in various sizes. It will also be seen that a cabinet is attached to the table. This cabinet has a drawer 7½ by 13 by 1¾ inch in size, a pocket 8 by 12 by 3 inches in size and a pigeon hole for holding rolled up tracings, which is 8 by 4 by 27½ inches in size. An upright for holding a light is also shown in the illustration. This drawing-board is a recent product of D. J. Kelsey, 77 Livingston St., New Haven, Conn.

WEBSTER & PERKS FLOOR TYPE GRINDER

The floor type grinder illustrated herewith is a recent product of the Webster & Perks Tool Co., Springfield, Ohio. The machine is driven by a five-horsepower alternating-current motor which is adapted for use on a sixty-cycle circuit and runs at 1150 revolutions per minute. The rotor is wound on a hollow steel shaft mounted in ball bearings, and the arbor of the machine passes through this hollow shaft, from which it is driven by a pair of dovetail steel keys. As the



Webster & Perks Motor-driven Floor-type Grinder

arbor is of smaller diameter than the hole in the rotor shaft, any ordinary deflection of the arbor cannot throw the rotor out of alignment and cause it to strike the fields. The arbor may be removed from the machine without in any way disturbing the motor. The arbor bearings are independent of the rotor bearings, being babbitted and provided with the self-oiling feature applied in the bearings of other machines of this company's manufacture.

The principal dimensions of this grinder are as follows: capacity for handling wheels, 16 or 18 inches in diameter by 3 inches face width; height from floor to center of arbor, 33 inches; size of base, 22 by 38 inches; and net weight of machine with motor, 1550 pounds. The machine is shown equipped with the exhaust type of wheel-guards which may be removed if necessary.

WOOD STOCK CONTROL CHUCK

The Wood Turret Machine Co., Brazil, Ind., is now equipping all its tilted turret screw machines and turret lathes with a new chuck; a machine equipped in this manner is illustrated in Fig. 1, and Fig. 2 shows a cross-sectional view of one of the chucks, from which the construction will be better understood. Referring to this illustration, it will be seen

that three grooves *A* are provided to keep the cutting compound from working into the spindle bearings. The holes *B* are provided to receive a spanner used in adjusting the chuck; *C* is the collet master or collet closing ring, and *D* is the collet. The spindle is recessed at the end to receive the collet closing ring *C*, this recess being ground to size by the use of a special fixture which is employed after the spindle is assembled in the bearings. This insures a more perfect and concentric bearing for the ring than could otherwise be obtained. The ring is hardened and ground both internally and externally, the internal opening being tapered to fit the nose of the collet.

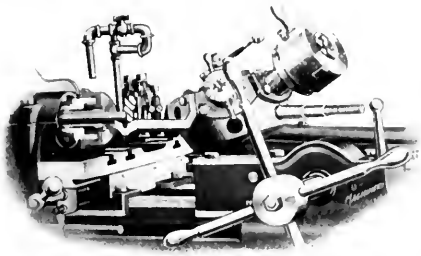


Fig. 1. Machine equipped with the Wood Improved Stock Control Chuck

In the old form of chuck in which the holder is screwed onto the spindle, the rear face of the chuck is so far removed from the point where the work is held that any slight variation between the chuck and spindle causes the work to be thrown materially off center. The necessity of frequently detaching the chuck from the threaded spindle causes the thread to become worn, with the result that lost motion develops between the chuck and spindle which causes a corresponding inaccuracy in the work. Furthermore, it was necessary to heat-treat a chuck of this style which resulted in distortion of the thread with a corresponding inaccuracy in the alignment of the work held in the chuck.

These objectionable features are entirely eliminated in the new Wood stock control chuck by simply mounting the collet in the spindle and centering it by means of the collet master *C*, which is hardened and then accurately ground. The master, in turn, is controlled by the hood on the end of the spindle, the hood keeping it from being pushed forward. With this construction the engagement of the hood with the spindle may be out of alignment without in any way affecting the alignment of the collet master and the collet. The collet master remains stationary when the chuck is in operation in chucking or unchucking the work. All wearing parts are hardened and ground.

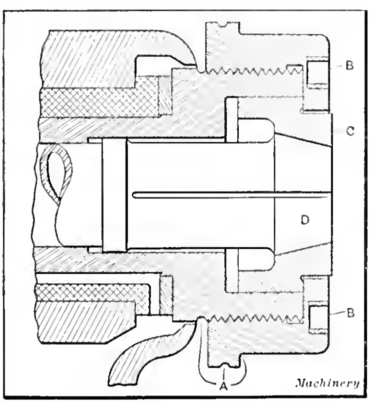

Fig. 2. Cross-sectional View of the Chuck

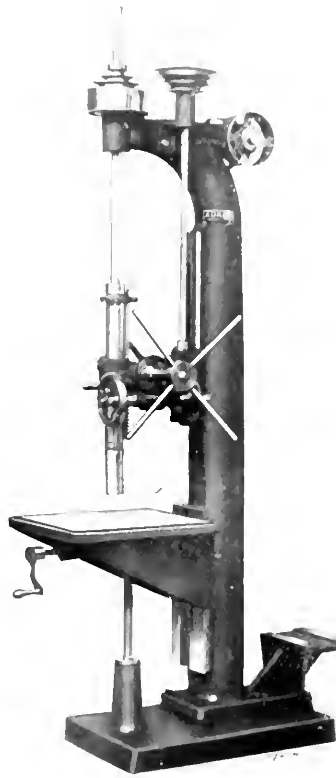
AURORA HIGH-SPEED DRILL

The high-speed drill equipped with both hand and power feed, an adjustment of 14 inches for the slide, 14 inches travel for the head and 11 inches adjustment for the table has recently been brought out by the Aurora Tool Works, Aurora, Ind. A number of these drills were built for use in the plant of the Fort Wayne Electric Works of the General Electric Co., according to specifications furnished by the mechanical superintendent. The machines are designed for heavy work in driving multiple spindle drill heads of the Langelier and similar types in which as many as eight 3/8-inch drills are working simultaneously.

The drive is provided by a direct current Fort Wayne motor mounted on a bracket on the base of the machine. The illustration shows the bracket provided for this purpose, but it will be seen that the motor is not in place on the machine. For the particular class of work for which these drills were built, a constant speed motor is used, driving the spindles at 1800 revolutions per minute. If a range of speeds was required, however, a variable speed motor could be employed or the motor bracket could be replaced by a bracket supporting a cone pulley. Three changes of feed are secured through the feed cone pulleys at the top of the machine,



Aurora Ball Bearing High-speed Drill

the available feeds being 0.0035, 0.007 and 0.010 inch per revolution. The pulleys are mounted in ball bearings and the spindle is equipped with a ball thrust bearing, which reduces friction losses to a minimum.

G. E. CONTINUOUS CURRENT GENERATORS

A new line of engine type, commutating pole, continuous current generators has been recently placed on the market by the General Electric Co., Schenectady, N. Y. These machines embody all the advanced refinements in the electrical and mechanical design of this class of apparatus, which enables them to meet the most exacting service requirements modern applications demand. The generators are offered in the usual complete line of standard sizes ranging from 25 K.W. to 400 K.W., inclusive. They are manufactured in both the two-wire, designated Form LD, and three-wire, known as Form LDS, types, with either shunt or compound field windings and with armatures wound to deliver the rated kilowatt output at any voltage from 115 to 125 volts or 230 to 250 volts. Larger sizes of both types and wound for 250 volts only are built on specification.

The speeds of these generators are in conformity with modern engine practice, and were selected after a careful consideration of the recommendations and requirements of leading engine builders. Compound wound machines auto-

matically compensating for line drop in the distribution system are built for any desired degree of compounding from no load to full load, although 1 to 5 per cent is usually sufficient for average conditions, and standard field windings provide for this amount. The frame is designed for installing on the engine bed plate or masonry foundations, and the armature is bored for mounting on the engine shaft. The utilization of commutating poles in these generators is one of the distinctive features of the new design, and permits operation over an extremely wide range of load and voltage with a fixed brush position and sparkless commutation. The commutating winding produces a magnetic field flowing in a direction that assists the reversal of current in the coil undergoing commutation, and is also directly opposed to the field generated by armature reaction tending to retard the reversal of current in this coil.

The commutating field thus completely nullifies the distortive effect of armature reaction on the main field flux in the commutating zone, and generates an electromotive force that helps the brush to commutate the current without sparking and with a consequent increased life of the commutator and brushes. Inasmuch as the commutating windings are directly in series with the armature, their strength varies directly with the armature current and provides the correct rectifying effect for proper reversal of current in the

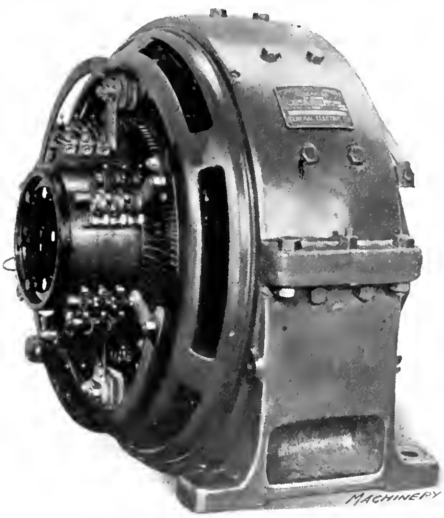


Fig. 1. Two-wire Form LD Engine Type Generator of 35 K. W. Capacity

coils at all loads. Hence it is unnecessary to shift the brushes as the load changes. A new and very important feature of this line of generators is the development of the three-wire machines with a special type of revolving compensator. The advantages of the three-wire system for the distribution of electrical energy at low voltages are well understood. The principal advantage is the fact that a 125/250 volt three-wire system requires about one-third the amount of copper in the distribution system required by a 125-volt two-wire system. Thus the adoption of the three-wire system for a combined lighting and power load saves about two-thirds the investment in copper.

The adoption of the revolving compensator with one collector ring for obtaining the neutral connection with three-wire operation is somewhat of a radical departure from previous designs. This design supersedes the familiar separate stationary compensator and two collector ring arrangement. The revolving compensator consists of a circular magnetic core upon which are mounted suitable exciting coils, the core with its coils being assembled on a cast bracket bolted directly to the back end of the armature spider. The compensator fits under the overhanging end windings of the armature, projecting but a short distance beyond the main winding, and requires no additional allowance in floor space. The compensator windings are connected to the main armature winding at proper points, and the neutral connection is taken through the armature spider to a single collector ring mounted on the outer end of the commutator shell. The neutral brushes bearing on this ring are supported by and insulated from the main brush-holder studs. The simplicity of this design, self-contained with the armature, eliminates floor space taken by the stationary compensator, requires fewer collector rings and brushes, and reduces the number of cable leads to the switchboard.

Revolving compensators may be applied and connected to standard Form LD two-wire armatures. Aside from the

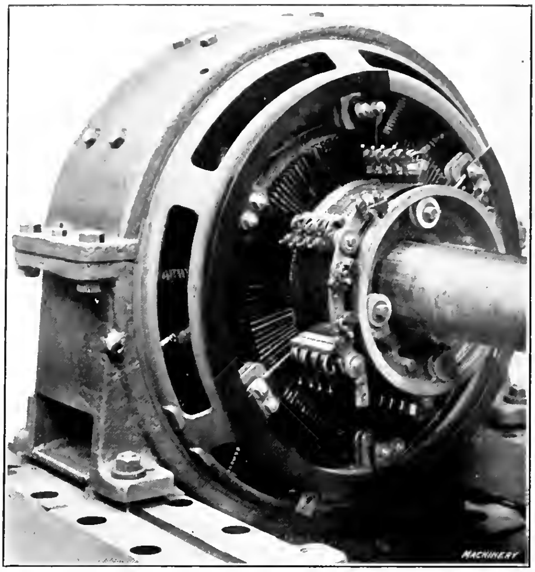

Fig. 2. Three-wire Form LDS Engine Type Generator of 100 K. W. Capacity

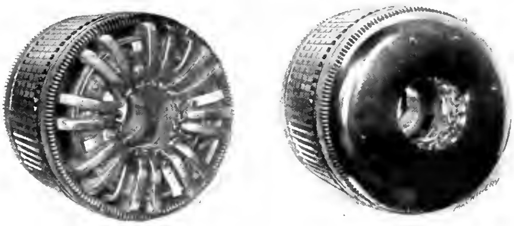
armature construction, the only important difference between a two-wire Form LD and a three-wire Form LDS generator is in the field connections. In the three-wire generator the series and commutating fields are equally divided between the two sides (positive and negative) of the armature, insuring exact compounding for all load conditions whether balanced or unbalanced. Three-wire generators are designed to carry on unbalanced current of 25 per cent of the rated full load current in the neutral. Particular attention has been given to the ventilation of these machines. Armature cores, windings, spiders and flanges, commutator shells and all field coils are of the open construction, allowing a free circulation of air through and around all component parts, which insures low temperatures, good efficiency and durability of the insulation. The magnet frame is cast steel split horizontally above the center line, so that the generator can be taken apart for cleaning, inspection or repair without removing any of the field poles.



Figs. 3 and 4. Armature with Revolving Compensator for Three-wire Machine

The main poles are of laminated steel, punched to suit the finished frame and held in place by bolts. The main field is constructed with the series coil mounted outside the shunt coil, and is separated a sufficient distance to permit thorough ventilation and insure easy access to either coil. The shunt coil is thoroughly insulated on a sheet metal body and is supported by heavy insulating collars. The commutating poles are of rolled steel held in place by bolts, and carry a

helical winding of edgewise-wound copper strip, insuring effective radiation of heat. Either the main or commutating poles with their coils are readily removed without interfering with the magnet frame or brush rigging. The armature windings, either multiple or series as best suits the design, are formed from bar stock in coils of endless type, without joints or clips on the back end; and the design of the coil is such that an exceptionally free circulation of air is obtained around and through the end windings. An improved wrapped type of insulation supersedes the trough type used on previous designs. The windings are held in the slots by hardwood wedges dovetailed in the punchings, and on the ends by binding bands, which do not, however, extend over the core. The end connections are supported by flanges bolted to the armature spider. Suitable equalizer connections are provided on all multiple wound armatures to prevent any difference in voltage due to variation in the air gap, and also to equalize the magnetic pull on the shaft.

The commutator segments are made of liberal depth, from hard drawn copper, insulated from the shell and from one another by mica gaged to uniform thickness and of such hardness as to wear evenly with the copper. On the smaller sizes the back clamping rings are cast integral with the commutator shell, the outer clamp ring being a separate casting. On the larger sizes both clamping rings are separate castings. The commutator segments are of sufficient length to permit staggering the brushes, which insures even wear of the entire commutator surface. The commutator is supported independently of the shaft, being mounted on an extension of the armature spider. The segments are connected to the armature winding by copper strips soldered into the segments and to the armature conductors. The armature core is built up of thin laminations thoroughly annealed, assembled and keyed to a finished seat on the armature spider. Through bolts hold the assembled core in place between two cast-iron flanges, one of which is cast integral with the spider. These bolts are located within the inner periphery of the punchings and do not pass through the core. A liberal number of radial air ducts is provided to insure good ventilation.

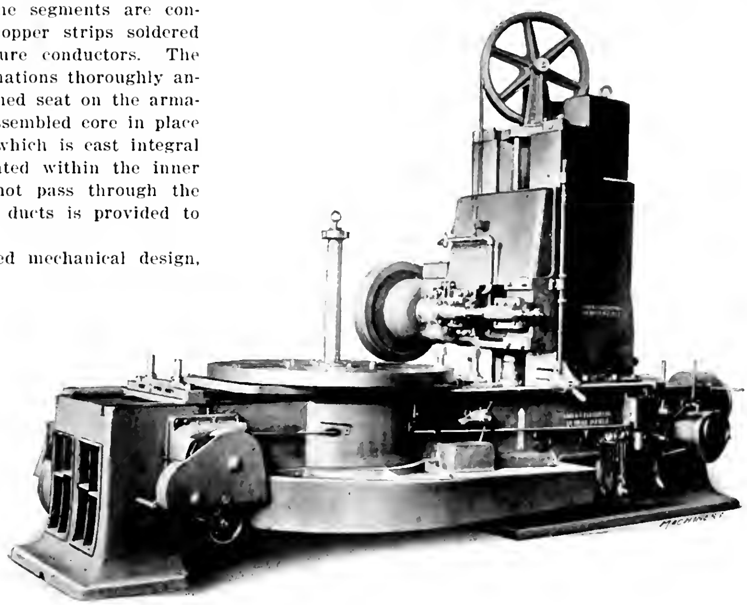
The brush rigging is of an improved mechanical design, the yoke fitting closely in a groove turned in the magnet frame. The brush-holder brackets are firmly attached to the yoke and are made adjustable to allow for natural wear of the commutator. The brush-holder studs are riveted in the brackets and are supplied with a liberal number of brush-holders. No shifting device is furnished nor required. After the brushes are once adjusted in their proper position, the yoke is locked in place and no further brush shift is necessary. The design of the brush-holder embodies distinctive features. The brush-holder body is a single-piece brass casting bored for the stud fit, while the broached box offers a long bearing surface that eliminates grooving of the brush. The punched steel lever is rigid and maintains its relation to the brush irrespective of wear. Tension is obtained by a steel wire spring, the design allowing a wide range of adjustment for brush pressure. A metal cap riveted to the brush avoids wear at the point of contact with the spring lever. A flexible copper connection with ample contact surface is supplied for carrying the current to avoid deterioration of the brush-holder spring.

Connection blocks are bolted to the under side of the magnet frame. To these are fastened the machine leads, which are fitted with suitable terminals for receiving the line cables. While commutating pole generators are superior to non-commutating pole generators for any character of service, these machines with their many additional improvements in design will operate in a thoroughly satisfactory and reliable manner under the most severe service conditions, where fluctuating motor loads frequently predominate, such as for lighting and power service in office buildings, industrial plants, mines, and other classes of service.

GOULD & EBERHARDT AUTOMATIC GEAR-CUTTING MACHINE

Gould & Eberhardt, Newark, N. J., have recently built the automatic gear-cutting machine which forms the subject of this article for Foote Bros., Chicago, Ill. The machine is of exceptionally large size, having a capacity for cutting spur gears up to 144 inches in diameter by 24 inches face width. Steel gears up to 4 inches circular pitch can be handled by the machine. This automatic gear-cutting machine is of the vertical cutting type, and owing to the exceptionally heavy gears for which it is designed, the indexing worm-wheel is mounted in a fixed position and the stanchion carrying the cutter-slide is adjustable by hand or power to accommodate gears of various diameters and also for setting the machine for the required depth of cut.

The cutter spindle is driven by a powerful worm and worm-wheel, and a heavy flywheel is mounted at the end of the main spindle to compensate for any inequality in the work or any other cause which might tend to make the speed of the cutter fluctuate. The cutter spindle is 3 inches in diameter and will take cutters up to 14 inches in diameter. An auxiliary cutter spindle is also provided which is driven through hardened helical gears from the main spindle. This auxiliary spindle makes it possible to use cutters of ordinary sizes, thus adapting the machine for cutting smaller gears. The use of these two spindles enables this machine to handle a great variety of sizes of gears ranging from small pinions up to the large size gears referred to in the preceding paragraph.



Gould & Eberhardt Automatic Gear-cutting Machine of Unusually Large Size

The machine is entirely automatic in operation and is equipped with many of the features of the Gould & Eberhardt gear-cutting machine of smaller size. A wide range of cutter speeds is provided and the cutter feeds, which are independent of the speeds, may be conveniently changed through an improved type of gear box. The indexing worm-wheel is of the split rim type and exceptional care has been taken to hob it accurately. The index and feed mechanisms are connected through a system of inter-locking levers which are so arranged that it is impossible for the feed clutches to be engaged until the indexing operation has been completed. A system of oil pans completely covers the worm-wheel and prevents oil from splashing onto the floor. An

oil pump of generous proportions supplies a liberal flow of cutting compound to the cutters.

In addition to being used in its regular capacity, the machine is so arranged that worm wheels can be hobbed automatically without previously gashing the teeth. The cutter spindle is geared in unison with the indexing worm and single or multiple thread hobs may be used with equal facility. The speed of the indexing wheel may be varied to suit the different sizes of gears. The cutter spindle may be locked in any desired position for hobbing and an automatic mechanism gradually feeds the hob into the wheel. The weight of the machine is about 35,000 pounds.

MARTELL ALIGNING REAMER

A garage engaged in handling a general line of repair work finds that the bearings constitute the greatest element of uncertainty in making an estimate on the price to be charged for overhauling a car. This is due to the great variation in the amount of wear which may be found in the bearings of different cars. With the view of overcoming this difficulty, the Martell Motor Co., 1928 Columbus Ave., Boston, Mass., has brought out an aligning reamer which is shown in operation in Fig. 1. When this reamer is used, badly worn bearings may be refinished with practically the same rapidity as those which have very little wear so that the repair man is able to estimate intelligently on this part of the work.

The reamer shaft is supported by a number of temporary bearings which engage directly with the holes to be reamed, thus making the device entirely independent of the form of the supporting members of the bearings. The fact that it is not necessary to bolt the crank-case down rigidly is also a feature which adds to the assurance of perfect bearing alignment. The reamer shaft is easily adjusted in relation to any given points, as, for instance, paralleling a surface or providing for the proper mesh of gears. An ample range of adjustment of the reamer blades is also provided. The reamer heads are secured to the shaft in such a manner that they may be rigidly clamped to the shaft in any desired position.

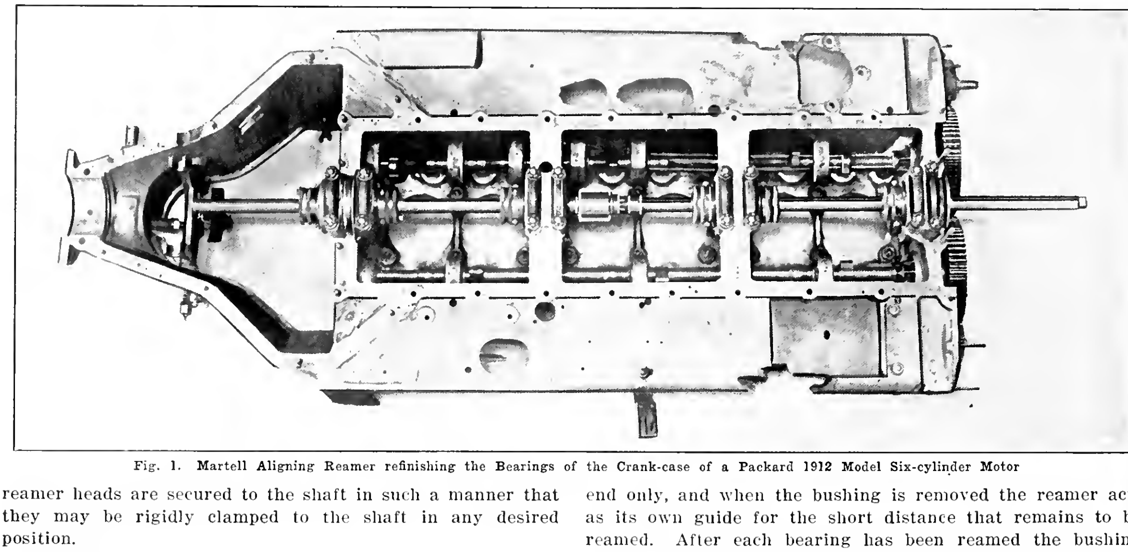


Fig. 1. Martell Aligning Reamer refinishing the Bearings of the Crank-case of a Packard 1912 Model Six-cylinder Motor

An eccentric flanged bushing that is mounted directly on the reamer shaft has the flanged portion provided with a radial slot concentric to the surface engaging with the bore of a second bushing. This second bushing is also of the eccentric flanged type and is an easy fit over the first bushing. The flanged portion of the second bushing is provided with six tapped holes which are located on a circle that is concentric with the bore; and a cap-screw passing through the radial slot serves to lock the two bushings together in any desired position. The edges of the flanges of these bushings are graduated, one bushing having nineteen divisions and the other twenty, thus affording a vernier which shows the eccentricity of the two bushings in thousandths of an inch. The range of variation is from zero to 0.095 inch. A conical bushing with the taper portion threaded with seventy threads per inch is screwed firmly into the end of the bearing or hole to be reamed. The bore of this conical bushing is ground to receive the larger of the two bushings previously referred to and is provided with four clamping screws to lock the position of the bushing when the desired adjustment has been obtained.

It has already been mentioned that the reamer is equipped with two heads, each of which carries six blades which are assembled in suitable slots. There are wedges at each end of these slots which engage the inclined surfaces of the blades and allow them to be moved toward or away from

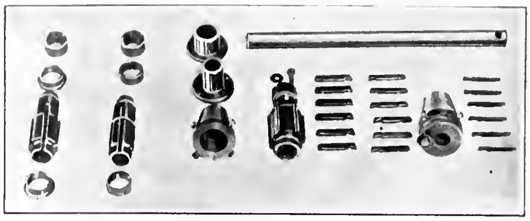

Fig. 2. Parts of the Martell Aligning Reamer

the center through the action of adjusting nuts. The reamer heads are held in any desired position on the shaft by means of locking nuts. The reamer blades are oil tempered and ground and provided with a 6-degree angle on the cutting edge.

The reamer is shown in Fig. 1 refinishing the crankshaft bearings of a 1912 Packard six-cylinder motor. The crankshaft gear is mounted directly on the reamer shaft by means of a special bushing, and the proper mesh of the gears is obtained by means of eccentric bushings. The rear end of the shaft is next aligned to bring it parallel to the top of the crank-case. In order to ream all the way through the bearings, the bushings at the back end must be removed. The reamer blades are provided with a cutting edge on the front end only, and when the bushing is removed the reamer acts as its own guide for the short distance that remains to be reamed. After each bearing has been reamed the bushing that was removed for the purpose is replaced in its former position. In this manner the work is easily and accurately handled. This reamer was designed for reaming automobile crankshaft bearings, the idea being to provide the repair man with a means of accurately aligning such bearings and saving time in the operation. An idea of the rate at which the tool works may be gathered from the fact that the job shown in Fig. 1 was completed in eleven hours without any attempt having been made to establish a record.

GARDNER MOTOR-DRIVEN POLISHING LATHES

The motor-driven polishing lathe shown in the accompanying illustration is a recent product of the Gardner Machine

Co., Beloit, Wis. The notable features of this machine are the application of motor drive, the motor starter and the way in which the spindle construction has been worked out. The fully enclosed direct-current motor is of the commutating pole type and runs without any sign of sparking. It has a continuous rating of 4 horsepower and a two-hour rating of 6 horsepower. The compound starter is mounted within the base of the machine and is accessible by opening the hinged door at the front. A speed variation of from 2000 to 3000 revolutions per minute may be obtained.

The spindle is of unusual size and mounted in ball bearings. In the No. 3 size machine shown in this connection, the spindle is 49 inches in length; its maximum diameter is 2¼ inches and the diameter between the flanges is 1¼ inch. The complete weight of the No. 3 machine is 850 pounds. The same type of machine is made in two smaller sizes, known as the No. 2 and No. 1 Gardner polishing lathes. The No. 2 machine has a spindle 42½ inches long, the diameter between the flanges being 1 inch; the No. 1 machine is equipped with a spindle 32 inches long and the diameter between the flanges is ¾ inch. The preceding spindle lengths are standard, but special spindles of different lengths may be supplied to meet the requirements of different classes of work.

No. 3. Gardner Ball Bearing Motor-driven Polishing Lathe

DETROIT SEMI-AUTOMATIC DRILLING MACHINE

The semi-automatic horizontal drilling machines which form the subject of this article were designed by the Detroit Tool Co., Detroit, Mich., for drilling small holes in small work. Drilling of this nature requires precision, speed and rapid handling, and these machines meet the requirements in a very satisfactory manner. The horizontal spindles permit the work to be held in fixtures of simple design, in which the work can be located without moving the fixture or risking interference by the drill. Both the work and drill are constantly visible. The working parts are all enclosed, thus protecting both the mechanism and operator from injury. On most classes of work, the capacity is governed entirely by the speed with which the operator can handle the work. The drills are fed automatically by cams, and as the feeds are entirely independent of the operator, it is necessary for him to maintain a steady rate of production or fall behind the machine. These drilling machines are made in two sizes, known as the No. 1 and No. 2. The principal features of both machines are identical and the following description applies to either machine. The No. 1 machine is designed particularly for drilling very small work at high speed, while the No. 2 machine is adapted for handling work of a more general character, and to adapt it for this purpose it has a wider range.

As previously stated, the operator is merely required to look after placing the blanks in the work-holding fixtures

Fig. 1. Detroit Semi-automatic Horizontal Drilling Machine

and removing the finished product. The drills advance automatically at the proper rate of feed so that they enter the work without breaking. If desired, the cams may be so formed that the feed increases automatically after the drills have started, and when so desired the drills may also be backed out to clear the chips out of deep holes. When a hole is finished, the drill is withdrawn and remains back long enough for the finished piece to be removed from the fixture and a fresh blank mounted in its place. In the meantime, a steady flow of cutting lubricant has washed away

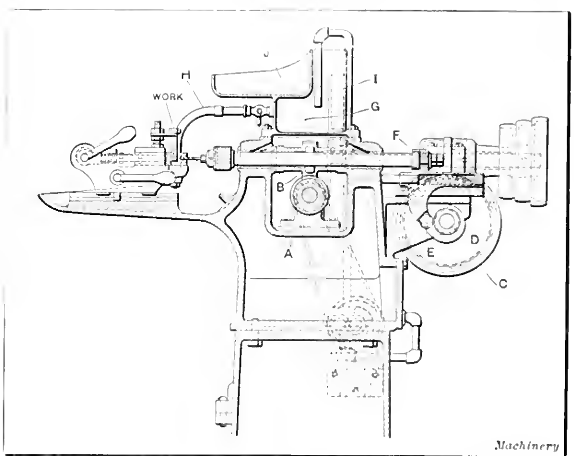

Fig. 2. Cross-section through Machine showing Feed Mechanism

the chips so that the work and fixture are clean. The cams for feeding each drill are so timed that the holes are drilled in rotation. In this way the operator is able to divide his time between the five work-holding fixtures, and by the time he has placed a blank in the fifth fixture, the hole has been finished in the piece held in the first fixture and he can go

back and replace this piece by a fresh blank. He then begins changing the finished product for fresh blanks in each fixture in turn, performing this cycle over and over. Fig. 2 shows a cross-sectional view of the machine, from which the design will be readily understood. The main driving shaft *A* extends through the bed at right angles to the spindles, which are driven from this shaft by means of spiral gears *B*. Between the first and second, and the fourth and fifth spindles and parallel to them, there are two shafts, one of which is driven by spiral gears from the main driving shaft *A* and the other connected to the cam-shaft *D* through a worm and gear *C*. These two shafts are connected at the rear of

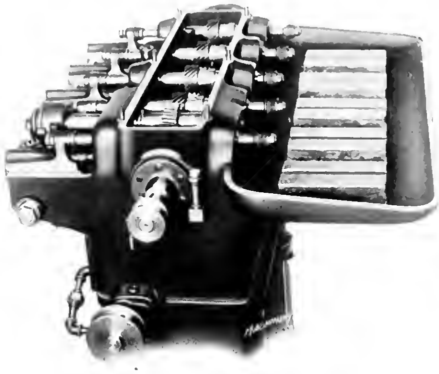

Fig. 3. Arrangement of Spiral Gears connecting Driving Shaft and Spindles

the machine by a belt running over three-step cone pulleys, thus providing three different spindle feeds for each spindle speed. The feed of the spindles is obtained by cams carried on the cam-shaft *D*, which operate against rollers *E* attached to slides carried on the rear end of the spindles. The cams force the spindles forward, thus feeding the drills into the work, and the spindles are withdrawn by springs.

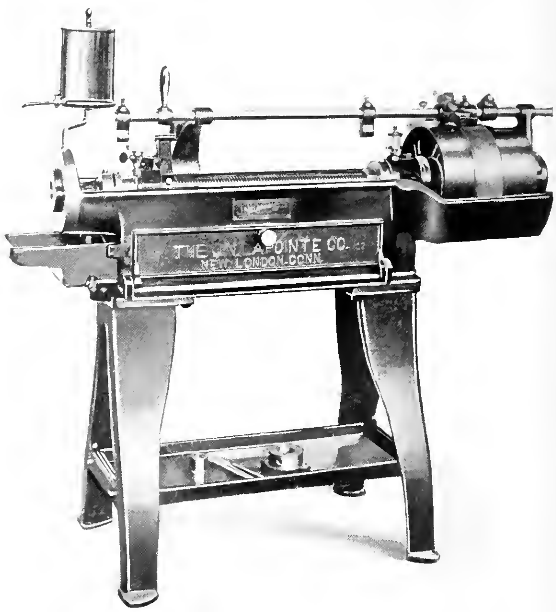
Spiral and worm gears are used throughout the machine. All of the gears are located in a compartment in the bed at the rear of the pan as shown in Fig. 3. The construction forms an oil-tight compartment which completely encloses the gears, and when supplied with oil constitutes a self-oiling system. Both the gears and the spindle bearings and main shaft bearings are lubricated from this source. The spindles are made of hardened alloy steel, and are ground to the required finish and carefully balanced. On the No. 1 machines the spindles are $\frac{3}{4}$ inch in diameter, and have a taper of 0.9 inch per foot to fit a standard No. 1 chuck. On the No. 2 machine, the spindles are 1 inch in diameter, and have a taper of 0.96 inch per foot to fit a standard No. 2 chuck. On both machines, the end-thrust of the spindles is taken on ball bearings at the rear, which are shown at *F* in Fig. 2. Each spindle is carried in two bearings of ample size, which are lined with bronze. The main driving shaft bearings and the bearings of the two shafts controlling the cam-shaft are also bronze bushed. All of the bearings are line reamed.

Cutting lubricant is supplied to the drills from the tank *G*, from which it is conveyed by curved pipes *H*. A uniform flow at a constant pressure is insured as the surplus oil is pumped into the upper tank where a uniform level is maintained by means of the overflow *I*. The oil is drained from the chip pan through a strainer into a settling pan in the base of the machine. From there it passes to a reservoir in the base, from which it is pumped back to the upper tank *G*.

The saving of drills effected by the automatic feed employed on this machine is an important feature. Where drills are fed by hand, the rate of feed and strain on the tool varies considerably and results in a serious breakage of drills. With the cam mechanism employed on the Detroit drilling machines, however, the most suitable feed may be determined and this feed constantly employed. Where the drill enters a piece at an angle, or where other conditions exist which make it difficult to start the hole, the feed cams may be so shaped that the feed is slow at the start and accelerates automatically after the drill has entered the work. On deep holes it is frequently good practice to form the cams in such a way that the drills are withdrawn after the hole has been drilled to about one-half the required depth, thus clearing the chips from the hole. The machine is of compact design, and this feature, together with its high rate of production, means a considerable saving of floor space, which is at a decided premium in many factories. This feature is further enhanced by having a work-pan shown at *J* in Fig. 2 provided at the top of the machine. This does away with the necessity of using a table or some other space consuming equipment to hold the supply of work.

J. N. LAPOINTE NO. 0 BROACHING MACHINE

The broaching machine, illustrated herewith, was designed by the J. N. Lapointe Co., New London, Conn., to meet the requirements of a manufacturer who had work to be broached that was too small to be handled conveniently on a larger sized broaching machine. The machine proved so successful in operation that it is now being built for the market. The driving mechanism is of the simple planer type used on other J. N. Lapointe broaching machines and an automatic brake is provided. A belt shifting rod is located at the top of the machine which extends for its entire length. The automatic adjustable stop dogs are mounted on this rod and they may be set at any desired position according to the length of the broach that is to be used. A handle is also mounted on this rod which provides for operating the shifting mechanism by hand. This feature is particularly convenient in allowing the machine to be stopped instantly—regardless of the position of the automatic stops—in case the broaching tool fails to operate satisfactorily. The sliding head is arranged with vertical adjustment to provide



J. N. Lapointe No. 0 Broaching Machine for Small Sized Work

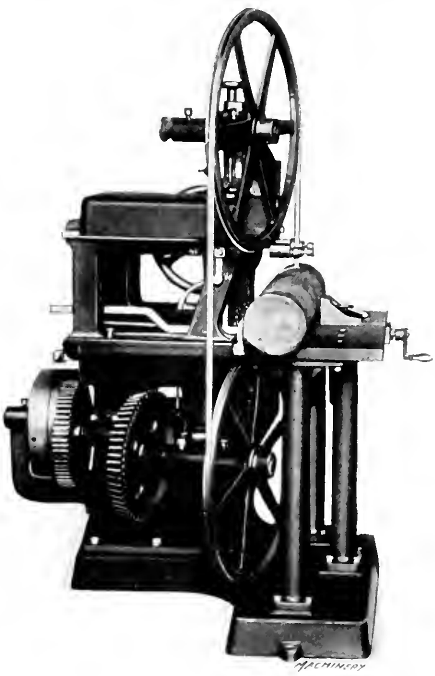
for regulating the position of the broaching tool to the desired height.

An oil pot at the top of the machine supplies lubricant to the broach and an oil pan is provided to catch the lubricant. This pan is detachable, permitting it to be removed and emptied when necessary. A small cupboard of sufficient length to hold the broaching tools when not in use is provided. The machine is made with legs and a pan as shown in the illustration; or it may be used without legs, in which case it is set up on a bench. The principal dimensions are as follows: Length of stroke, 21 inches; diameter of driving pulley on machine, 10 inches; width of driving belt, $1\frac{1}{2}$ inch; width of return belt, 1 inch; weight of machine with legs, 445 pounds and without legs, 325 pounds. The capacity

of the machine is for cutting a keyway up to 1/4 inch wide and of any reasonable length; holes up to 1/2 inch square by 1 inch long may be broached.

HOUGHTON & RICHARDS METAL CUTTING BAND SAW

In the August, 1913, number of MACHINERY, the drop-arm type of metal cutting band saw built by Houghton & Richards, 1394 W. 3rd St., Cleveland, Ohio, was illustrated and described. Since that time, the company has developed a straight-line metal cutting machine which is illustrated herewith. This machine is designed to cut to any required depth



Houghton & Richards Metal Cutting Band Saw

in irregular sections of all kinds, such as bar stock, piping, beams, etc.; in fact, any shaped wooden piece that can be cut on an ordinary wood band saw can be cut in metal on this machine. The construction is exceptionally heavy, and an automatic stopping device is provided in conjunction with an adjustable stop for regulating the depth of cut from zero to 6 inches. The feed is controlled by a weight located inside the standard which carries the sliding carriage. This weight is entirely covered but is easily accessible and provides a constant pressure of the saw against the work. The arrangement of the weight and cable is in the form of a Chinese windlass.

The sliding carriage which carries the wheels over which the band saw runs has large bearing surfaces with V-slides on the bottom and flat slides on the top. The adjustable stop is regulated by means of a small lever at the side of the sliding carriage; this lever is connected with a radius rod which slides the square rod that carries the stop either in or out, traveling with the carriage and controlling the depth of cut. When the small lever is set for any required depth of cut and the sliding carriage has traveled the required distance, the stop on the square bar comes into contact with the lever which holds the belt shifter on the tight pulley. The engagement of the stop and lever causes the shifter to be released and a spiral spring then throws the shifter over, moving the belt onto the loose pulley and stopping the machine. The sliding carriage is returned by means of a handwheel which is connected with a small steel pinion and steel rack on the sliding carriage. The carriage is held in place by a self-acting lock which must be released by hand before it can advance for another cut.

The guide rollers are of tool steel, hardened and ground, and hold the band saw in line for making the cut. An adjustment for alignment of the band wheels is furnished on the upper arm at the tension side of the saw and when once set, the wheels are set for all bands. The band saw used on the machine is 5/8 inch wide by 0.0312 inch thick, and for the machine having a capacity for cutting work up to 6 inches in diameter the saw is 12 feet 6 inches long. The heavy construction adapts the machine for standing up under hard usage. The illustration shows a machine equipped for belt drive, but if so desired, motor drive through a silent chain or direct gearing may be employed. An idea of the capacity may be gathered from the fact that the time required to cut through a 6-inch bar of tungsten steel is about 24 minutes and the disk will be within 0.001 inch of parallel. Operating at this rate, the capacity of a band saw will be to cut from 1200 to 1500 square inches of steel, depending on the speed and the material. The floor space occupied by the machine is about 9½ square feet.

Since the preceding type of drop-arm band saw built by Houghton & Richards was described in MACHINERY a number of important improvements have been made, among which the following may be mentioned: A positive worm geared feed has been provided for use when the saw is engaged in cutting work of large diameter. This mechanism applies exactly the same pressure on the saw all the way through the cut and adds to the life of the blade on this account. The friction feed can be used on work up to 3 inches in diameter but the use of the positive feed mechanism for all sizes of work is recommended. When the positive feed is used the machine requires absolutely no attention after it has been started. Using the friction feed, it is possible to cut a 3-inch bar in seven minutes, but operating at such a speed the life of the band saw blade is relatively short. When the positive feed is used, the life of the saw is considerably increased, as the pressure on the saw is constant. A band saw blade 5/8 inch wide by 0.031 inch thick will cut from 1000 to 1500 square inches of steel when running at a speed of 135 feet per minute. This improved drop-arm saw has a capacity for cutting stock from zero to 8 inches in diameter

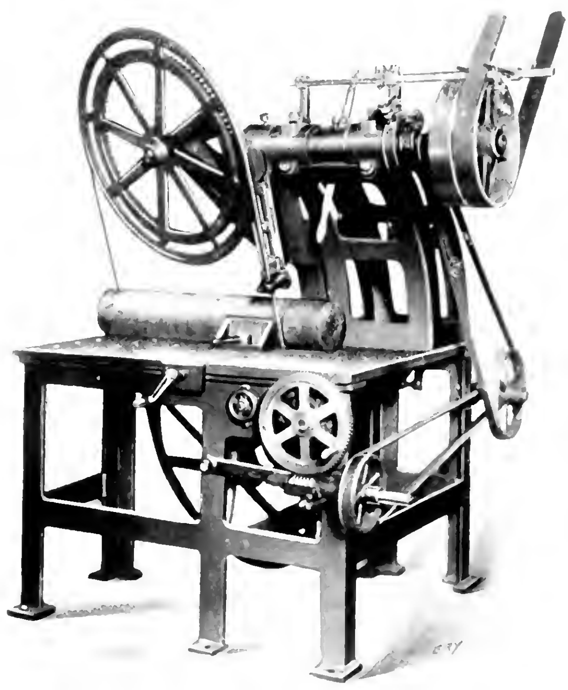


Fig. 2. Improved Type of Houghton & Richards Drop-arm Saw

and it will cut off 8-inch tungsten or carbon steel disks so that the two faces will not be more than 0.002 inch out of parallel.

CORBIN SAFEGUARD FOR PRESSES AND DROP HAMMERS

The Corbin Cabinet Lock Co., New Britain, Conn., is now manufacturing a safeguard to protect the operators of power presses and drop hammers from injury. A power press equipped with one of these guards is illustrated in Fig. 1, and Fig. 2 shows one of the guards in place on the drop hammer. The number of accidents which occur to the operators of power presses and similar machines has led to the development of a great variety of safeguards to provide for the safety of the operators of such machines. In a great many cases, however, these guards have proved inefficient because they hinder the operator in the performance of his work.

The important feature of the Corbin safeguard is that the view of the work is unobstructed at all times and the guard affords adequate protection to the operator without hindering his work in any way. The principle on which this guard operates can best be explained by referring to Fig. 1. It will be seen that a bracket is attached to the frame of the press, from which a horizontal bamboo stick is suspended in such a way that it is free to swing. This stick rests against the operator's arms at a point a little above the elbows. When he reaches forward to adjust a piece of work in the die, the stick is pushed forward. A thin metal rod is attached to one end of the bamboo stick, and when the stick is pushed forward this rod slides a stop into place, which locks the treadle rod in such a way that it is impossible to trip the press. When the operator has adjusted the work and draws his hands back from the die, the bamboo stick drops back to its former position and the stop is drawn back so that the press can be tripped. From this description it will be evident that the operator is not required to pay any attention to the safeguard, and it works so smoothly that he is not conscious of it. Consequently, it does not reduce his efficiency in any way.

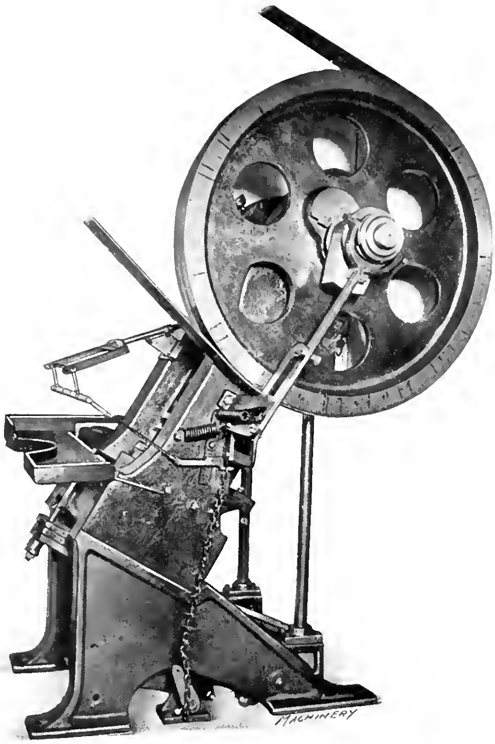

Fig. 1. Power Press equipped with Corbin Safeguard

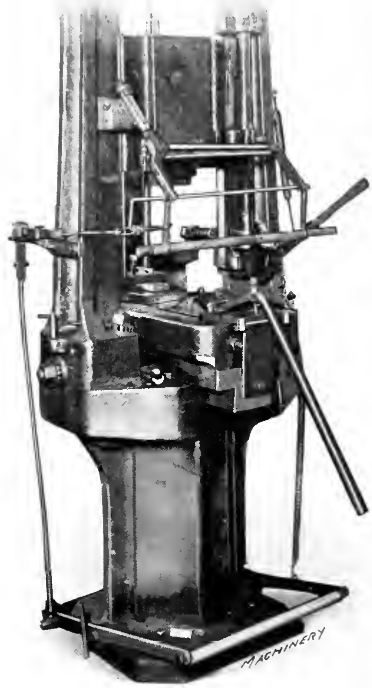

Fig. 2. Corbin Safeguard in Place on a Drop Hammer

LANGELIER SEMI-AUTOMATIC TAPPING MACHINE

The accompanying illustration shows a vertical semi-automatic multiple spindle tapping machine equipped with a stationary head and movable work table which is built by the Langelier Mfg. Co., Providence, R. I. This machine is designed to tap a large number of holes in a single operation and in practically the same time that it would ordinarily take to tap one hole with a single spindle tapping machine. With the new Langelier machine, the duties of the operator are reduced to merely placing the blanks on a simple work-holding fixture and taking off the tapped parts. The cycle of operations is so rapid and exact that as many as fourteen brass plates 1/16 inch in thickness, with seven holes tapped in each plate, have been turned out by this machine in a minute. The machine is especially adapted for use in plants making large quantities of similar parts—such as factories engaged in the manufacture of automobile parts, clocks, typewriters, electrical instruments, camera shutters, telephones and a great variety of other products.

The operator starts the machine by tripping a knee lever or by lowering the opposite end of this lever by hand. This operates the belt shipper and moves the belt to the forward driving pulley. In so doing, an upright shaft whose main function is to drive the main spindle of the multiple tapping head is set in operation, thus starting the multiple spindle tapping head. The tapping spindles in this head are crank driven; they are machined from steel bars, heat-treated and carefully finished by grinding. All of the spindles are accurately located on fixed centers and run in phosphor-bronze bearings. The head can be quickly removed from the machine to provide for the substitution of another head having a different spindle layout. In this way various parts can be tapped with the same machine by using different tapping heads interchangeably.

The spindles can be arranged in practically any desired way over a circle 5 inches in diameter. Each spindle is provided with a special compensating arrangement which permits the tap to follow its own lead independently of the way in which other taps are working. This insures having

every hole tapped with clean cut threads. It also makes it possible to operate taps with different pitches simultaneously and insures uniform and truly interchangeable work. On reaching the desired depth, the taps are reversed automatically.

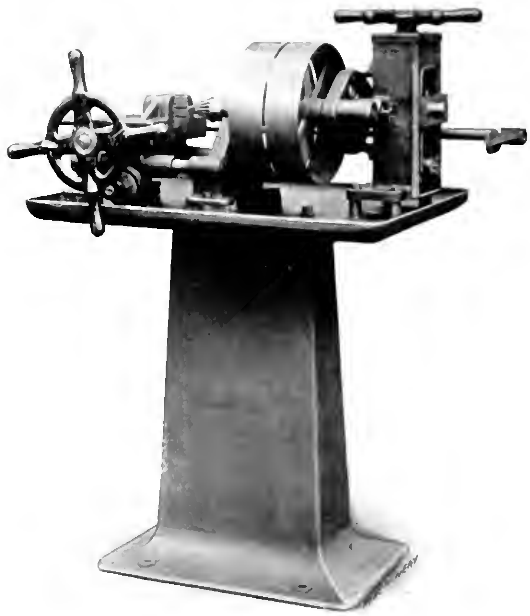
The upright shaft which drives the multiple tapping head also drives a short horizontal shaft at the right of the machine, power for this purpose being transmitted through steel and bronze spiral gears. A steel worm is mounted at the front end of this horizontal shaft which meshes with a worm thread cut in a vertical hub under the work table. This hub has an edge cam path cut on its upper end, and a cam roller which is trunnioned to the stub post of the work table runs over this path when the hub is rotated by the worm on the horizontal shaft. During the tapping operation, the work table is raised by this cam and roller until the taps have penetrated to the desired depth. An automatic trip then operates, shifting the driving belt over to the reversing pulley, reversing the taps and lowering the table at almost double the speed at which the tapping operation was conducted. When the table reaches its lowest position, the trip again shifts the driving belt to the loose pulley and the machine stops, ready for the finished work to be removed and blanks substituted in its place. This cycle of operations is repeated with great precision and rapidity. The automatic stop may be set to stop the table at practically any desired point and the forward and reverse speeds may be closely adjusted to suit the conditions of different classes of work.

Langelier Semi-automatic Multiple Spindle Tapping Machine

The base of the machine carries tight and loose pulleys 6½ inches in diameter which carry a 2-inch driving belt. An automatic oil feed maintains a constant flow of oil on the taps while the machine is running and returns this oil to a self-straining reservoir connected to the pump suction. This enables the same oil to be used over and over without waste and without much attention from the operator. The oil feed operates intermittently, *i. e.*, when the machine stops, the flow of oil also stops automatically, thus preventing flooding the work and fixtures. All running bearings and movable parts are lubricated by means of efficient oilers.

OSTER CUTTING-OFF AND REAMING MACHINE

The machine for cutting off and reaming pipe and tubing which is illustrated herewith has recently been placed on the market by the Oster Mfg. Co., 2107 E. 61st St., Cleveland, Ohio. This machine represents the outcome of an order for a special machine of this type which was received by the



Oster Machine for cutting eff and reaming Pipe

Oster Mfg. Co. some three years ago. The machine proved so satisfactory in operation that it was decided to build machines of the same type for the market. The capacity is for all sizes of pipe up to 2 inches in diameter.

The machine is equipped with a single wheel tube cutter. The pipe to be cut off rests on a pair of rollers, and by turning the handwheel at the top of the machine, the pipe is brought in contact with the cutting disk and quickly severed. A slight pressure on the wheel regulates the speed at which the cutting operation proceeds. The two rollers which support the pipe while it is being cut off are made of steel and revolve in steel bearings. These rollers rest on the bottom of a yoke which slides up and down in the frame. An adjustable gage provides for cutting off duplicate pieces of pipe of various lengths.

The pipe to be reamed is held in the vise jaws which are opened or closed by the handwheel at the front of the machine. The method of control is rapid, so that work can be handled in an efficient manner. The work is fed to the reamer by operating a lever mounted behind the wheel which controls the movement of the vise jaws, this lever causing the pipe to move back or forth as desired. The reamer is held stationary by a set-screw and can be readily removed for sharpening. The bearings of the machine are provided with oil cups which insures efficient lubrication. The range of the machine is for pipe from ¼ to 2 inches inside diameter. The floor space occupied is 24 by 16 inches, and the weight of the machine 510 pounds.

WISCONSIN PORTABLE ELECTRIC GRINDER

The "Dumore" portable electric grinder was designed by Mr. Chester H. Beach, engineer of the Wisconsin Electric Co., Racine, Wis., by which firm the tool is manufactured.

This grinder operates at high efficiency, and when extreme accuracy is desired it is found to give excellent satisfaction. The armature is dynamically balanced, thus insuring satisfactory operation at all speeds and eliminating chatter; what

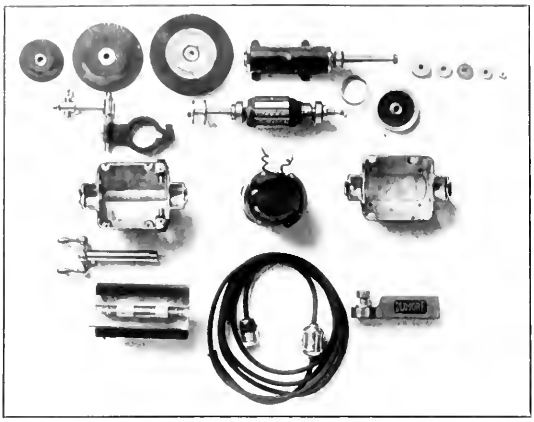


Fig. 1. Parts of the Wisconsin "Dumore" Grinder

is known as the "critical speed" is also avoided. The tool is suitable for handling a great variety of work, such as grinding milling cutters, taper reamers, lathe centers and dies and tools of different kinds.

The tool is of rigid construction and ball bearings are used throughout. The motor casings and internal housings are die-castings. The main shaft or spindle and also the spindle of the internal attachment are ground to within 0.00025 inch and carefully balanced. The motor, which is of the universal type manufactured by the Wisconsin Electric Co., develops $\frac{1}{4}$ horsepower. Wheels $4\frac{1}{2}$ inches in diameter may be driven at 10,000 revolutions per minute which provides a suitable surface speed, and the internal attachment may be driven at

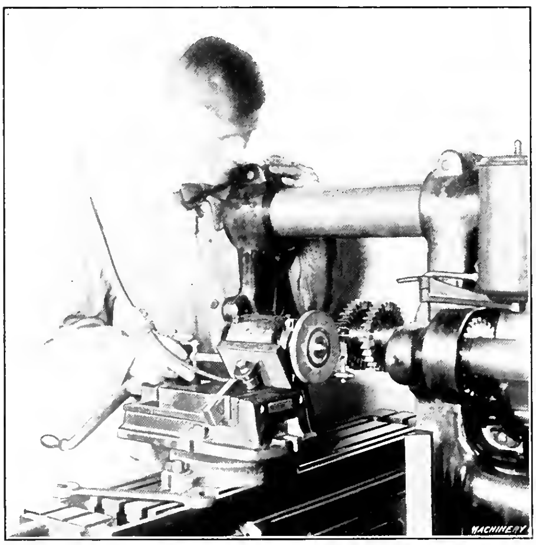

Fig. 2. Sharpening Milling Cutters with the Wisconsin Grinder

speeds up to 35,000 revolutions per minute to obtain the required cutting speed with the smallest wheel used on the grinder.

The parts of the grinder are illustrated in Fig. 1, from which the extreme simplicity and small number of parts will be appreciated. Referring to this illustration, the method of mounting the armature spindle in ball bearings will be readily understood. A complete set of wheels ranging in size from $4\frac{1}{2}$ inches to $\frac{3}{8}$ inch in diameter forms part of the regular equipment of the tool; these wheels will be seen at the top of Fig. 1. The total weight of the grinder is only sixteen pounds.

Fig. 2 shows the grinder employed in sharpening a pair of cutters on a milling machine arbor without requiring them to be removed. For this purpose, a rest is provided for supporting the cutters and the feed-screw of the grinder enables the wheel to be traversed back and forth. This feed-screw is also useful for grinding operations on a lathe which is not provided with a compound rest. Either angular, straight or spiral milling cutters may be ground and the elimination of the necessity of removing them from the arbor means a material saving of time.

In Fig. 3 the "Dumore" grinder is shown grinding a piece of work between centers. In Fig. 4 the internal attachment

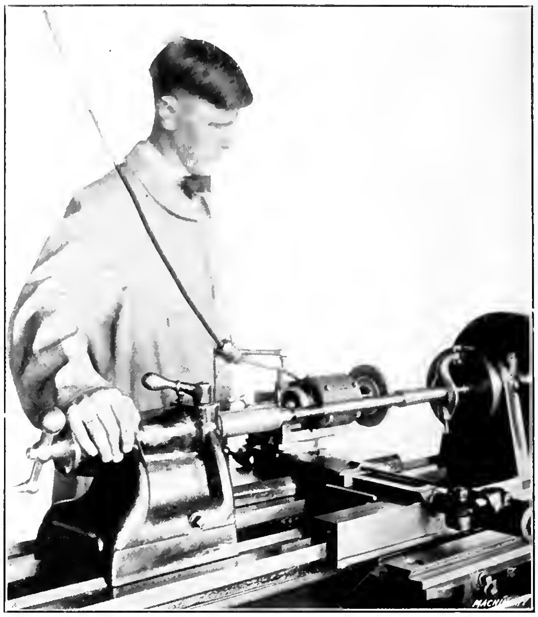

Fig. 3. Grinding Work on Centers with the Wisconsin Grinder

is shown in use. The work shown in this illustration is hardened and has an elongated slot and also a small hole, which are to be finished by grinding. Such work is easily handled by this portable electric tool. The preceding illus-

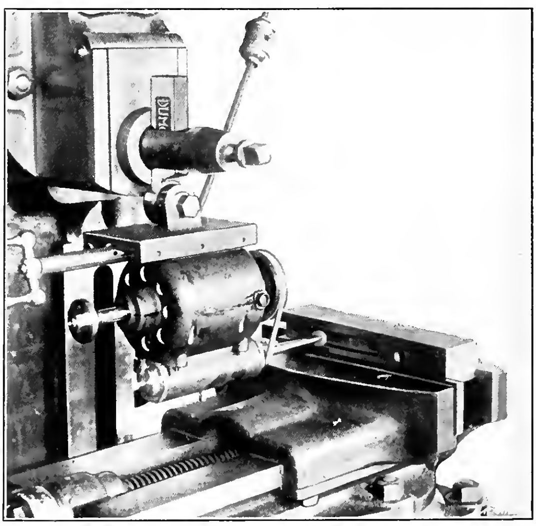

Fig. 4. Application of the Internal Attachment of the Wisconsin Grinder

trations are merely indicative of the classes of work which may be handled, and they will suggest to any practical mechanic a great variety of operations which could be handled to equal advantage.

NIAGARA SIDE SEAMING MACHINE

Fig. 1 shows a side seaming machine which constitutes a recent product of the Niagara Machine & Tool Works, Buffalo, N. Y. This machine is intended for use in forming the longitudinal seam in sheet metal used in the manufacture of oil and asphalt barrels, ash cans and similar products. Fig. 2 shows in diagrammatical form the ends of two pieces of sheet metal before and after making the lock seam. This seam is formed by two consecutive strokes of the machine. Aside from forming the body, no preliminary work is required. The motion of the machine is controlled by a positive clutch, and the horn has a swinging support on its outer end to provide for entering and removing the work. A safety lock is provided which makes it impossible to trip the clutch before the horn support is in the proper position. This machine has a capacity for work ranging from 9 to 24 inches in diameter, and up to 36 inches in length. Sheet metal up to No. 24 gage can be handled.

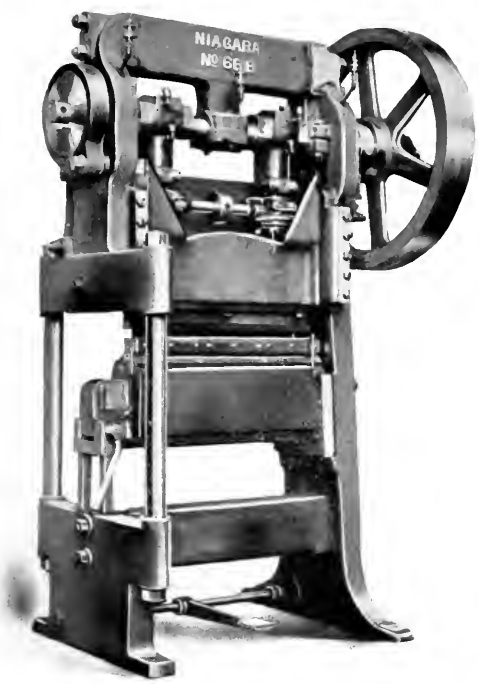

Fig. 1. Niagara Side Seaming Machine

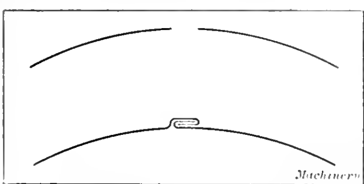

Fig. 2. Diagram showing Ends of Work before and after the Seaming Operation

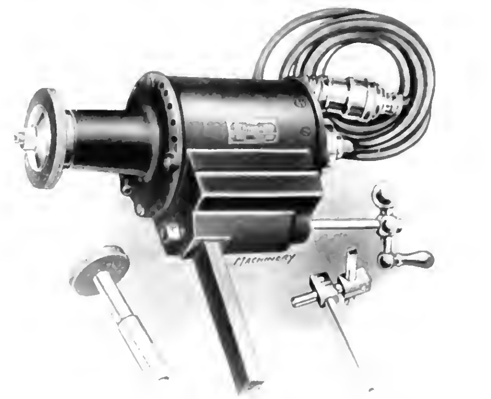
STANDARD UNIVERSAL ELECTRIC GRINDER

The Standard Electric Tool Co., Cincinnati, Ohio, is now making a line of portable electric toolpost grinders equipped with universal motors. These motors are designed to operate on either direct current or alternating current of zero to 60 cycles, although they are particularly adapted for 25-, 30- or 40-cycle circuits. The spindle runs in ball bearings which are enclosed in dust-proof cases and packed with grease. This arrangement eliminates the necessity of oiling and prevents damaging the motor windings with thin oil used to lubricate the bearings. These grinders are made with either 1/6- or 1/4-horsepower motors and run at a speed of approximately 6000 revolutions per minute, which makes them effective for internal grinding.

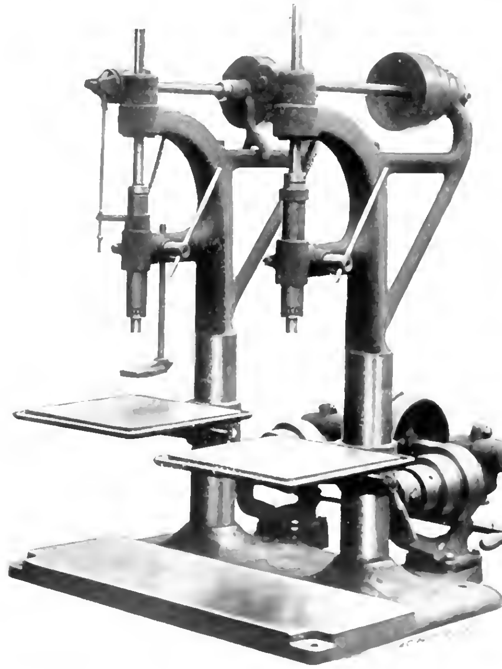
The Standard Electric Tool Co. has also added to its line of universal drills two tools of [illegible] and 1 inch capacity, respectively. These two drills constitute an addition to the seven sizes of the same type of tool which have been on the market for some time. The motors of both the grinders and drills are form wound and impregnated with bakelite which is known to be very effective in preventing short circuits and other trouble incident to the operation of motors at high speed. The motors are air cooled by means of a fan, and are capable of being severely overloaded without damage. The design is simple and rigid, although particular care has been taken to keep the weight down as far as possible. The tools are built on the unit plan so that they are easily taken apart.



Standard Electric Grinder for Use on either Alternating or Direct Current Circuit

PIONEER DUPLEX DRILLING AND TAPPING MACHINE

A 12-inch combination drilling and tapping machine built to meet modern manufacturing requirements has recently been added to the line of the Pioneer Machine Co., Rockford, Ill. The right-hand spindle of this machine is used for drilling and the left-hand spindle for tapping, but the tapping



Pioneer 12-inch Duplex Drilling and Tapping Machine

spindle can also be used for drilling or reaming operations by raising the sliding rod in front of the machine to its highest position and taking off the lower dog on the rod. Referring to the illustration, it will be seen that the front part of the base is planed to form an auxiliary table for use in handling work for which the regular table of the machine is inadequate. The capacity of the machine is for drilling holes up to 1/2 inch in diameter and for tapping holes up to 3/8 inch in diameter.

NEWTON DIE-SINKING MACHINE

The Newton die-sinking machine illustrated in this connection was particularly designed for machining large metal molds, and the control is so flexible that cutters as small as

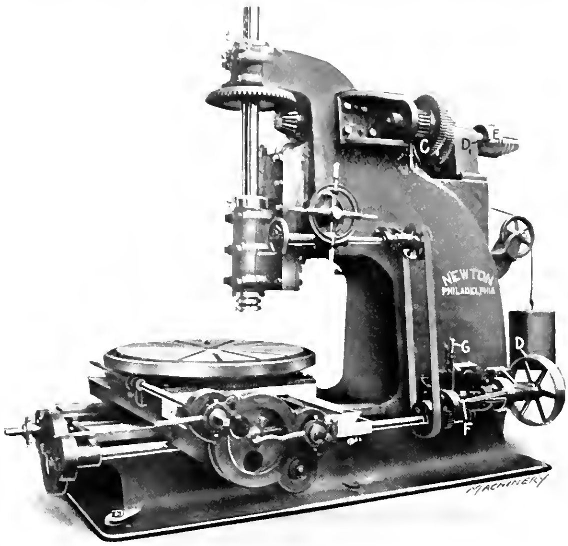


Fig. 1. Operating Side of Newton Die-sinking Machine

1/4 inch in diameter may be used. These cutters are several inches in length and tapered to machine the "drag" in the mold. The machine is driven by an alternating-current

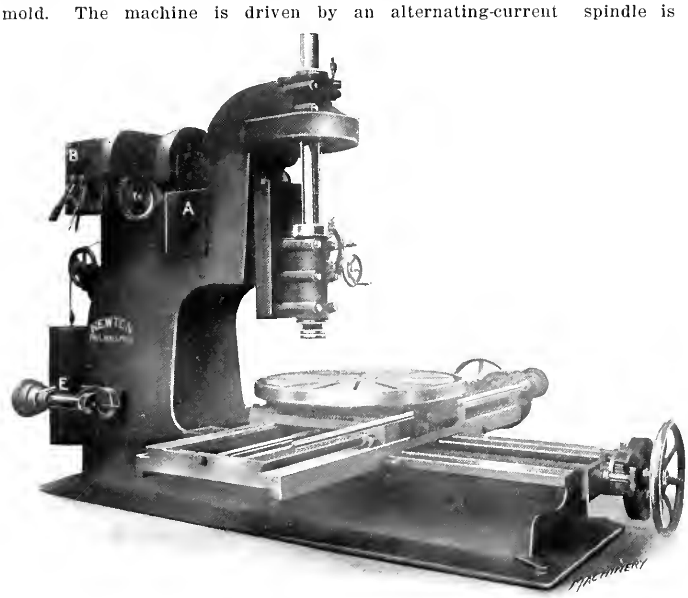

Fig. 2. Left-hand Side of Newton Die-sinking Machine

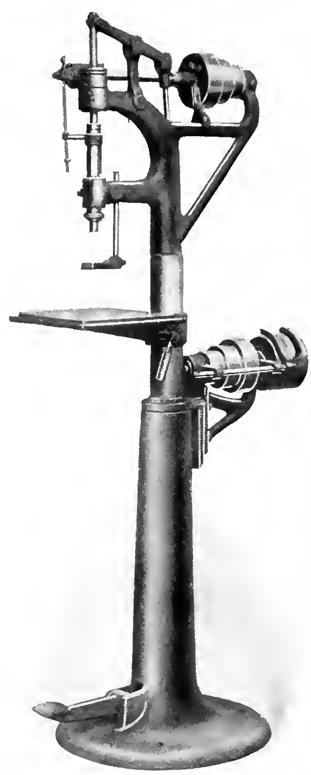
motor, the pad for the motor being shown at *A* in Fig. 2. Changes of speed are provided by gears in the oil-tight case *B*, in which there are eight gears which provide six changes of speed. In addition to these changes, reductions of speed for driving cutters of large diameter are obtained through the back gears shown at *C* in Fig. 1.

Reversing feed and reversing fast power traverse are provided in addition to hand adjustment, and each movement is independently clutched. The motion for the fast power traverse is transmitted from the pulley *D* at the base of the machine in Fig. 1 to the pulley D_1, and the motion for the feed is from the cone pulley *E* to the cone E_1. The lever *F* controls the engagement of the fast power traverse and feed, and the lever *G* controls the direction of traverse and rotation. As the same mechanism provides vertical feed and fast power traverse to the counterweighted spindle saddle, the control is centralized. Movement of the spindle saddle by hand is also available.

This machine was recently built for export, and as it is intended for producing work dimensioned according to the metric system, special indexes were mounted on the feed-screws. In view of the fact that an ordinary die-sinking machine weighs about 6000 pounds, while the present machine has a weight of 30,000 pounds, the accuracy with which it operates is really remarkable. The principal dimensions are as follows: diameter of the spindle, 5 inches; diameter of working surface of table, 48 inches; cross-feed of table, 72 inches; in and out feed, 62 inches; height from center of table to under side of spindle, 22 inches; and distance from center of spindle to face of upright, 38 inches. This machine is a product of the Newton Machine Tool Works, Inc., Philadelphia, Pa.

PIONEER DRILLING AND TAPPING MACHINE

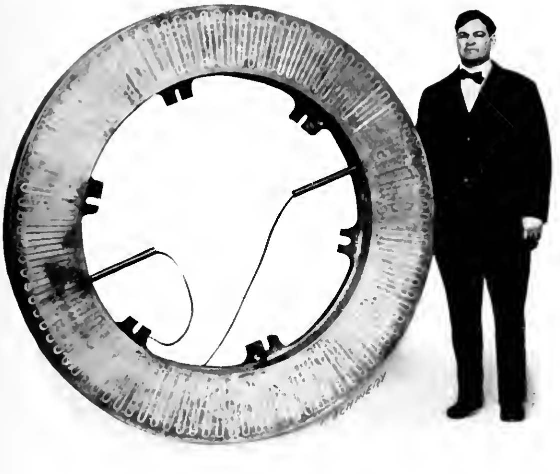
The accompanying illustration shows a 12-inch combination drilling and tapping machine which has been recently brought out by the Pioneer Machine Co., Rockford, Ill. Referring to the illustration, it will be seen that the machine is equipped with a foot treadle for operating the spindle, which leaves both of the operator's hands free to handle the work. The spindle is driven by a pair of spiral gears running in grease and all bearings are equipped with ring oilers. These machines are also built with hand lever feed.



Pioneer Combination Drilling and Tapping Machine

WALKER MAGNETIC CHUCK

O. S. Walker & Co., Worcester, Mass., have just completed what is said to be the largest rotary magnetic chuck ever built. It is 70 inches in diameter (see illustration) and weighs 2400 pounds. It will be seen that the magnetic face of the chuck is ring-shaped; the width of the face is 11 inches and the chuck is $5\frac{1}{2}$ inches thick. It will be used for holding a large quantity of three-inch washers while grinding them and the chuck is designed to be used with water. It will be mounted on a special grinding machine and rotated in a horizontal plane; two grinding wheels will do the facing.



Walker Rotary Magnetic Chuck 70 Inches in Diameter

A general idea of the size of the chuck will be obtained from the illustration. Two hundred and fifty pounds of magnet wire was required for the coils, and there are ninety-six separate poles in the chuck and forty-eight magnetizing coils. As previously stated, the diameter of the chuck is 70 inches; before building this chuck, O. S. Walker & Co. have seldom had a call for rotary chucks larger than from 38 to 44 inches in diameter. The magnetic face of the chuck is very finely divided so that small work may be firmly held on it. The chuck requires 5500 watts to energize it, *i. e.*, 50 amperes at 110 volts. The face of the chuck can be instantly demagnetized by operating a special switch provided for that purpose.

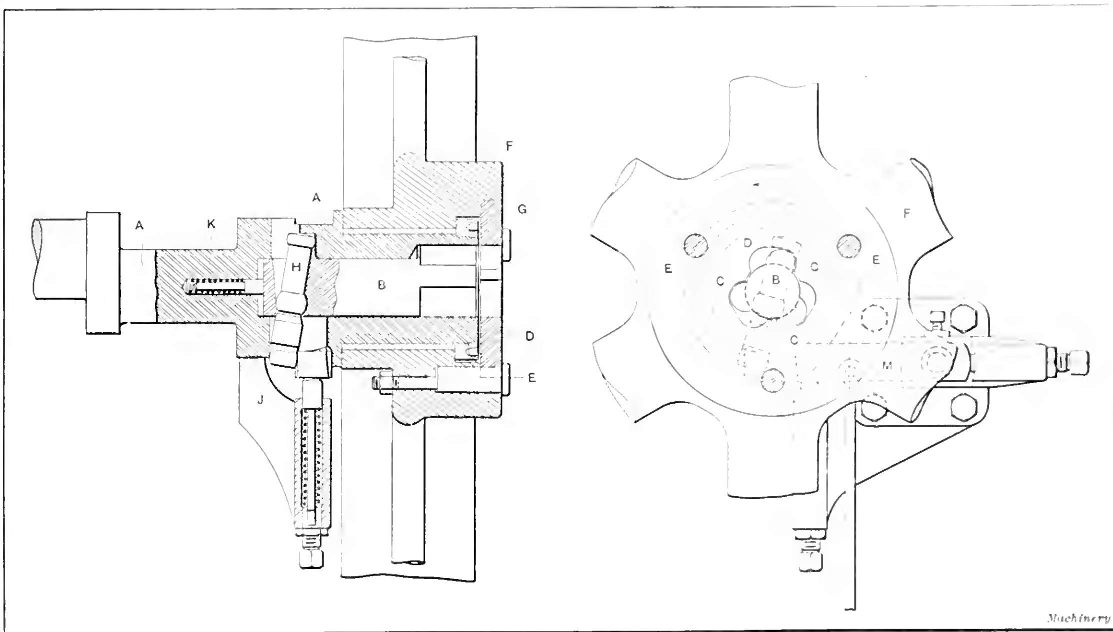
The firm for which this chuck was built intends to feed the work to the chuck through a chute and after grinding the work, it will be swept off while the chuck is rotating.

MAX AMS POWER PRESS CLUTCH

The Max Ams Machine Co., Mount Vernon, N. Y., has brought out a positive type of clutch for use on power presses, and this clutch will be applied on nearly all of the machines built by this company. A cross-sectional and an end view of the clutch are shown, from which the design and method of operation will be readily understood. Referring to this illustration, *A* is an enlargement of the press shaft; *B* is a sliding key or locking pin which has two or more prongs *C* formed on it; and *D* is a hardened plate with an opening in the center which is formed with notches to receive the prongs on the locking pin *B*. Two or more bolts *E* are used to secure the plate *D* to the flywheel *F*. The flywheel runs continuously on the shaft *A* and is held by a nut *G*.

The locking pin *B* is operated by means of the rolling lever *H* and the wedge *J*. The clutch is operated in the usual way. The wedge *J* is connected with the treadle rod and when the treadle is depressed, the spring *K* forces the locking pin *B* into the notched plate *D*, thereby forming connection between the shaft and flywheel. After one revolution of the shaft, the wedge *J* acts upon the lever *H*, withdrawing the locking pin *B* and disconnecting the flywheel from the shaft.

The distinctive features of this clutch are its durability and simplicity. The flywheel is centrally gripped on two or more points, thus avoiding irregular wear in the flywheel bearing. The striking surfaces are as near to the center of the shaft as possible, thereby reducing the velocity to a minimum and avoiding a hard blow; they are of ample size and located at the end of the shaft, where they are easily inspected. The parts subject to wear can be removed quickly and easily without interfering with the flywheel or any other parts. The locking pin *B* can be removed in an instant by simply pushing it against the spring *K* so that the rolling lever *H* can be pushed out sideways, thereby leaving the locking pin free. The steel plate *D* can be removed by simply taking out the bolts *E*; this enables the plate to be



Cross-sectional and End Views of Max Ams Power Press Clutch

reversed when one side has become worn. The wedge *J* is cushioned in order to avoid clicking. It is made with a shoulder which prevents the press from making a second stroke unless the treadle is completely depressed. This wedge is mounted on a separate bracket. Proper oiling devices are provided and a positive stop adjustment can easily be applied, thus making it necessary for the operator to depress the treadle for each stroke of the press.

KOKOMO "HI-SPEED" DRILL

The Kokomo "Hi-speed" drill equipped with power feed and an automatic stop is shown in Figs. 1 and 2, and Fig. 3 shows the same style of machine equipped with hand feed and a friction tapping attachment. It will be seen that these machines are of the sliding head type and they are suitable for driving high-speed drills up to $\frac{3}{4}$ inch and taps up to $\frac{1}{2}$ inch. Removable bronze bushings are provided throughout the machines, which not only insure high efficiency, but also provide perfect alignment and long life. Another advantage of the bronze bushings is that they can be renewed when worn out or damaged without disturbing the alignment of the machine, it being merely necessary to take out the damaged bushing and insert a new one in its place. This can be done with little loss of time.

The tapping attachment shown on the machine in Fig. 3 is easily operated and enables the reverse to be made very quickly. A friction is mounted in the crown gear which gives the forward drive for the tap; and a similar friction mounted in the reverse pulley provides for backing out the tap. A clutch mechanism is located between these frictions,

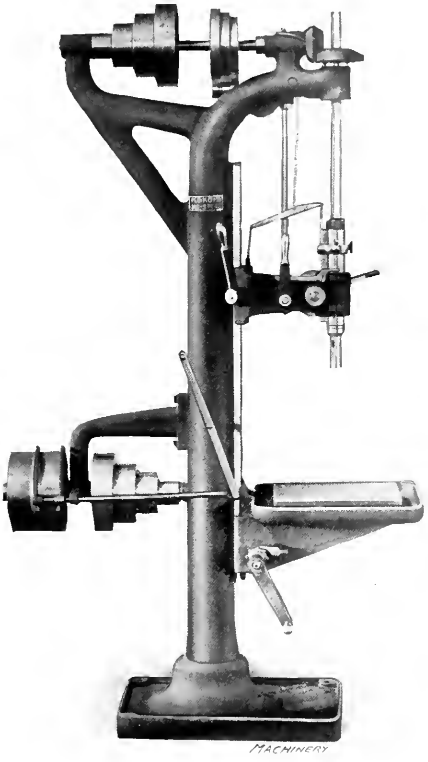


Fig. 1. Kokomo "Hi-speed" Drill equipped with Power Feed

the clutch being operated by a lever by means of which forward or reverse movement of the tap may be obtained, or the lever may be brought to a neutral position to stop the spindle. An important feature of the attachment is that the tap is backed out at practically twice the speed at which it is advanced, thus effecting a material saving of time. A positive clutch is furnished on the horizontal shaft, by means of which the reverse driving mechanism can be disengaged when the tapping attachment is not in use.

The power feed mechanism is of very simple construction. Referring to Fig. 2, it will be seen that power is taken from the horizontal shaft by means of a cone pulley. From the small cone pulley, the power is transmitted through the worm and worm-wheel pivoted on the yoke, thence through the vertical shaft to a second worm and wheel which transmit power to the feed pinion. The lower worm is brought into engagement with the worm-wheel by means of a lever at the left-hand side of the sliding head. This lever,

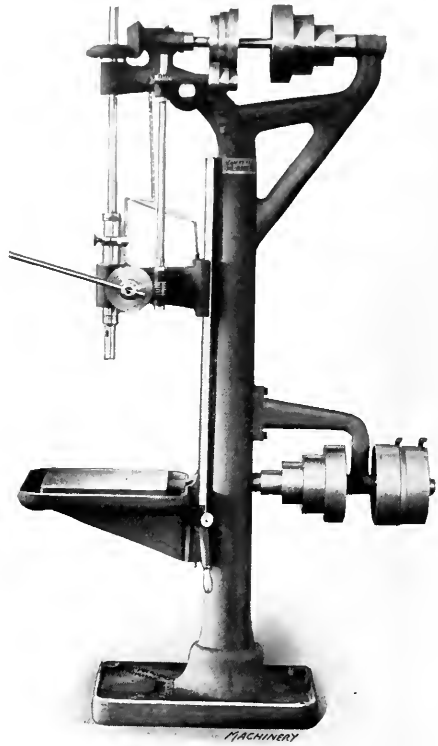

Fig. 2. Opposite Side of Drill shown in Fig. 1

when engaged with the trip finger, applies the power feed to the spindle until the adjustable stop on the sleeve comes into contact with the trip finger, at which time the power feed is automatically disengaged. An auxiliary lever is mounted at the end of the spindle feed shaft, permitting the feed to be operated by this hand lever when the power feed is disengaged or when using the tapping attachment.

The column is of tubular section and is bolted to the base. It is provided with a dovetailed face to which the sliding head and adjustable table are clamped. The column face is accurately planed and scraped into perfect alignment before the column is bored to receive the removable bronze bushings which carry the lower driving shaft, the top shaft and crown driving gear. This method insures perfect alignment of all moving parts. The sliding head is counterbalanced by a weight in the column and it may be clamped to the column face by means of a dovetailed gib. Suitable means of adjustment are provided to take up wear. The table is of the knee type and is raised or lowered by means of a rack and pinion actuated by a lever at the left-hand side of the machine. It is held in any desired position by means of a ratchet and pawl. The working surface of the table is entirely surrounded by an oil channel, and a binder lever clamps it to the column in any desired position.

The spindle is forged from crucible steel and finished by grinding. It is provided with a ball thrust bearing at the lower end of the sleeve and a bronze friction nut and hexagonal jam nut at the upper end of the sleeve. The sleeve is bronze bushed and graduated in inches; it is connected to the spindle feed shaft by means of a steel rack. A substantial depth gage extends entirely around the sleeve

and rack. The power feed will advance the spindle at the rate of 0.0055, 0.0081 and 0.0135 inch per revolution. There are four changes of speed, the available speeds being 110, 235, 460 and 990 revolutions per minute, which give suitable operating speeds for all sizes of drills within the range of the machine. These machines are manufactured by the Superior Machine Tool Co., Kokomo, Ind.

WHITCOMB-BLAISDELL PLANER

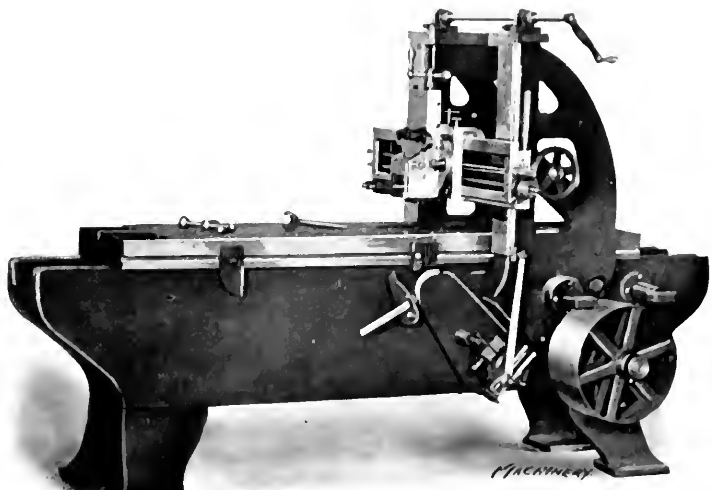
The Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass., is now building the 17 by 20 inch planer shown in the accompanying illustration. While nominally a 17 by 20 inch machine, the actual capacity is 21 inches between the housings and 17 inches under the cross-rail. These planers are built with any length of bed from 4 to 10 feet inclusive. This machine replaces the 17 by 17 inch planer formerly manufactured by the Whitcomb-Blaisdell Machine Tool Co. It weighs approximately 1000 pounds more and is a slightly larger machine in every respect, all parts being made from new patterns of increased dimensions. It has been carefully designed to meet the requirements of modern machine shop practice.

The old 17 by 17 inch machine had a spur geared drive while the present machine is equipped with the "second belt drive" as successfully applied to all of the larger sizes of machines built by this company. In addition, an improved type of belt shifter cam has been incorporated in the design which is enclosed in a box on the inside of the bed, where it is thoroughly protected from dirt and chips. The belt eyes are of an improved type and the intermediate pinion and gear in the driving train are of the spiral type. This feature, combined with the second belt drive, does away with the possibility of noise from high-speed spur gears and gives a quiet, smooth running machine.

The machine is equipped with all of the features of the larger sizes of Whitcomb-Blaisdell planers including the cross head fastener; the patented shipper dogs, which are self acting, and may be released by a slight pressure of the finger; and the self-relieving friction box driven by a silent chain, which works with great precision and without drag. An automatic stop for vertical, angular and cross power feeds can be applied, which constitutes a useful feature to have on a machine for tool-room work, as it enables the toolmaker to start the machine working and set the stop, after which no further attention is required.

Particular attention has been paid to the provision of a strong drive, and with this idea in mind, the bearings for the shafts have been made of exceptionally large size. All bearings are self oiling and the ways in the bed are provided with self-oiling rolls. When so desired, individual motor drive may be applied. For this purpose, the motor is either mounted on the housings and belted direct to the driving pulleys; or it is mounted on the floor or on a bracket secured to the bed of the planer and belted to a self-contained countershaft. A two- or three-horsepower motor is required, according to the character of the work and the speed at which it is desired to run the planer. The platen can be run at very high cutting speeds. For example, on bronze work a cutting speed of from 110 to 115 feet per minute is recommended, and operating under these conditions the planer is said to be capable of producing absolutely perfect work. This planer is well adapted for either tool-room or manufacturing work which comes within its range.

Fig. 3. Kokomo Drill equipped with Hand Feed



Whitcomb-Blaisdell 17 by 20-inch Planer

NEW MACHINERY AND TOOLS NOTES

Cleaning Gun: G. H. Dyer Co., 39 Piedmont St., Boston, Mass. A pneumatic cleaning device in the form of a gun which applies a blast of air to the required location. The air blast is controlled by a trigger.

Portable Welding Outfit: Dyer Apparatus Co., 39 Piedmont St., Boston, Mass. A portable welding outfit in which the torch is so arranged that a straight tube may be inserted instead of the bent tube when welding is to be done at the bottom of a hole.

Grinder: Royersford Foundry & Machine Co., 54 N. 5th St., Philadelphia, Pa. A floor type of dry grinder with an oil reservoir cored out of the head below the spindle. A wick with both ends dipping into the oil keeps the bearings continually lubricated. The bearings are dust-proof.

Oil Cup: Penn Pressed Metal Co., Camden, N. J. An oil cup formed from sheet brass and provided with a cap that has three projecting lugs. Normally the cap is closed through the action of a spring but it is easily opened by bringing the top of the oil-can spout into contact with one of the lugs.

Portable Welding Outfit: Metals Welding Co., Cleveland, Ohio. This outfit consists of the usual pair of tanks for holding the oxygen and acetylene together with suitable connections, flexible tubing and torches. The machine is built primarily for use in garages but is capable of application for use in other shops.

Rail Drilling Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A rail drilling machine equipped with four spindles, the fourth being an auxiliary spindle. The three right-hand spindles are employed for the principal drilling operations. The machine is driven by a 10-horsepower Westinghouse motor.

Improved "Kwik-Kut" Machines: E. C. Atkins & Co., Indianapolis, Ind. The "Kwik-Kut" machines of this company's manufacture have recently been improved by the addition of a guide consisting of an upright, through which the blade passes to insure accuracy in cutting. A hydraulic attachment has also been added to regulate the blade pressure.

Lock-nut: Harvey J. Hipple, 121 Charlotte St., Lancaster, Pa. This locking device consists of a wire ring with one end of the ring extended at right angles to its plane. The ring goes between the nut and its seat and the end fits in a groove in the bolt. When the nut is screwed down, this end wire is bent over into the castellations in the nut.

Driving Wheel Lathe: Putnam Machine Co., Fitchburg, Mass. An improved model of the preceding machine of this type. In the new machine the feed is taken directly from the main driving shaft. The tailstock may be operated by an independent motor or from an independent countershaft. The driving shaft is of nickel steel and all gears are of steel.

Eight-spindle Drilling Machine: Edward Board, 619 Filbert St., Philadelphia, Pa. A machine for drilling the mixer ends of gas stove units. This consists of shallow drilling or "spotting." Eight drills 1/8 inch in diameter are used, which are spaced 3/16 inch apart around the arc of a circle. The burner to be drilled is clamped by means of an eccentric binder.

Friction Clutch: Carl G. Westlund Co., Worcester, Mass. A friction clutch made in a variety of sizes. All parts are split so that the clutch may be installed without requiring the shaft to be taken down. The working mechanism is entirely enclosed and all screws and nuts are set flush with the surface. The clutch is designed for both high and low speeds.

Drilling and Boring Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. This machine can be used either as a post drill or horizontally. The maximum length of feed of the spindle is 17 inches and three changes of power feed are provided in addition to hand adjustment of the spindle. The distance from the center of the spindle to the face is 14 inches.

Plate Shear: Long & Allstatter Co., Hamilton, Ohio. A plate shear which has a capacity for plates up to 3/8 inch in thickness and up to 16 feet wide. This machine is provided with the regular type of automatic hold-down for clamping the work which is used on shears built by this company. The slide is provided with an air balance in place of the usual weights.

Blueprint Finishing Machine: Revolute Machine Co., 417 E. 93rd St., New York City. A machine for washing, drying, ironing and finishing blueprints which are either in the form of separate sheets or in a continuous roll. The four essential parts of the machine consist of a washing tank, a wringer, a hot drying and ironing drum and an automatic winding device for long prints.

Open-gap Shear: Cleveland Punch & Shear Works Co., Cleveland, Ohio. A motor-driven machine built for the Pennsylvania railroad for use in the Altoona shops. The machine is intended for shearing 0.40 per cent carbon bars 3 by 12 inches in size. The frame is of steel and the bearing surfaces are bronze bushed. Power is supplied by a 35-horsepower direct-connected motor.

Knuckle Joint Press: Max Ams Machine Co., Mount Vernon, N. Y. A line of embossing and swaging presses made in various sizes. The frames of all machines with a capacity for pressures exceeding 250 tons are reinforced by steel rods. The knuckle joints have adjustable wearing surfaces and hardened steel pins. The range of sizes includes presses with capacities varying from 50 to 1000 tons.

Pipe Fitting Tapping Machine: Pottstown Machine Co., Pottstown, Pa. A single-spindle machine for tapping flanges, single-end fittings and similar parts. The work is held in toggle operated chucks. Ample adjustment is provided on the machine to adapt it for turning out small lots of work quickly. Different sizes are built, the capacity of the largest machine being for fittings up to 12 inches in diameter.

Cutting-off Machine: Matson Machine Co., Concord, N. H. A cutting-off machine which has a capacity for round or square work up to 4½ inches in diameter or thickness. The machine is driven by a worm-gear and is provided with ball thrust bearings at the ends of the driving shaft and feed-screw. The feed is started by engaging a positive clutch which is automatically released. The range of feeds is from 1/8 to 3/8 inch per minute.

Screw Press: Pruyn & Bilodeau, 1876 Broadway, New York City. This machine is intended for use in machine and repair shops. It has columns mounted at each side of the bed which are 15 inches apart and distance pieces 5, 10 and 15 inches in length are provided. This arrangement enables the screw to be brought to any desired position for performing different operations. The table is 26 by 19 inches in size and has an opening in the middle.

Motor Starter: Cutler-Hammer Mfg. Co., Milwaukee, Wis. A high voltage automatic motor starter to provide for starting 1100 and 2200 volt A. C. squirrel cage motors used in industrial plants. The apparatus consists of a frame made of angle iron, upon which the high tension oil immersed solenoid switches, and the relays required to control the motor and auto transformer circuits are mounted. The starting switches are operated by single phase solenoids.

Motor Operated Shear Gage: Long & Allstatter, Hamilton, Ohio. A back gage for use on a shearing machine, which is driven by a 3/4 horsepower electric motor. The gage is provided with a lead-screw near each end for running it forward or away from the shear blade. The movement is controlled by means of a lever at the right-hand side of the machine. After the gage has been run out to an approximate setting, it may be accurately located by means of a handwheel.

Hand Drill and Drill Vise: North Bros. Mfg. Co., Philadelphia, Pa. The drill is provided with an automatic trip for disengaging the feed when the spindle has reached the extreme of its travel. The machines are built in two sizes with capacities for handling drills up to 1/4 and ½ inch in diameter, respectively. The drill vise is 6 inches long by 2 3/4 inches wide by 2 inches high. The jaws are 1 3/8 inch deep and open 3 inches without the swivel jaw or 2 5/8 inches with it.

Balance Indicator: Emery Johnson, Newberg, Oregon. A balance indicator, the operation of which is based on the principle that a perfectly balanced rotating disk which is loosely supported on its axis is free to move in any direction, although its axis may be unsteady. The instrument is momentarily applied to the end of the shaft to be balanced and if this shaft is unbalanced, the spindle of the indicator proceeds in a circuitous path while the disk seeks its own course and revolves steadily.

Pipe Fitting Tapping Machine: Pottstown Machine Co., Pottstown, Pa. A 5-way automatic tapping machine for tapping T's, L's, and Y's, crosses and other fittings of any angle and with side outlet. The tapping heads are carried on a plate which is slotted so that the heads may be adjusted to the required angle. Four spindles are carried in bearings mounted on this plate and a fifth spindle projects through the center of the plate. The spindles are fed in and out by means of interchangeable lead-screws.

Elevating Truck: Cowan Truck Co., Holyoke, Mass. This company has added to its line an elevating transveyor which has a lift of 3 inches and a capacity for handling loads up to 5000 pounds. This transveyor is known as the Type H and has been particularly developed for use in factories where it is required to load work into freight cars. For such service, it has been found that a truck capable of lifting work 1½ or 2 inches is not adequate. The large capacity of the truck enables material to be moved with greatly increased efficiency.

Air Compressors: Sullivan Machinery Co., Chicago, Ill. Two types of a power driven air compressor. The special feature of one of these machines consists of the combination of one horizontal and one vertical cylinder with both pistons driven from one crankpin on a center crank, and both valve gears driven from one crank disk on the end of the shaft. The other unit referred to is a small size single stage compressor. This unit is of the center crank, straight line, single stage type and is belt driven. The design is such that the crankshaft may be taken out and reversed end for end to provide for driving the compressor from either side.

Edging Machine: Waterbury Farrel Foundry & Machine Co., Waterbury, Conn. A machine for edging drawn shells used in the manufacture of products made of pressed and formed steel. The machine takes the shell after it leaves the press, trims the ragged edge, smooths the edge and cuts the shell off to the desired length. The machine is semi-automatic in operation, the shells being fed into the hopper by the operator, after which they are carried automatically to a position directly in line with the chuck. The shells are then pushed into the chuck against a positive stop and the operations performed on them. Machines of this type are made in several styles to meet the requirements of different classes of work.

Horning Press: Cleveland Machine & Mfg. Co., Cleveland, Ohio. In the November, 1913, number of MACHINERY a wiring and horning press built by the Cleveland Machine & Mfg. Co., Cleveland, Ohio, was illustrated and described. This machine has a capacity for closing seams up to 12 inches in length and for wiring work up to 10 inches in diameter. Its weight was 1850 pounds. Since that time a larger machine of the same type has been added to the line of the Cleveland Machine & Mfg. Co. The large machine will close seams up to 20 inches in length and wire work up to 18 inches in diameter. The weight of the machine is 9000 pounds. Both of these machines are equipped with a knee pivoted on the left-hand side of the machine. When it is desired to use the press for horning operations, this knee is swung around out of the way and the horn is set up in a hole in the frame of the press provided for that purpose. In addition to the knee supported on the left-hand side of the press, the large machine is equipped with an auxiliary knee for use in wiring deep cans and similar classes of work. The auxiliary knee is pivoted from the right-hand side of the press, the method of support being the same for both knees.

ROSNER PROCESS OF WELDING HIGH-SPEED STEEL

A process for welding high-speed steel to low carbon steel has been developed by Adolph Rosner, of Bridgeport, Conn. This process enables a small piece of expensive high-speed steel to be fused or welded to a piece of low carbon steel to produce a tool for lathe or planer work, when a high-speed steel cutting edge is necessary. The piece of high-speed steel is not dovetailed or let into the carbon steel shank, but is welded to a flat surface making it one piece with the shank; and the strength of the union is such that the high-speed steel cannot be broken off by the pressure of the heaviest cut. The heat is radiated from the cutting point of a tool built up in this way as readily as in the case of tools which are made entirely of high-speed steel. The Rosner welded tools can be annealed, reshaped, machined over and rehardened as often as necessary. It is also possible to bend and forge such tools to a certain extent without breaking the weld, providing the operation is performed at a high temperature.

The cutting edge of a tool is the only part which need be made of high-speed steel. With ordinary tools, a lot of expensive high-speed steel is wasted in reforging and grinding the tool, but with the Rosner method the shank is made out of steel having from 0.20 to 0.30 per cent of carbon which can be bought for about two cents a pound. The welding is done in a gas furnace at a temperature of over 2000 degrees F.; a special flux is used, and the shank of the tool is cooled in water after completing the welding operation for the purpose of stiffening it. The problem of hardening tools is eliminated in the case of Rosner built-up tools, as the hardening is done at the same time that the welding is performed, but without the use of an air blast. Immediately after hardening, the tools are ready to be ground for use in the lathe or planer.

Die blocks can be made by the Rosner process of welding. For this purpose a thin layer of high-speed steel is welded to the top of the low carbon steel die block. Dies made in this way are much cheaper than those in which expensive steel is used for the entire die, and they do not shrink or crack in hardening. In making such dies, the pieces are machined very close to the desired shape and size before welding; and after the welding operation has been performed, the die will have to be annealed, machined to the required size and then rehardened. There are a great many special cutting tools,

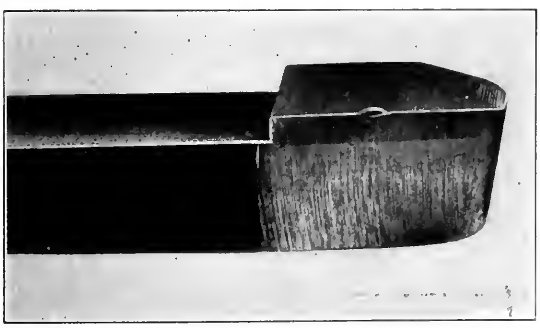


Fig. 1. A Built-up Tool welded by the Rosner Process

such as forming tools, used in machine shops, in which only a small part of the tool can be utilized. This process of welding a high-speed cutter to a shank of cheaper steel lowers the cost of such tools very materially. Cutters for boring bars can be made by welding a piece of high-speed steel to each end of a low carbon steel shank. When the cutter becomes too short through grinding, it may be brought back to the required length by peening the metal in the middle of the shank. The Rosner process has also been successfully applied for making the cutters used on a variety of wood-working machines.

The use of welded, built-up tools means a saving of from 30 to 40 per cent as compared with the cost of solid high-speed steel tools for use in the lathe or planer. The welded tools do not require any reforging and consequently the shop equipment for handling this work is not necessary. When a tool made entirely of high-speed steel has been ground down so that it is too short for further use, it does not pay to draw it out to a smaller section of greater length, because the cost per pound of drawing it out to this section is higher and the quality of the steel considerably lower than that of new metal. The expense of high-speed steel tools has been materially reduced by using tool-holders in which a small piece of high-speed steel is held by means of a set-screw. But these tools are not entirely satisfactory especially for heavy and rapid cutting. It has been found that a small piece of high-speed steel inserted in a holder does not conduct the heat generated in cutting to the shank as well as a solid tool does. The result is that the cutting edge of the small tool does not stand up so well as that of a tool made of one piece of steel.

It is possible to weld high-speed steel to low carbon steel electrically, but this process cannot be applied in making lathe or planer tools. The reason is that in such electrically welded tools, the high-speed steel is full of fine cracks caused by the rapid heating of the metal, and these cracks result in the breaking of the cutter. To give satisfactory results, high-speed steel must be heated slowly. Oxy-acetylene welding cannot be used for the same reason. In addition, these processes do not unite the high-speed and low carbon steels firmly enough to enable a tool made in this way to stand up under the pressure of heavy cuts.

Fig. 2. Test of a Rosner Weld—the Steel broke first

The following outlines the expense involved in reforging and hardening a lathe or planer tool 3/4 by 1½ by 10 inches in size made entirely of high-speed steel. It is estimated that a tool of such dimensions can be reforged and hardened six times, after which the tool will be only 4 inches long—allowing 1 inch for each reforging—and it is then too short to be used satisfactorily. This relation is shown diagrammatically in Fig. 4, where the cutting edge of the tool is marked *A*, the portion of the entire tool actually used *B* and the scrap *C*. The portion of the steel wasted in grinding is marked *D* and the metal cut off in reforging the tool, *E*. It will be evident that the scrap *C* amounts to 40 per cent of the entire tool.

First heating to 1500 degrees F.	4 minutes
Trimming and forging	2 minutes
Second heating	1 minute
Finish-forging	1 minute
Grinding	1 minute
Heating to 2100 degrees F. for hardening	3 minutes
Quenching	1 minute
Time lost in fixing the fire, etc.	2½ minutes
Total time	15½ minutes
Labor	
1 blacksmith	$0.30 per hour
1 blacksmith's helper	0.20 per hour
	$0.50 per hour
	$0.0083 per minute
15½ minutes at $0.0083	$0.1286
General shop expenses 60 per cent	0.0771
Actual cost one reforging and hardening	$0.2057

Good high-speed steel costs from seventy-five cents to $1.50 a pound. An ordinary lathe side tool, 10 inches long, which is made entirely of high-speed steel can be reforged and rehardened about six times, but about 40 per cent of the metal is lost as the tool becomes too short for use. The cost of reforging tools varies with the cross-section. The following tabular matter outlines the cost of reforging the tool six times, together with the cost of the material.

3 pounds of high-speed steel at seventy-five cents	$2.25
Reforging 6 times and rehardening at twenty cents	1.20
Total cost	$3.45
Value of scrap	.08
Net cost of one high-speed lathe tool	$3.37

For comparison with the all high-speed steel tool considered in the preceding discussion, we will consider a Rosner welded tool 10 inches long, which has a piece of high-speed steel $1\frac{1}{2}$ inch long welded to it. It is estimated that five of these built-up tools will do the same work as one all high-speed steel tool of the same length and cross-section. When one Rosner tool is used up, a new one is obtained from the stock-room so that the tool is always of the most efficient length. The low

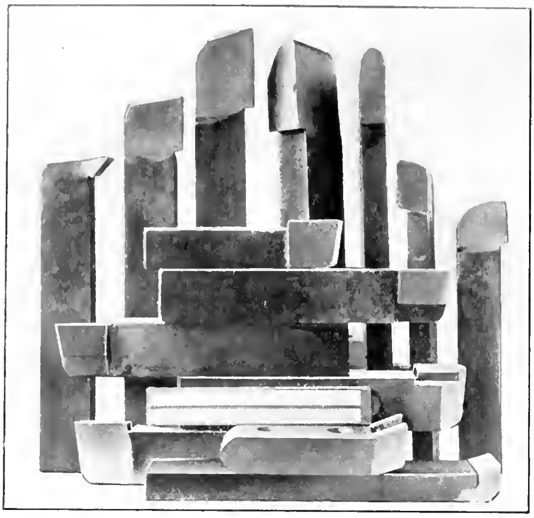

Fig. 3. A Group of Rosner Tools for the Lathe and Planer

carbon steel shank of a worn out Rosner tool may be scrapped or another piece of high-speed steel may be welded to it. On this basis the relative cost of tools of these classes would be as follows:

1 3-pound high-speed steel tool at seventy-five cents per pound and six reforgings $3.37
5 Rosner tools sold for forty cents each.. 2.00

Saving by using welded tools......$1.37 = 41%

By using certain shapes, it is possible to get as much service out of three welded tools as can be obtained from one all

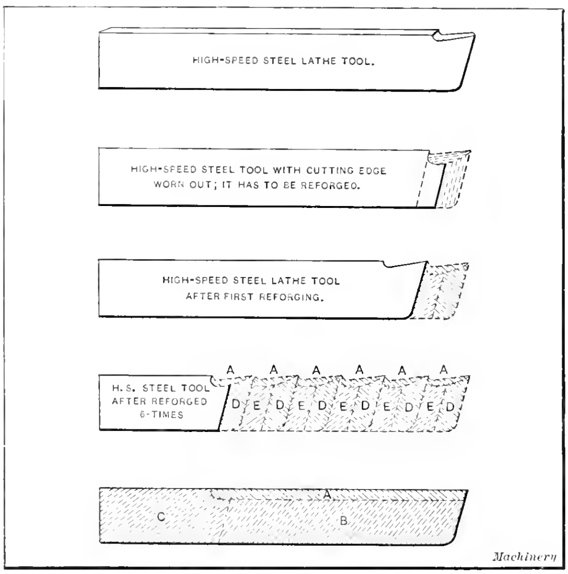

Fig. 4. Diagram showing reduction of a Lathe Tool in reforging and grinding

high-speed steel tool. To do this, the high-speed steel strip welded to the shank of the tool is longer than that ordinarily employed. With such tools, a comparison of efficiency would be as follows:

1 3-pound all high-speed steel tool at seventy-five cents per pound and six reforgings $3.37
3 Rosner tools sold for sixty cents each.. 1.80

Saving by using welded tools.......$1.57 = 47%

As the results of extensive experience in the use of these tools are not available, the comparisons drawn cannot be regarded as iron-clad. They are, however, sufficiently close to give a very fair approximation of the saving made possible through the use of high-speed steel cutters welded to shanks made of less expensive material.

U. S. COMMISSION ON INDUSTRIAL RELATIONS

The United States Commission on Industrial Relations will hold its first formal public hearing in Washington, April 6, at which collective bargaining, conciliation and arbitration as means of adjusting differences between employer and employe will be considered. Corporation officials and trade union leaders who have negotiated and maintained trade agreements

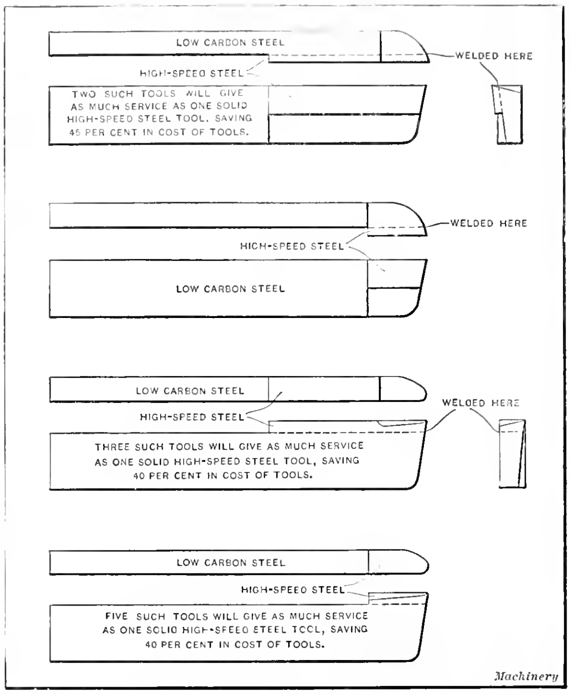

Fig. 5. Rosner Built-up Lathe Tools with Points of Various Lengths

in five of the nation's largest industries will be called to testify. The commission hopes to elicit information that will disclose to what extent improvement in industrial relations might be expected from the general adoption of such agreements in other industries. The hearing will include systematic efforts at peaceable settlement of disputes in the coal mining industry, railroads, clothing and printing trades, the building trades and the molders' trade.

* * *

COLONIAL EXPOSITION IN SEMARANG

A Colonial Exposition will be held in the city of Semarang, Java, Dutch East Indies, in the months of September-November, 1914, to celebrate the centennial of the return of the Dutch East Indies under Dutch rule after political affairs in Europe had been readjusted following the defeat of Napoleon and his banishment to St. Helena. The Dutch East Indies, of which Java, Sumatra, Borneo and Celebes are the principal islands, and which, geographically speaking, form a link between the mainland of Asia and Australia, have a population of over 30,000,000 inhabitants. Further information regarding the Colonial Exposition may be obtained from T. Greidanus, 136 Water St., New York City.

PRESENTATION OF THE E. H. HARRIMAN MEMORIAL MEDALS

The presentation of the E. H. Harriman memorial medals awarded by the American Museum of Safety to the Southern Pacific Co. was made Saturday evening, March 14, in the beautiful studio of A. A. Anderson, 80 West 40th St., New York City. The gold medal was awarded to the Southern Pacific Co., represented by Julius Kruttschnitt, chairman of the executive board, at the annual dinner of the American Museum of Safety, December 12, but the actual presentation of the medals was deferred until the names of the operating official and the employe most deserving of the honor were known. The gold medal is given to the railroad company that has done most for the safety of passengers and employes during the year, a replica in silver to the member of the operating department of the road who has done the most to bring about this condition and a replica in bronze to the employe of the winning road who has been the most conspicuous in the promotion of safety by suggestions or otherwise.

The gold medal was presented to Julius Kruttschnitt by Mrs. E. H. Harriman, assisted by Arthur Williams, president of the American Museum of Safety, who presided; the silver medal was presented to William Sproule, president of the Southern Pacific Co., and the bronze medal to William Schwab, conductor on the Sacramento Division. Mr. Schwab traveled a distance of over 3000 miles across the continent to be present. In acknowledging the receipt of the medal, Mr. Schwab mentioned the encouragement that he had received from the superintendent of the Sacramento Division to make safety suggestions. He cited an example of the suggestions made. Two stations, Fair Oaks Bridge and Fair Oaks Junction, are only two miles apart, and the names are so similar that confusion often resulted and mistakes in reading train orders were made. Mr. Schwab suggested that the name of one of the stations be changed to avoid the confusion, which was immediately done. Mr. Kruttschnitt, in receiving the gold medal, spoke of the great volume of traffic on the Southern Pacific Co., and the team work necessary to conduct such great operations without serious accidents and loss of efficiency. Not one passenger has been killed in the past five years, though 41,783,000 passengers were carried 1,756,482,000 miles. Mr. Sproule, president of the Southern Pacific Co., said that the record was made possible by the loyalty of the men and their general cooperation.

The E. H. Harriman memorial medals are awarded yearly to the railroad that has made the best record for safety of life and limb of passengers and employes. It was especially gratifying to the principals concerned that the first award should go to the Southern Pacific Co., the reorganization of which had been an important part of Mr. Harriman's work.

Mr. Williams announced that the American Museum of Safety has been assigned the awarding of another annual medal, this being the Anthony N. Brady memorial medal for the street railways making the best safety records.

PERSONALS

Roland Cole of Rochester, N. Y., has joined the Ferro Foundry & Machine Co., Cleveland, Ohio, as advertising manager.

M. P. Fillingham has been appointed district sales manager for Van Dorn & Dutton Co., Cleveland, Ohio, with an office at 50 Church St., New York City.

William Sloane Accles, European manager of the Niles-Bement-Pond Co., sailed from Southampton, England, on the *Olympic* February 18 for a visit to the United States.

Joseph M. Schaeffer, European representative of the Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., sailed for England on the *Minnetonka* February 28.

Dyer Smith, patent attorney, has removed from the Woolworth Bldg., New York City, to 32 Liberty St., where he is now associated with Samuel O. Edmonds in the practice of patent and trade-mark law.

Harry A. Hey, office manager of the American Society of Mechanical Engineers, New York City, has resigned to become assistant to Henry Souther, vice-president of the Ferro Foundry & Machine Co., Cleveland, Ohio.

George A. Gallinger of Pittsburg, Pa., has been placed in charge of the pneumatic tool department of the Ingersoll-Rand Co., with the title of manager of pneumatic tool sales. His headquarters will be at 11 Broadway, New York City.

Harry E. Harris has taken a position as consulting engineer with the Greenfield Tap & Die Corporation, resigning his former position as superintendent of the Wells Bros. Co., now a division of the Greenfield Tap & Die Corporation.

Charles T. Lamb, for many years assistant treasurer and office manager of the F. E. Reed Co., Worcester, Mass., manufacturer of Reed lathes, and for the past two years office manager of the Reed-Prentice Co., has resigned, to take effect May 1. Mr. Lamb will engage in other business.

Dr. W. M. Leiserson, state superintendent of employment offices in Wisconsin, has been engaged by the United States Commission on Industrial Relations to take charge of its investigations into irregularity of employment and to assist in formulating recommendations for remedial legislation.

Frank A. Mossberg, president of the Frank Mossberg Co., Attleboro, Mass., was re-elected president of the board of trade of Attleboro at the annual meeting, February 18, and was also presented with a loving cup for his energetic and able services in the interests of the association during the past year.

Henry Souther has been elected vice-president and general manager of the Ferro Foundry & Machine Co., Cleveland, Ohio. Mr. Souther is a graduate of the Massachusetts Institute of Technology and for some years was consulting engineer to the Association of Licensed Automobile Manufacturers.

Robert W. Barwood of Philadelphia, an experienced machine tool salesman, has made an agreement with the Carter & Hakes Co., Winsted, Conn., to act as its representative in New England and the territory adjacent to New York and Philadelphia. Mr. Barwood's headquarters will be the Bourse, Philadelphia.

A. J. Borget, formerly of the Chalmers Motor Car Co., Detroit, Mich., has been made district sales manager of the Van Dorn Electric Tool Co., of Cleveland, Ohio, manufacturer of portable electric tools. Mr. Borget's office is at 1013 Mutual Life Bldg., Buffalo, N. Y. He will cover the territory in New York State west of Rochester.

A. B. Hazzard, general manager of the J. Morton Poole Co., Wilmington, Del., for the past six years, has resigned to take a position on the staff of managers of the Detroit Engine Works, Detroit, Mich. The employes of the J. Morton Poole Co. presented Mr. Hazzard with a loving cup February 21, and a farewell dinner was tendered him by his friends at the Hotel DuPont, at which a number of handsome presents were given him as tokens of kindly remembrance.

A. S. Baldwin, for the past three years general manager of the Alberger Pump & Condenser Co., Newburg, N. Y., builder of turbines, condensers, vacuum pumps, Corliss engines, ice machines and all types of centrifugal pumps, has resigned his position. Mr. Baldwin was for four years and a half superintendent of shops for the Driggs Seabury Ordnance Corporation of Sharon, Pa., and previous to that superintendent of the American & British Mfg. Co., of Bridgeport, Conn., for two and one-half years.

* * *

OBITUARIES

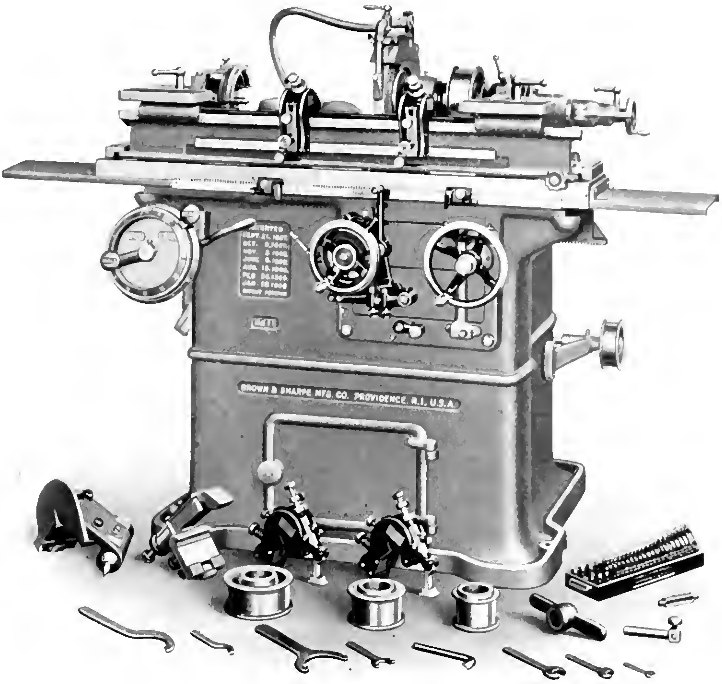
Robert C. Moodey, president of the Cleveland Machine & Mfg. Co., and several other corporations, died in Cleveland, March 15, aged fifty-six years.

Adolph Zuest, vice-president and treasurer of the G. A. Gray Co., of Cincinnati, Ohio, died on February 19 following an attack of pneumonia. Mr. Zuest was fifty-nine years of age and a bachelor. He was born in Cincinnati, and for over twenty-seven years had been connected with the G. A. Gray Co. Mr. Zuest's engaging personality and kindly manner made many friends among those having business relations with that company and in the circle, who regarded him highly. His loss will be greatly felt by his business associates.

GEORGE WESTINGHOUSE

George Westinghouse, the famous inventor and engineer, died of heart disease at his New York City residence March 12, aged sixty-seven years. His health had been failing for some time and consequently his death, though a great shock to his friends and acquaintances all over the country, was nevertheless in a measure anticipated. The mental alertness and wonderful vitality that had so characterized his brilliant career remained with him to the end. Although actively associated with a large number of industries, he had during the last few years begun to transfer his responsibilities to the shoulders of his trusted lieutenants, the fortunate selection of which has always been one of the leading characteristics of his varied career.

Mr. Westinghouse was born at Central Bridge, Scholarie Co., N. Y. His father was an inventor, who, in 1856, removed his family to Schenectady, N. Y., where he established



No. 11 Plain Grinding Machine

The principle of the mechanism of the speed case shown opposite is simple. A series of several tapered friction disks, rotating at constant speed, transmit power to a series of recessed disks. The disks interlock and the point of contact is on the edge of each recessed disk. Thus, as one series is swung toward the other, the part of the disk actually driving decreases in radius and the speed decreases.

There are two of these mechanisms in the case, one for driving the work, the other for the table. Powerful springs serve to hold the disks in contact, the whole furnishing ample power for all work within the machine's capacity.

The No. 11 Plain Grinding Machine in addition to the new speed changing mechanism embodies many other features which make it an easily operated machine for handling the most accurate classes of work in large quantities.

Have you ever investigated our automatic cross feed which can be set to grind to a required diameter and then automatically release? It feeds as fine as one quarter-thousandth for each traverse and is quickly set to remove any desired amount on the diameter.

Then there are the Universal Back Rests which follow the work down to the required diameter with equal pressure to a positive stop. If you are interested in these production points we will send you a circular.

ROVIDENCE, R. I., U. S. A.

Read page 75

the Schenectady Agricultural Works. The boy attended the public and high schools of the town, spending much of his leisure time, after studies, in his father's machine shop. What to other lads would have been regarded as irksome and confining young Westinghouse found to be a source of amusement and instruction. Before he was fifteen he invented and made a rotary engine, and passed at an early age the examination for the position of assistant engineer in the United States Navy. Following honorable military service from 1863 to 1865, he entered Union College, where he remained until the close of his sophomore year, and obedient to his impulse toward experiment, abandoned his classical studies and entered upon active life, to find a wider scope for his inventive genius. In 1865 he invented a device for replacing railroad cars upon the track, which, being of cast steel, was manufactured by the Bessemer Steel Works, at Troy, N. Y. Going to Troy one day, a delay caused by a collision between two freight trains, suggested to Mr. Westinghouse the idea that a brake under the control of an engineer might have prevented the accident. His first thought was an automatic brake attached to the couplers which was unsuccessful. This was followed by steam, which proved also to be unsatisfactory because by the time it reached the brake from the engineer's cab it had lost its power. At this point fate seems to have entered his life. In the pages of a magazine he had subscribed to, through the solicitation of a young girl, he saw an account of the use of compressed air in digging the Mont Cenis Tunnel, three thousand feet under ground. Instantly the inventor saw light. After much further study and investigation, the feasibility of compressed air further impressed itself on him. Drawings of the air-pump, brake cylinder and valves were made, but considerable time elapsed before a practical trial of the brake was obtained. The first patent was issued April 13, 1869, and the Westinghouse Air Brake Co. was formed on July 20 following.

About 1880 Mr. Westinghouse became interested in the operation of railway signals and switches by compressed air, and soon after there was developed and patented the system now manufactured by the Union Switch & Signal Co. The pneumatic interlocking switch and signal apparatus, whereby all the signals and switches are operated from a given point, using compressed air as the motive power and electricity to bring that power into operation, has been successfully introduced in Boston, Jersey City, Philadelphia, Chicago, St. Louis, and many other places. In 1886 the Westinghouse Electric Co. was formed for the manufacture of lamps and electric lighting apparatus, Mr. Westinghouse having become interested in the subject. The business rapidly developed, and in 1889 and 1890 this company absorbed the United States Electric Co. and the Consolidated Electric Light Co. In 1891 all these properties were reorganized into the Westinghouse Electric & Mfg. Co., which owns extensive works at East Pittsburg, employing over 22,000 people.

The question of the steam turbine and its applications was investigated by Mr. Westinghouse and he secured the patent rights of Charles A. Parsons of England on the turbine in 1897-98. This development of a new prime mover soon led the inventor to consider the use of the turbine as a prime mover for ships. The trouble was the high speed. Mr. Westinghouse then developed and brought out one of the most ingenious devices of modern engineering. This was the mechanical reduction gear for reducing the inherently high speed of a turbine to the slow speed of a ship propeller or direct-current dynamo. He accomplished this work in collaboration with the late Rear Admiral George W. Melville, U. S. N., and John H. MacAlpine. Within the last few years he also occupied himself with the development of an air spring for automobiles and motor trucks.

Mr. Westinghouse rendered an invaluable service to the electrical development of the world when, in spite of opposition, ridicule and all the unfair efforts to crush his alternating-current system, he remained steadfast in his belief that this class of high-tension transmission would make distant electrical distribution possible. This system his en-

George Westinghouse

gineers developed, and, incidentally, secured the cooperation of Nicola Tesla, 1887, who invented the alternating-current induction motor. The world today, lighted by distant waterfalls and central stations, now recognizes its debt to Mr. Westinghouse's foresight and perseverance. A struggle almost identical with that of the earlier fight for alternating-current transmission is the recent development of alternating-current traction by means of the single-phase motor which the Westinghouse Electric & Mfg. Co. has now wrought into an accomplished reality in the case of a number of traction lines, railroad terminals and tunnels.

Originating with the air brake, the growth of the various Westinghouse industries has been largely identified with railway progress, and it is interesting to note that this progress has represented increased security of life, increased capacity of the railway and reduced cost of operation. It is simply stating a fact to say that Mr. Westinghouse has been a great factor in the advance of civilization as represented by the important part he has played by introducing improved means of transportation. When the apparatus had passed the experimental state and was ready for commercial exploitation, he established factories which are themselves models, and which show the same anticipation of future development. Not only are the buildings handsome and well equipped with the best tools, but the comfort of the employes has been generally considered. It is worth noting that the nine-hour day, or rather the fifty-four week, was started with the Westinghouse Air Brake Co. in 1869, and has been adopted in all the other works as they were established.

Owing to his many achievements in mechanics, electricity, steam and gas, his name was known the world over, and he had many honorable distinctions conferred upon him for his achievements and in recognition of the services he rendered the various branches of engineering. He was an honorary member of the American Society of Mechanical Engineers, of which body he was also president in 1910. He was one of the two honorary members of the American Society for the Advancement of Science. He received the Edison gold medal for meritorious achievements in the alternating-current system of electrical distribution and the Grashof gold medal from the Society of German Engineers in Germany, which acknowledged him the greatest American engineer.

Mr. Westinghouse was connected with a large number of industries at home and abroad, many of which bore his name. These companies employ 50,000 men, and are capitalized at $200,000,000. He was married in 1867 to Marguerite Franklin Walker. His widow and son George survive him.

COMING EVENTS

April 4-11.—First National Efficiency Exposition and Conference, Grand Central Palace, New York City. Walter H. Tallis, director, Efficiency Society, Inc., 41 Park Row, New York City.

April 18-25.—Better Industrial Relations Exhibit at 2 W. 64th St., New York City. The exhibit will show the devices in modern business which tend to make more harmonious the relations between employer and employe and to better the conditions of employment. C. J. Primm, exhibit manager. Further information can be obtained from J. R. Rankin, 2 W. 64th St., New York City.

April 21-22.—Annual meeting of the National Metal Trades Association, Worcester, Mass. Hotel Bancroft, headquarters. H. D. Sayre, secretary, Peoples Gas Bldg., Chicago, Ill.

April 23-24.—Semi-annual convention of the National Machine Tool Builders' Association, New York City. Hotel Astor, headquarters. Charles E. Hildreth, general manager, Worcester, Mass.

April 29-30.—Annual meeting of the National Association of Cotton Manufacturers, Boston, Mass., in the Paul Revere Hall of the Mechanics Bldg. C. J. H. Woodbury, secretary, 45 Milk St., Boston, Mass.

May 1-October 31.—Anglo-American Exposition, London, England, to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

June 10-12.—Annual convention of the Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill.

June 15-17.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill.

June 15-17.—Annual convention of the American Supply & Machinery Manufacturers' Association at White Sulphur Springs, West Virginia; New Green Brier Hotel, headquarters. General offices of the association, Woolworth Bldg., New York City.

June 16-19.—Spring meeting of the American Society of Mechanical Engineers, Minneapolis and St. Paul, Minn. Calvin W. Rice, secretary, 29 W. 39th St., New York City.

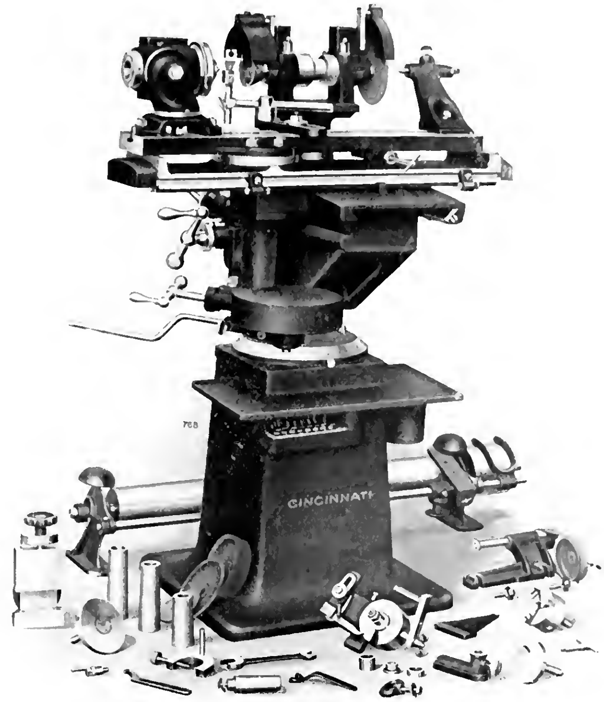
June 30-July 4.—Annual meeting of the American Society for Testing Materials, Atlantic City, N. J. Hotel Traymore, headquarters. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Pa.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

NEW BOOKS AND PAMPHLETS

The Pentane Lamp as a Working Standard. By E. C. Crittenden and A. H. Taylor. 17 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Reprint 216 of the Bureau of Standards, Vol. 10.

CLEARANCE



The No. 1½ Cincinnati Universal Cutter and Tool Grinder

Patent Rights Fully Reserved

Incorrect cutter clearance will reduce the output of your milling machines twenty per cent.

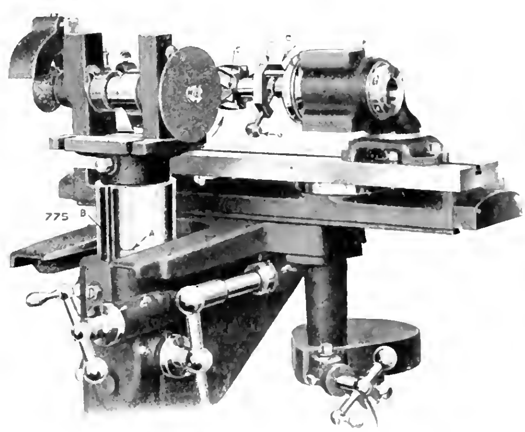
Clearance depends upon certain mathematical relations between the cutter and the grinding wheel.

To obtain these on the ordinary grinder requires several measurements and reference to diagrams, tables or charts.

The average operator doesn't understand these and after a couple of trials grinds until the clearance looks right—and your milling department suffers.

Compare the Cincinnati method. After a simple preliminary setting the swivel head is revolved the desired amount, the clearance angle being read directly from the dial—and your milling department profits.

This is only one of our *exclusive features.*



Method of setting for clearance.

Catalogue tells them all.

Cincinnati Milling Machine Company

CINCINNATI **OHIO, U. S. A.**

Modern Punch and Die Construction. Third revised and enlarged edition. 48 pages, 6 by 9 inches. Published by the Industrial Press, New York City. Price, 25 cents.

The Testing of Barometers. 12 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Circular 46 of the Bureau of Standards.

Fuel Briquetting Investigations. By C. L. Wright. 277 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 58.

Micrometer Microscopes. By Arthur W. Gray. 16 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Reprint 215 of the Bureau of Standards, Vol. 10.

Note on the Setting of a Mercury Surface to a Required Height. By M. H. Stillman. 6 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Reprint 214 of the Bureau of Standards, Vol. 10.

Mud-laden Fluid Applied to Well Drilling. By J. A. Pollard and A. G. Heggem. 21 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Technical Paper 66.

Hydraulic Mine Filling with Reference to Its Use in the Pennsylvania Anthracite Fields. By Charles Enzian. 77 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 60.

The Action of Acid Mine Water on the Insulation of Electric Conductors. By H. H. Clark and L. C. Ilsley. 26 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Technical Paper 58.

Accuracy of the Formulas for the Ratio, Regulation and Phase Angle of Transformers. By P. G. Agnew and F. B. Silsbee. 16 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as No. 211 of the Scientific Papers of the Bureau of Standards.

How to Build Up Furnace Efficiency. By Joseph W. Hays. 126 pages, 5 by 7½ inches. Illustrated. Published by the author at Rogers Park, Chicago, Ill. Price, $1.

This book, which is the seventh edition, revised and enlarged, treats of fuel waste, how to find fuel wastes and how to stop them. The treatise is one that can be profitably studied by fuel users in general.

Machine Forging. By Douglas T. Hamilton. 36 pages, 6 by 9 inches. 36 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This book describes the machines and methods used in the forming, welding and upsetting of machine parts by modern forging machinery. Typical machines are shown and a great number of examples of operations are illustrated with line-engravings. Applications to the automobile field and to the engine-building field are especially prominent.

The Mortar-making Qualities of Illinois Sands. By C. C. Wiley. 44 pages, 6 by 9 inches. Illustrated. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill., as Bulletin 70.

The bulletin discusses the effects of the characteristics of the sand upon the quality of mortar. The results of a series of tests on thirty-two representative Illinois sands are given in tabular form and are discussed. A classification of different sands is then proposed and specifications for each sand suggested.

Electric Toy Making for Amateurs. 206 pages, 5 by 7 inches. 77 illustrations. Published by Norman W. Henley & Son, New York City. Price, $1.

This work treats of the making of electrical toys, apparatus, motors, dynamos and instruments in general. Its popularity is attested to by the fact that it has passed into the twentieth edition. The work has been revised and several new chapters added, thus bringing it up to date. The contents by chapter heads are Batteries, Permanent Magnets, Electromagnets, Electric Motors, Electric Bells, Miscellaneous Toys, Spark and Induction Coils and Allied Subjects, Hand Power Dynamo, Miscellaneous Receipts and Formulas, etc.

Bevel Gearing. By Ralph E. Flanders. 48 pages, 6 by 9 inches. 38 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This is the fourth edition of this popular book, of which 28,000 copies have been published. This edition is practically the same as the third, except that part of the chapter on the strength and durability of bevel gears has been revised. The book contains seven chapters, headed as follows: Bevel Gear Rules and Formulas; Examples of Bevel Gear Calculations; Systems of Tooth Outlines used for Bevel Gearing; Strength and Durability of Bevel Gears; Design of Bevel Gearing; Machines for Cutting Bevel Gear Teeth; and Cutting the Teeth of Bevel Gears.

High-speed and Carbon Tool Steels. 44 pages, 6 by 9 inches. 16 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This treatise is No. 117 of MACHINERY'S Reference Books. It contains a collection of the best articles that have been published on the subject in MACHINERY during the past few years. The first chapter gives specifications for high-speed and carbon tool steel used in the United States navy yards. Chapter II is on the relation of the price of tool steel to manufacturing costs. Chapter III deals with the influence of heat on hardened tool steels with relation to their cutting qualities. Chapter IV is quite a complete review of the development and use of high-speed steel, while Chapter V deals in detail with the hardening and tempering of steel, giving specifications for quenching baths and tempering baths, and showing illustrations of practical designs of tanks for these baths.

Arbors and Work-holding Devices. 18 pages, 6 by 9 inches. 53 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This is No. 120 of MACHINERY'S Reference Books and contains a number of chapters dealing with holding devices and appliances used when turning, boring and grinding work of difficult and unusual character. The devices are all illustrated by line engravings showing, in detail, the design and constructional features. Two of the chapters contain the descriptions of the holding devices for first and second operation work recently published in articles in MACHINERY by Albert A. Dowd. One chapter shows devices designed by the Jones & Lamson Machine Co. for holding work in the Fay automatic lathe. These devices, however, are applicable to any engine lathe. This book will be of especial value to all tool designers and to other mechanics who have to devise ways and means for setting up work in lathes and boring mills.

Bolt, Nut and Rivet Forging. By Douglas T. Hamilton. 43 pages, 6 by 9 inches. 44 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This book contains the articles on bolt, nut and rivet forging machinery, methods and operations which have appeared in MACHINERY during the past year. The book is divided into three chapters, the first of which deals with bolt heading machines of a general type, describing the main features of their construction and operation; the second chapter deals with continuous-motion bolt and rivet headers, and the third with nut-forging machines. Tables of standard proportions of forged bolts and nuts are included. The book deals with a subject on which little has been published, and will, therefore, be of interest as a record of the present state of this branch of the forging art; it should appeal both to those directly interested in this field and to mechanics in general, who wish to keep informed on the progress of their trade as a whole.

The Manufacture of Steel Balls. By Robert H. Grant. 48 pages, 6 by 9 inches. 40 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

Little has been published on the manufacture of steel balls, no complete review of the process of manufacture ever having been attempted. In fact, no treatise on this subject has been published except a number of articles by Mr. Grant, which appeared two years ago in MACHINERY. These articles have been collected in the book under review and present a complete description of the manufacture of steel balls, including a historical review; the book begins with the various methods employed for making the blanks, rough-grinding, hardening and finish-grinding the balls, concluding with a chapter on the inspecting, gaging and testing of balls. Being the only treatise on this subject published, it will, no doubt, appeal to mechanical men in general, who are interested in the somewhat unique processes employed in this specialized manufacture.

Experimental Mensuration. By H. Stanley Redgrove. 328 pages, 4¾ by 7¼ inches. Illustrated. Published by D. Van Nostrand Co., New York City. Price, $1.25.

The author presents the science of geometry by the inductive rather than by the deductive system. He holds that the argument in favor of the old style geometry as providing for a training of the faculty of deduction must be given up. The distinction between geometry and mensuration is held to be artificial; while it is true that no experiments can establish absolutely that the sum of three angles of a triangle is equal to two right angles, practical methods, using the most accurate instruments that can be made, show that the three angles of a triangle are as nearly equal to two right angles as human beings ever require. This is sufficient for the present state of development. The work contains fourteen chapters and three appendices as follows: Geometrical Fundamentals—Measurement of Length; Measurement and Properties of Angles; Rectangles and Parallels—Measurement of Area; The Construction of Properties of Triangles; The Areas of Parallelograms and Triangles; Construction and Mensuration of Polygons; Mensuration of the Circle and Ellipse; Some Geometrical Properties of the Circle; Mensuration of Prisms and Cylinders — Measurement of Volume; The Theorem of Pythagoras and Its Applications; Proportion—Drawing to Scale; Mensuration of Pyramids and Other Solids; Mensuration of Irregular Figures; The Trigonometrical Solution of Triangles; Duodecimals; Trigonometrical Tables; Answers to the Numerical Exercises. The numerical exercises interspersed throughout the work offer the student many examples to be worked out. The book lends itself to home study as well as regular school work. The typographical make-up is excellent.

NEW CATALOGUES AND CIRCULARS

A. W. Cadman Mfg. Co., Pittsburg, Pa. Catalogue and price list No. 5 of valves and other specialties.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin No. 150 on Chicago pneumatic coal drills.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Bulletin on the automatic motor control as applied to LeBlond motor-driven lathes.

Volcano Torch & Mfg. Co., Erie, Pa. Circular of the "Volcano" gasoline blow-torch which generates the pressure required to operate it.

Sprague Electric Works of General Electric Co., 527-531 W. 34th St., New York City. Price list of portable ozonators for house and general use.

Lagonda Mfg. Co., Springfield, Ohio. Catalogue of Lagonda automatic cut-off valves, showing installations in manufacturing plants, power stations, hospitals, railroad stations, etc.

National Tube Co., Frick Bldg., Pittsburg, Pa. Booklet of the N. T. C. regrinding globe valves, containing a catechism designed to show the advantages of this make of valve.

Perfection Spring Co., Cleveland, Ohio. Short treatise on physics and chemistry with reference to the care of automobiles and the manufacture of springs as conducted by the company.

Stow Mfg. Co., Binghamton, N. Y. Bulletins of Stow ½-inch electric breast drill, electric bench grinder, electric toolpost grinder and "Gee Whiz" radial flexible boring machine for wood-working.

Dyer Smith, 32 Liberty St., New York City. Reprint of an address entitled, "Patents—Some Essential Facts for the Engineer," presented before the students of Lehigh University, January 9, 1914.

Grant Engineering Co., Free Press Bldg., Detroit, Mich. Booklet on "Pioneers," being an appreciation of John James Grant by Elbert Hubbard. The many friends of Mr. Grant will read this short account of his life and works with interest.

Oster Mfg. Co., 2107 E. 61st St., Cleveland, Ohio. Circular of the new Oster cutting-off and reaming machine for pipes and tubes, having a maximum capacity for ¼-inch to 2-inch pipe inclusive, and a minimum capacity for ¼-inch pipe.

Ronald Trist & Co., Ltd., 4 Lloyds Ave., London, England. Circular of the thermo-feed differential governor for steam boilers. The apparatus will keep the water level at the same height within one-eighth inch, its operation being entirely automatic.

Argentine Social Museum, Buenos Aires, Argentine. Pamphlet giving part of the statutes of the Argentine Social Museum, treating of the object, methods of action, lectures, library, monthly bulletin, members and adherents, international relations, permanent exposition, etc.

Sprague Electric Works of the General Electric Co., 527-531 W. 34th St., New York City. Catalogue No. 329 of electric fans for 1914, comprising both direct current and alternating current desk and bracket fans, oscillating fans, residence fans, ceiling fans and exhaust fans.

Jackson Machine Tool Co., Jackson, Mich. Circular of the No. 6 duplex die sinker, designed for cutting drop-forge dies or metal core boxes. It has a longitudinal feed of 40 inches, cross feed of 13 inches and vertical feed of 21½ inches. The net weight of the machine is 4700 pounds.

Wheelock Mfg. Co., Wheelock, Vt. Circular of flexible metallic tubing made wholly of steel wire with no packing. This tubing is recommended for use on automatic screw machines, gear-cutters, milling machines, and other machines using oil or other lubricant on the cutting tool.

Windsor Machine Co., Windsor Vt. Catalogue of the Gridley automatic multiple spindle drill designed for rapidly drilling parts which are difficult to handle in the ordinary manner. Details of the machine are shown and examples of drilled work for which it is especially suited.

Hammacher, Schlemmer & Co., 4th Ave and 13th St., New York City. Catalogue of casters for machine shops and factories and all purposes, containing thirty-eight 9 by 12 inch pages and 190 illustrations. The catalogue shows twenty-four distinct lines of casters, including a full line of truck casters.

General Electric Co., Schenectady, N. Y. Bulletins A 4200, 44590, 45600, 45601 and 47400 on strain insulators and strain clamps, type ML governor for motor-driven air compressors, vacuum tube lightning arresters, artificial lightning arresters for alternating current circuits and Type F form K 12 oil switches, respectively.

Coates Clipper Mfg. Co., Worcester, Mass. Bulletin 24 on Coates "Flexishaft," showing applications of this type of flexible transmission shaft to drilling, polishing, grinding, erasing, setting screws, etc. The bulletin is profusely illustrated and shows many interesting applications of Coates tools and devices in manufacturing, repair and jobbing work.

Allen-Bradley Co., 495-497 Clinton St., Milwaukee, Wis. Bulletin B-541 on Type H resistance starting switch for alternating current induction motors which is claimed to give the motor absolute protection from running single phase should only one fuse blow or if for any other reason one line becomes interrupted, and to give positive no-voltage protection in all phases.

Detroit Tool Co., Detroit, Mich. Catalogue of a semi-automatic four-spindle drilling machine, in which the drill spindles are cam-operated, thus insuring positive feed. The claims made for the machine are: saving of time, drills, floor space and belt troubles. The catalogue shows a number of examples of automobile work advantageously drilled on this type of machine.

Mummert-Dixon Co., Hanover, Pa. Catalogue of oilstone grinders for fine edge tools. Several sizes and types of machines for grinding the knives of wood-working machines are shown and an oilstone

face and tool grinder for machine shops. This is a two-purpose machine, designed for sharpening scrapers, lathe tools, planer tools, etc., and for face grinding and all kinds of vise work.

Blanchard Machine Co., 64 State St., Cambridge, Mass. Circular of the Blanchard high-power vertical surface grinder, listing work being done on Blanchard grinders in customers' shops. The numbered paragraphs describe the work and give production figures, limits, etc. The circular will be found of suggestive value to manufacturers having work that can be finished on this type of machine tools.

Standard Gage Steel Co., Beaver Falls, Pa. Catalogue and price list of turned and cold-drawn steel shafting; cold-drawn screw stock; finished flats, squares, rounds, hexagons, angles, channels and special shapes; compressed steel elevator guides; connecting rods; crankshafts; finished machine keys; Woodruff keys; taper pins; machine racks; feed screws; lead screws and worms; automatic machine work and drop-forgings.

Richardson-Phenix Co., Milwaukee, Wis. Bulletin 57 of the Phenix sight-flow indicator, illustrating and describing a device which can be inserted in any pipe line carrying a liquid, such as the water lines of jacket-cooled transformers and the supply pipes of gas engines and air compressors. The device shows at a glance or indicates electrically by lighting a lamp or ringing a bell when the flow of liquid is interrupted.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Data sheets showing mountings of Hess-Bright ball bearings for vertical armature shaft of electric motors, release fork for automobile clutch, front and rear truck hubs, marine propeller shafts, shafts without shoulders to support radial loads and opposed thrusts, double exhaust fan and wheel hubs. Tables of dimensions of annular radial bearings and thrust bearings are included.

Acme Machine Tool Co., Cincinnati, Ohio. Bulletins of the "Acme" combination flat turret lathes, single pulley drive, 3¼ by 36 inches capacity and 2¼ by 26 inches capacity; Cincinnati "Acme" screw machine from ⅝ by 4 inches capacity to 2¼ by 11 inches capacity in seven sizes; Cincinnati "Acme" turret lathes in 14-, 16- and 18-inch and 20-inch sizes. The bulletins illustrate details of construction of headstocks, roller feeds, turret toolholders, etc.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin 15 containing a set of specifications for pipe used for drilling purposes; an illustration showing samples of "National" pipe after torsional tests have been made ranging from 180,000 to 215,000 inch-pounds; also illustrations and tables showing weights and dimensions of "National" drill pipe, "National" special rotary pipe, "National" special upset rotary pipe and "National" seamless interior upset drill pipe.

Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mount Gilead, Ohio. Catalogue 40, containing 128 pages 8¾ inches by 11 inches. The first fifteen pages show the home office, factory and branch office facilities. In the following pages hydraulic presses and pumps for all high pressure purposes are illustrated and described. Various designs of hydraulic presses and pumps recently described and illustrated in MACHINERY are shown which convey an idea of the scope of the field covered by the company.

Niles-Bement-Pond Co., 111 Broadway, New York City. Circular of Niles new design boring and turning mills of 44 inches, 53 inches, 62 inches and 73 inches table capacity. These machines are furnished with direct-current motor drive, push-button control and automatic brake for table, with alternating-current motor drive or belt drive through a single pulley. Independent motors located on the top brace of the mill are provided for adjusting the cross-rail and providing rapid power traverse to the bars and saddles.

Garvin Machine Co., Spring and Varick Sts., New York City. New 1914 catalogue containing 322 pages, 4 by 6¼ inches. This catalogue illustrates and describes the complete line manufactured by this company and contains a number of tables of value to mechanics, draftsmen, etc. Among the machines described are milling machines, profilers, cam cutters, die slotters, screw slotters, tapping machines, duplex horizontal drills, screw machines, monitor lathes, grinders, and various classes of special machinery.

Lees-Bradner Co., Cleveland, Ohio. Catalogue of Lees-Bradner thread milling machines made in four sizes, all having the same diameter capacity but varying in length. The machines are primarily designed for milling screws such as worms, lead-screws, feed-screws, rear axle worm drives and steering worms for automobiles, etc. Spiral gears and spur gears can also be cut on the machines. The catalogue is a handsome publication 8½ by 11 inches, illustrated with fine halftones. Three diagrams are shown to designate the various parts by name.

Bill Deezy Co., 141 Milk St., Boston, Mass. Catalogue of construction material for toy making, model making, etc. The principal parts are a four-arm flexible joint and coppered steel rods. With these parts a great variety of forms can be constructed by modifying the flexible joint. This is trimmed, bent or twisted as required. Inventors, model-makers, engineers and others can sometimes, no doubt, utilize these construction materials, especially as wheels are also furnished which enable the constructor to make working models.

Garvin Machine Co., Spring and Varick Sts., New York City. Circular No. 205, being a pocket daily reminder of the Garvin products. It illustrates the line of Garvin milling machines, including knee-type, vertical spindle type and Lincoln type milling machines, cam or form milling machines, duplex milling machines, profile milling machines, die slotting machines, screw slotting machines, etc. Grinding machines, hole grinding machines, right angle drilling machines, automatic tapping machines, and automatic oil grooving machines are also shown.

Keystone-Hindley Gear Co., 701 Pennsylvania Bldg., Philadelphia, Pa. Catalogue of Keystone-Hindley worm gears. The lists are accompanied with diagrams and the gears and worms are numbered so that customers can order any combination desired within the range of the lists by giving the number and the hand of the helix. For example, gear No. 2013 is 16 to 1 ratio; 10.18 pitch diameter of wheel; 1 circular pitch; 32 teeth. The pitch diameter of the worm is 4.57 inches; lead, 2 inches; number of threads, 2; distance from center to center, 6.625 inches; either right or left hand.

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletins 1037 and 1038, superseding Bulletins 1035 and 1036 on Type B limit stops for direct-current motors and Form H dynamic braking Dinkey controllers for direct current motors, respectively; also reprints of article, "Application of Electric Power in the Foundry," illustrating and describing the application and use of electric controllers on cranes, sand mills, sprue cutters, tumbling barrels, cupola blowers, pipe core machines, roller-ramming molding machines and grinders. The use of lifting magnets in foundries for handling castings is illustrated with a number of striking views.

Link-Belt Co., 39th St. and Stewart Ave., Chicago, Ill. Data book 125 on "Silent Chain" drives, which will be welcomed by the mechanical public. For the first time a book has been published by a manufacturing concern which will enable users of power to select the correct silent chain drives for their work and to determine the exact costs from list prices shown in the book. Besides giving engineering information in simple and compact form, this data book describes many uses of silent chain for the efficient transmission of power and shows illustrations of a large variety of applications. It contains 112 pages bound in flexible red covers. Copies can be obtained free of charge by addressing the Link-Belt Co.

New York Belting & Packing Co., 91-93 Chambers St., New York City. General catalogue of mechanical rubber goods. Rubber belting for all purposes is listed and rules for calculating the horsepower of belts and directions for the use and care of rubber belts are included. Rubber hose, armored hose, steam and air hose, suction hose, etc., are listed, the various types being illustrated. Packings in great variety, diaphragms, hot water valves, washers, perforated mats, rubber tubing, hat bags, rubber stoppers, hammer cushions, rubber tiling, are a few of the specialties also included. The catalogue is a fine example of typographical excellence, illustrations, printing and paper being high grade. The illustrations of rubber tiling are beautifully printed in colors.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin 11-B on the history, characteristics and advantages of "National" pipe, containing eighteen chapters, as follows: 1. A Short History of Pipe and Early Methods of Manufacturing. 2. First American Pipe Furnaces. 3. History of National Tube Company. 4. Materials for Pipe. 5. The First Steel Pipe. 6. Pipe Threading. 7. Spellerizing "National" Pipe. 8. Full Standard Weight Pipe only Manufactured. 9. The Continuous Uniformity of "National" Pipe. 10. Physical Properties. 11. Bursting Pressure. 12. The Inspections and Tests of "National" Pipe. 13. Changes in the Tubular Industry (1888 to 1913). 14. "National" Pipe for Refrigeration Systems. 15. Corrosion of Pipe in Hot Water Systems. 16. The Design of Hot Water Supply Systems to Minimize Corrosion. 17. Corrosion of Pipe in Coal Mines. 18. Remarkable Ductility of "National" Pipe.

TRADE NOTES

Keuffel & Esser Co., Hoboken, N. J., announces that the price of Smith's fountain drawing pens which were described in the July, 1913, number of MACHINERY has been reduced from $7 to $5.

Monarch Machine Co., Sidney, Ohio, manufacturer of engine lathes, is putting up an office building; also an addition to its plant 90 by 150 feet. The company reports a rapidly increasing business.

Interstate Machinery Co., Troy, N. Y., recently erected a large addition to its plant. The company buys and sells used iron- and wood-working machinery and is also a jobber in new machinery.

C & C Electric & Mfg. Co., Garwood, N. J., announces that the Indianapolis territory will be temporarily taken care of by its Cincinnati representative, F. A. Saylor, 6th and Vine Sts., Cincinnati, Ohio.

National Tube Co., Frick Bldg., Pittsburg, Pa., because of certain articles published in the technical press in regard to wrought-iron pipe, makes the statement that it has not made wrought-iron pipe for some years.

Carpenter Steel Co., Reading, Pa., has appointed James W. Sederquist district sales agent for Boston and Eastern New England with offices at 131 State St., Boston, Mass. Mr. Sederquist will be assisted by William T. Dunn.

Hill Clutch Co., Cleveland, Ohio, manufacturer of power transmission machinery, announces the appointment of P. W. Alling as Eastern representative in charge of the company's New York office at the Hudson Terminal, 50 Church St., New York City.

Index Office, Inc., 31 W. Lake St., Chicago, Ill., has been incorporated for indexing, compiling and abstracting literary and statistical material for the use of manufacturers, scientists and investigators. Aksel G. S. Josephson, secretary. The annual membership fee is $5.

D. H. Stoll Co., Inc., Buffalo, N. Y., manufacturer of presses, shears, dies and other sheet-metal working machinery, has recently arranged for the construction of a three-story addition to its plant. The building will be 40 feet wide by 118 feet long and will be constructed of brick and steel.

Allen-Bradley Co., 495-497 Clinton St., Milwaukee, Wis., announces that its Chicago representative, Frank L. Gohl, has moved from his old headquarters at 540 Commercial National Bank Bldg. to 307 Webster Bldg., 327 La Salle St., Chicago, Ill. The change was necessitated by an increase in business, the old offices proving too small to accommodate the same.

Carter & Hakes Co., Sterling Place, Winsted, Conn., manufacturer of Lincoln milling machines and special machinery, has made Robert W. Barwood of Philadelphia, Pa., a well and favorably known machine tool salesman, its representative in New England and the territory adjacent to New York and Philadelphia. Mr. Barwood's headquarters will be at the Bourse, Philadelphia.

Lapointe Machine Tool Co., Hudson, Mass. Walter F. Rice, Joseph F. Owens, and their associates have taken over the common stock formerly owned by J. Keyes Hall and Joseph N. Lapointe. The officers of the company are Walter F. Rice, president; Joseph F. Owens, treasurer; and William P. Everts, secretary. The new management will put on additional men at once in order to make better deliveries.

Acklin Stamping Co., Toledo, Ohio, reports an unusually bright outlook for business during the coming year. A few days ago the company entered its order No. 1000. When it is remembered that the company began business about two and one-half years ago and that many orders for stampings are from 500,000 to 2,000,000 pieces, it can be readily seen how much business is represented by one thousand orders.

Tate-Jones & Co., Inc., Empire Bldg., Pittsburg, Pa., installed the new heat-treating department of the Ingersoll-Rand Co.'s plant at Phillipsburg, N. J. The plant handles a large output of drills and compressors and the furnace equipment consists of two large double chamber annealing furnaces, two semi-muffle furnaces for pre-heating, six lead and two solution baths for hardening and three oil baths for tempering. All the furnaces are fired with fuel oil.

Dodge Mfg. Co., Mishawaka, Ind., has purchased the gear patterns, gear machinery and powder machinery patterns of the I. & E. Greenwald Co., Cincinnati, Ohio, together with all records, drawings and the good will of the business. Most of the patterns and all the records are now in Mishawaka. The addition of the gear patterns to the already extensive list of Dodge gears gives the company the most complete line and widest list of gears in the United States.

H. W. Johns-Manville Co. has removed its Indianapolis, Ind., and Louisville, Ky., branches to larger quarters with better facilities for handling increased business. The new address of the Indianapolis branch is 408-410 N. Capitol Ave., and that of the Louisville branch, 659-661 So. Fourth Ave. Both branches will include ample warehouse accommodations in addition to showrooms for the display and sale of the company's line of asbestos roofing, pipe coverings, insulating materials, lighting fixtures, automobile accessories, etc.

L. S. Starrett Co., Athol, Mass., has accepted the invitation of the Rice Leaders of the World Association to join its organization. This association will be limited to fifty manufacturers from all lines, and the invitation is extended only to the recognized leaders in the various kinds of manufacturing. Competitors in any line cannot be members. The association which was founded by Elwood E. Rice, president, has for its principles honor, quality, strength and service, and an emblem which signifies these principles will be worn by salesmen and other representatives of the members of the association.

Ingersoll-Rand Co., 11 Broadway, New York City, has placed George A. Gallinger, of Pittsburg, in charge of its pneumatic tool department with the title of manager of pneumatic tool sales, headquarters at 11 Broadway. The company felt warranted in establishing this special department and in placing at the head of it a man who understands the business from a mechanical as well as a commercial standpoint. Mr. Gallinger's time and service are at the disposal of those contemplating the use of pneumatic tools and his long experience and practical knowledge commend him to the consideration of the trade in general.

H. W. Johns-Manville Co., Madison Ave. and 41st St., New York City, states that the new South Works of the J. I. Case Threshing Machine Works at Racine, Wis., is roofed with asbestos and Trinidad Lake asphalt, two of the most enduring mineral substances known. Asbestos is an indestructible fibrous rock, and for roofing purposes it is made into a felt, layers of which are cemented together with asphalt. This roofing is not affected by changes of temperature. The hottest weather does not cause it to dry out, melt or run, and the coldest weather does not crack it. A booklet describing the roofing in detail will be sent to anyone interested.

Cleveland Twist Drill Co., Cleveland, Ohio, has begun the publication of a monthly house organ called "Drill Chips" edited by Andrew E. Coburn,

MACHINERY

MAY, 1914

MODERN EQUIPMENT FOR INDUSTRIAL PLANTS

A COLLECTION OF METAL EQUIPMENTS THAT ARE DURABLE AND FIREPROOF

BY HARRY C. SPILLMAN

THE design and selection of factory equipment, such as partitions, bins, racks, etc., seldom receive the proper attention. Often a wood partition is installed which has to be removed in a few months; likewise, a bin or rack becomes obsolete in a short time, and whenever a condition like this occurs the material is broken up and usually ends in a bon-fire. Few manufacturing plants realize the vast loss which occurs in this way, and, in reality, it is one of the serious wastes in a plant. Going concerns are compelled to make changes almost continuously, and as a large amount of this equipment is built in their own shops by millwrights and carpenters, they do not appreciate the enormous cost involved. Often the foremen of a plant are allowed to order the necessary equipment for their departments, and they do not appreciate its cost. One large manufacturing concern discovered the folly of this plan and appointed a committee which had to pass and sanction the building and purchasing of all new equipment. Modern factories are usually housed in fireproof buildings but the value of fireproof equipment is often overlooked. Most industrial plants have very few firewalls, and in case a fire starts in a large room containing a quantity of wooden equipment, which, as a rule, is more or less saturated with oil, it is almost certain to spread very rapidly and the fireproof construction of the building will have very little effect in checking it.

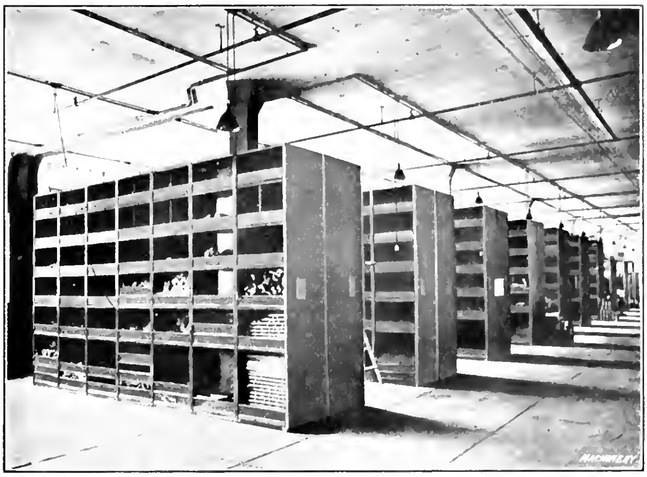


Fig. 1. Arrangement of Metal Stock Bins made up in Sections

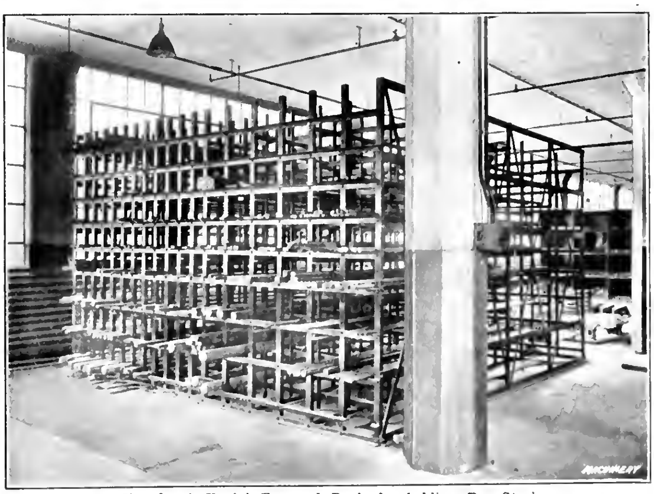

Fig. 2. A Useful Form of Rack for holding Bar Stock

The illustrations in this article show some of the devices which can be made out of metal at a cost that compares favorably with wood. Fig. 1 shows metal bins made up in sections which allows any size or combination of shelves. It is a unit system of construction by which the sections are made to form a concrete whole. These bins are designed to carry a load of 400 pounds per square foot of shelf with a large factor of safety. The sections are bolted together which allows them to be easily altered or taken down and stored away when not required. Considering the slight difference in the first cost of metal and the great advantage of being fireproof, sanitary, adjustable and made up in sections, it is more than good policy to give preference to metal bins. An inexpensive bar rack is shown in Fig. 2. This bar rack is made out of 2 by 2 by ¼ inch angle irons bolted together. Flat bars 2 by ¼ inch in size are bolted along the sides and placed diagonally in order to add to its strength and rigidity. A bar rack is subject to a large amount of abuse, and at times it must support an enormous load. This rack will meet these requirements and it is self supporting and can be easily made and erected.

The problem of taking care of workmen's clothes can only be solved by using individual lockers. Nothing is more unsightly in a work-room than the street clothes of the work-men scattered along the walls and work-benches. Fig. 3 shows a locker room containing metal lockers which are well adapted for shop use. These are set up in solid groups and each group contains a number of lockers which costs less than having each compartment built as a separate unit. Each locker is 36 inches high, 12 inches wide and 15 inches in depth, and they are made up in double tiers. They are supported on legs 6 inches high which gives sufficient space to sweep underneath. Each compartment contains a hat shelf and five two-prong steel hooks. The doors are made of ¾-inch, diamond-mesh, 15-gage expanded metal which gives good ventilation and shows at a glance the contents. Each locker is numbered and has a master keyed flat key lock fitted with a three-way locking device. The compact and sanitary features, protection against fire and security against petty theft make these lockers particularly suitable for industrial plants. The use of pipe for railings, belt guards and skeleton racks is another valuable feature to adopt for industrial plants. Fig. 4 shows an excellent method for supporting time clocks on a skeleton rack. They are rigidly supported on 1¼-inch steel pipe securely anchored to the floor and ceiling. A pipe railing is installed beside each clock in order that the workmen will form in line and only one man at a time can reach the clock. As a rule time clocks receive

Fig. 3. Sanitary Metal Lockers for holding Workmen's Street Clothes

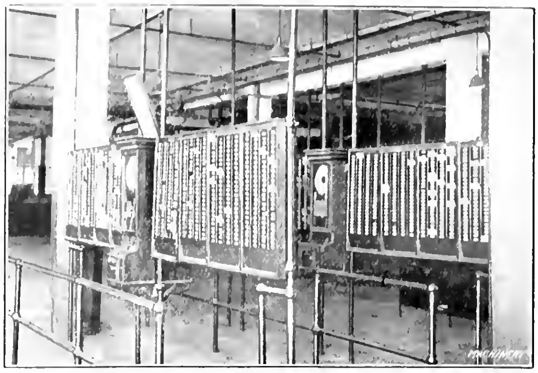

Fig. 4. Time Clocks supported by Pipe Racks and Rails to keep Men in Line

very rough treatment and are easily thrown out of adjustment. A framework of this kind is rigid and also makes a neat and attractive support for the clocks.

Wooden partitions are a fire menace and according to insurance reports they supply excellent fuel to a fire. Metal partitions are far more attractive; they have a larger percentage of glass area, and if made up in standard width sections, it is an easy matter to remove them to some other location. Unfortunately, wooden partitions cannot be moved without practically wrecking the material. A partition which is self supporting and made up in unit sections is shown in Fig. 5. This style of partition has recently been placed upon the market and its many advantages are shown in the illustration. Fig. 6 shows a very inexpensive metal partition which can be built at almost the same cost as a wooden one. This style of partition is made up in sections 4 feet wide, and a 4 by 1/4 inch stiffening bar is placed between each section, which adds to its stiffness. The framework of the panel is made up of 1-inch angle irons having a metal panel 4 feet high for the lower portion. This panel is made out of No. 10 gage steel and riveted to the angle iron frame. The upper space of the panels is divided into sections for supporting the glass. Either 1/8 inch ribbed or double strength American glass is used. The glass is bedded in metal putty and wooden pegs are used instead of glazing points; the glass is also back puttied which holds it rigidly in place. The doors are made of the same material, using 1 by 1/8-inch angle iron for the framework and 1-inch channels for the door stops. The glass in the doors is held in place with metal strips instead of putty. This illustration also shows a watchman's and fire alarm box located on the column. Near the ceiling is an autocall bell and on the floor is shown an inexpensive shop cuspidor made out of pressed steel. The wiring is encased in steel conduit, and although the building is fireproof a sprinkler system is installed. Equipment of this kind is an excellent means for keeping the insurance rate down to a minimum, and it shows the results which can be accomplished by giving the subject the proper study.

Fig 7 gives an excellent example of wire partitions worked out on the unit basis. These partitions are made up in sections 4 feet wide and have a metal panel below. The framework is 1-inch channel iron and the woven wire is No. 10 gage, having a 1-inch mesh. The corners of these partitions and all door openings are reinforced with a 2-inch steel pipe securely anchored to the floor and ceiling. This gives the partition more strength and protects the corners and openings in an effective manner. The design of work-benches should have careful attention, as most plants have considerable bench work. A work-bench poorly installed continually demands repairing. Fig. 8 shows a work-bench with a 3- by 12-inch maple plank along the front and the remainder of the top covered with maple flooring having a 2-inch face. A 1- by 6-inch timber along the back supports the maple flooring and also allows the legs to be placed from 8 to 10 feet apart, instead of the usual 6-foot spacing. The metal legs are provided with two cross braces for supporting shelves underneath the bench. A strip of wood is placed along the back and ends to keep small parts from rolling off. The woodwork is given a coat of shellac which adds to its appearance and preserves the wood. The bench drawer shown in this illustration is made out of heavy metal and is equipped with trays divided into compartments. The drawers have separate change keys which are master keyed with the lockers. The price of these bench drawers ran slightly lower than the same size made out of wood, which shows that metal equipment compares favorably with wood. The design will be fully understood by referring to Fig. 9.

Fig. 10 shows a Dormant scale which is built into the floor. The scale has an indicating dial and tare beam which makes a quick and effective method for weighing material in a receiving room. The scale is made entirely out of metal except the central portion of the platform; this is made flush with the floor, which is convenient for weighing material carried on trucks. Metal channel irons and I-beams bolted to the ceiling and trusses for supporting hangers and shafting is a far better method than using wood stringers. The power transmission equipment does not get out of alignment from the shrinkage of the stringers and there is less danger of the bolts and nuts becoming loose and doing considerable damage.

The introduction of a factory fence made of metal is fast

Fig. 5. Metal and Glass Partitions made up in Unit Sections

Fig. 7. A Good Example of Wire Partitions built on the Unit Plan

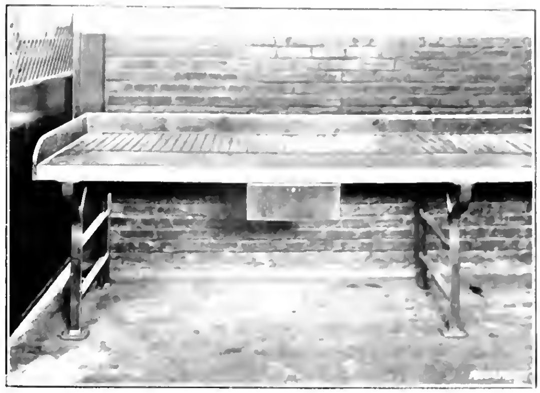

Fig. 8. A Substantial Form of Work-bench

causing the disappearance of the wooden fence which continually demands repairs. Fig. 11 shows a non-climbable fence which will stand up under rough abuse. The posts are spaced eight feet apart and imbedded in concrete. They are made out of 2-inch galvanized pipe and a 3/4-inch pipe ties the top of the posts together. A close woven wire mesh made out of No. 9 gage galvanized wire is stretched between the posts and the fence is made unclimbable by means of five strings of heavy barbed wire along the top. An industrial plant enclosed with a fence of this type is made far more attractive than one enclosed with tight boards. By careful planning and giving metal the preference, the equipment of a plant can be made completely fireproof. It will possess the greatest possible strength and stability and have the combined qualities of adjustability and adaptation for the many uses and changes necessary for the equipment of a going concern.

ALUMINUM CHEAPENING

The housewife who steps into the hardware store to price an aluminum kettle or saucepan and pays handsomely for it without complaining because the kettle is worth it in convenience and durability, perhaps does not always realize that aluminum is no longer the rare, expensive metal it was portrayed to be not many years ago. She does not know that aluminum is now quoted on the open market at 19 cents a pound, with copper at 14½ cents and tin at 38½ cents. Furthermore, the price figures of 19 and 14½ cents for aluminum and copper are misleading, since, because aluminum is only three-tenths as heavy as copper, for most purposes only three-tenths as much by weight of the metal is needed. The metal for a vat weighing ten pounds made of copper ought to cost $1.45; the aluminum for a vat of the same size would weigh three pounds and ought to cost 57 cents. The use of aluminum in the industries is still in its early stages, and the manufacturing cost is still excessive, but we may shortly expect lower prices.

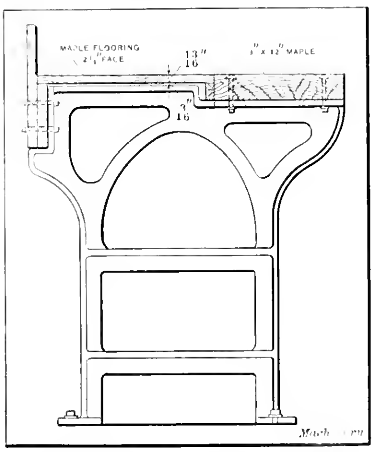

Fig. 9. End View of Bench shown in Fig. 8

It is no doubt the prevailing opinion that iron is the most abundant of all metals. As a matter of fact, of all the seventy odd elements which make up the earth, only two are more abundant than aluminum—namely, oxygen and silicon—and these are not metals. Besides, it is of common occurrence, being a principal ingredient of the ordinary clay that the farmer turns up every time he lets the points of his plow down into the subsoil. This clay contains sometimes as much as 25 per cent of aluminum in chemical combination with silicon. However, as yet no process has been devised by which it can be recovered cheaply from common clay. The metal now on the market is reduced from the mineral bauxite, which is found in Georgia, Alabama and Arkansas in this country, in County Antrim in Ireland, and in the north of France. The process for its reduction was developed in the years from 1886 to 1889 by C. M. Hall in this country and P. T. L. Heroult in France. The pure oxide of aluminum is heated to melting by an electric current and separated electrolytically while in this condition from the oxygen.

Weight for weight, aluminum is stronger than any other metal except the best cast steel and some of its own alloys. Therefore it is coming into considerable use in boat building and other kinds of construction where lightness is an object. As a conductor of electricity, an aluminum wire 0.126 inch diameter carries the same current as a copper wire 0.100 inch diameter and weighs only 69 pounds per mile, while the copper weighs 162 pounds per mile.—*Michigan College of Mines Bulletin.*

OIL SEPARATOR EQUIPMENT OF THE NEW PROCESS GEAR CORPORATION

The New Process Gear Corporation, Syracuse, N. Y., manufactures gears, automobile differentials, transmission gears, etc., and in the various machining operations performed produces about two tons of oil-soaked chips daily. The oil is removed from the chips in the separator room shown in Figs. 1 and 2. The apparatus used includes a steam turbine driven separator made by the Oil & Waste Saving Co. of Philadelphia, Pa., a machine simple in construction, consisting of a vertical shaft carrying a bucket wheel and a basket in which the chips are deposited. Steam for driving the wheel is admitted through a nozzle from which it impinges on the bucket wheel and drives it and the separator basket at high speed. The use of steam for driving a centrifugal separator directly eliminates the belt troubles incident to belt-driven separators and it also provides heat for warming the chips, thus facilitating the separation of the oil.

Fig. 1. Steam Turbine Oil Separator used in New Process Gear Corporation Plant

Fig. 2. Steam Turbine-driven Oil-drying, Filtering and Sterilizing Machine

The separator baskets are filled with chips shoveled from the chip bin in the corner and are then transported to the separator by the overhead trolley and pneumatic hoist. They are lowered into the separator and a heavy cast-iron cover mounted on a vertical spindle is swung into place when the basket is in position. Thus, all heavy lifting by the attendants is avoided.

The operation of starting the machine and separating the oil from a basket of chips requires but a few minutes. The separated oil runs through a pipe into a sump and from the sump it is lifted to a tank shown in Fig. 2 with a geared pump driven by a small electric motor. This tank acts as a settling place where the fine chips and dirt are partially removed. From the tank the oil is directed into a centrifugal oil drying and sterilizing machine made by the same concern that manufactures the steam turbine separator. The function of this machine is to evaporate the water contained in the oil and to subject the oil to a temperature that will sterilize it and thus reduce the danger of blood poisoning of screw machine operators to a minimum. It also filters the oil.

A cross-section of the machine is shown in Fig. 3. It consists of a cast-iron case in which is mounted a vertical spindle carrying the steam turbine bucket wheel and the separator basket. The oil flows into this separator and is hurled by centrifugal force through the filtering medium lining it. The oil flies from the outside of the basket against the steam coils which are filled with high temperature steam. Then being in a finely divided condition, it is instantly raised to a high temperature and the water is evaporated, escaping as steam through the holes in the top. The dry and sterilized oil flows from the machine into another sump, from which it is raised by a hand pump shown at the right in Fig. 2, and drawn into cans for distribution throughout the plant. Two men are employed in the separator room. They handle about three tons of oil-soaked chips daily, from which about 200 gallons of oil is extracted. The oil, being free from water and in a practically sterile condition, is an efficient and safe lubricant.

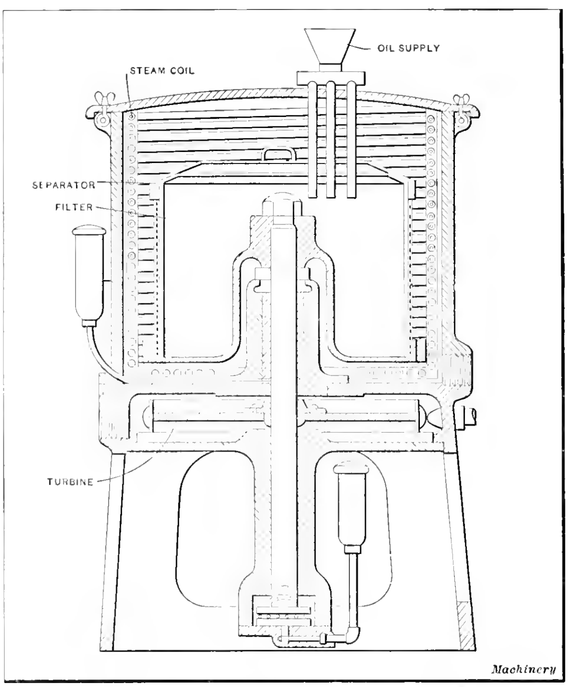

Fig. 3. Vertical Section through Oil-drying, Filtering and Sterilizing Machine

* * *

An invention has been made by a citizen of Reichenberg, Bohemia, for producing a substitute for all classes of marble, including the most highly priced Italian marble. It is claimed that the artificial product is fully as strong or stronger than the genuine article, that it is less liable to cracks or surface damage, and that especially in working, drilling, or mounting work upon it, the danger of injury to it is less than with the real marble, although it is only one-third the price. Factories for producing this product are already in operation in Vienna, Berlin, Mannheim and Hamburg, and arrangements have been made for selling the British patent rights to a London company.

THE CLEVELAND AUTOMATIC SCREW MACHINE—2

DESIGN, CONSTRUCTION, OPERATION, TOOL EQUIPMENT AND ATTACHMENTS

BY DOUGLAS T. HAMILTON*

THE turret end of the Cleveland automatic screw machine incorporates a number of interesting mechanical movements and features of design that are well worth attention. Among these are the details used for indexing and locking the turret, the methods of rotating, and the means employed for regulating the feed of the tools. These various details will be taken up in the order of their relation, as regards position, to the turret drum.

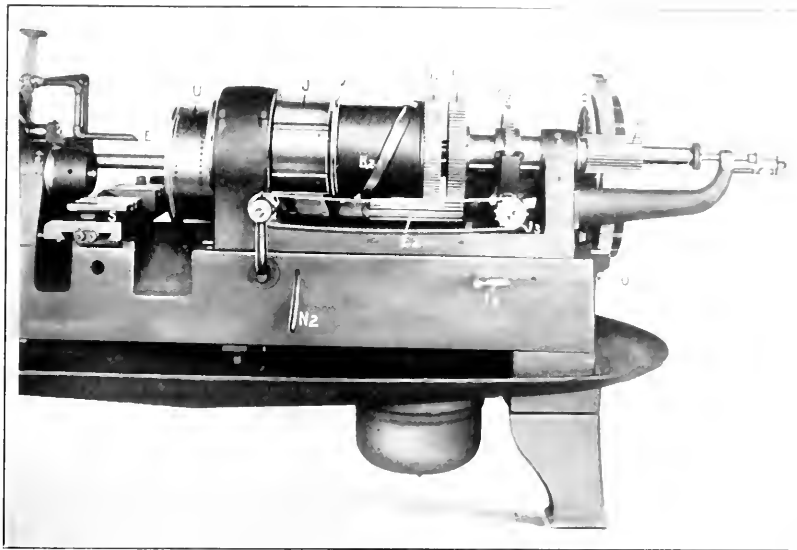

Fig. 11. Turret End of 3¼-inch Cleveland Automatic Screw Machine

Turret and Turret Slide

The turret J, as shown in Figs. 11, 13 and 14, is of the drum type and is carried on a shaft A_2, parallel with the axis of the work-spindle. The turret on the 3¼-inch machine accommodates six tools, which are held by two clamping bolts each, in the holes in the front end of the turret, and are located concentrically with the axis of the work-spindle. The turret J is driven forward and backward by a cam drum K which is free to rotate on shaft A_2 and carries segment cams B_2 fastened to its periphery. These cams work against the roll C_2 which is held on a stud driven into a hole in the base of the machine, and owing to its positive relation to the axis of the tools in the turret gives a very rigid drive; that is, the angle made by the position of the roll in relation to the axis of the tools is very slight, obviating any cramping of the turret and giving almost a straight-line drive to the turret tools. Cast integral with a drum K is a spur gear D_2 which rotates it. Gear D_2 receives power from the pinion E_2 beneath it that acts as a "continuous" key. Pinion E_2, in turn, is rotated by gear F_2 keyed to the same sleeve as that on which the worm-wheel G_2 is held. The method of driving the worm-wheel at different speeds—for the cutting and idle movements of the machine—will be described later.

* Associate Editor of MACHINERY.

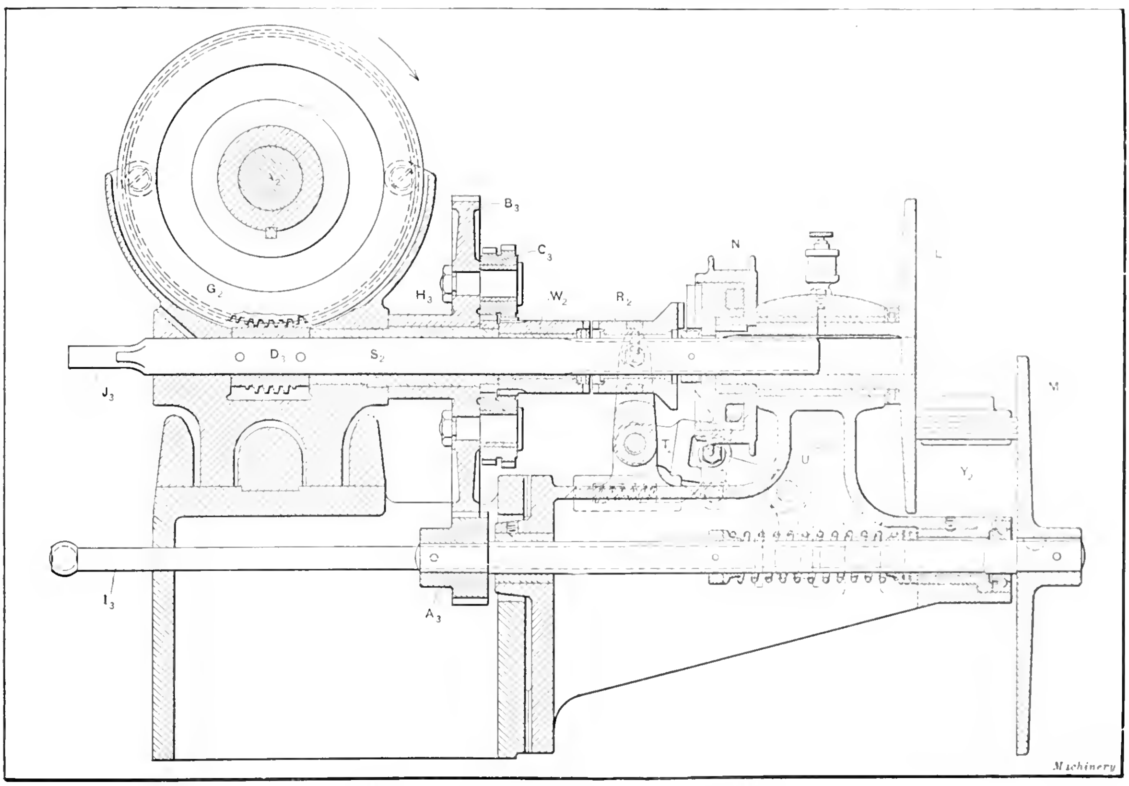

Fig. 12. Sectional View showing Feed driving Mechanism

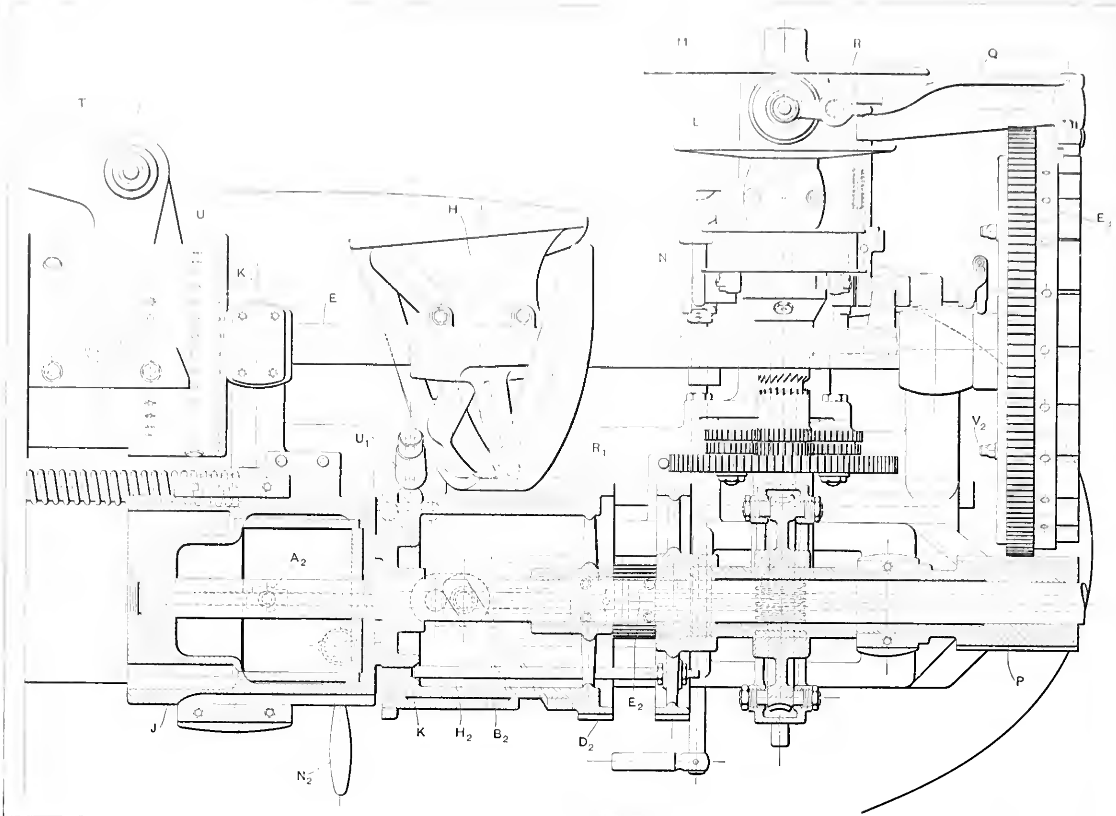

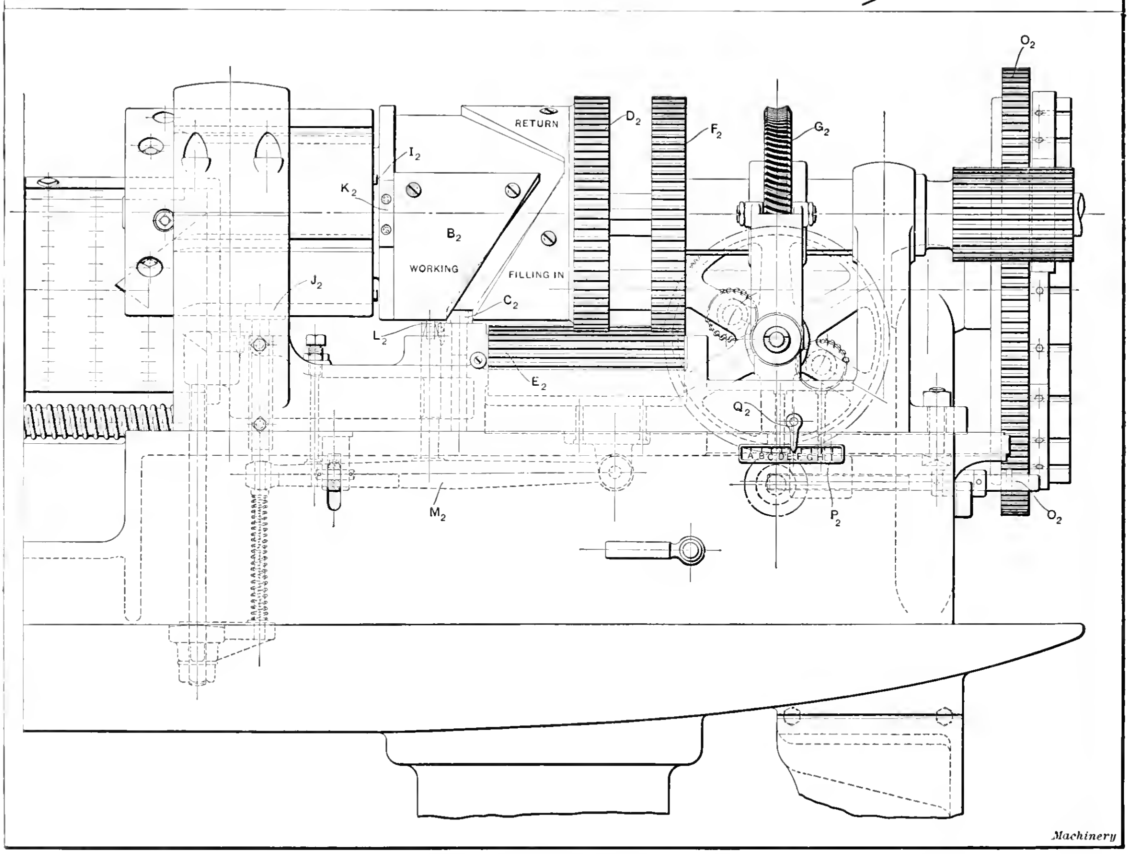

Fig. 13. Sectional Plan View of Turret End of Cleveland Automatic, showing Construction of Turret, Regulating Drum and Auxiliary Mechanism. Fig. 14. Front Elevation of Turret End of Cleveland Automatic

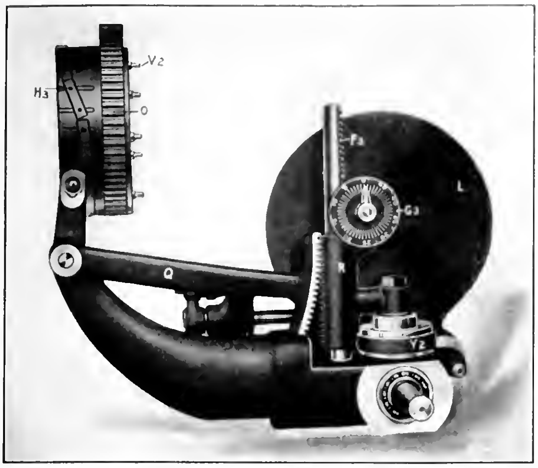

Fig. 15. Detailed View showing Feed Roll

The turret is indexed upon its back stroke by means of a rod H_2 held adjustably by locking nuts in the gear F_2, which comes in contact with hardened pins I_2 held in the rear face of the turret. Before the turret can be turned around, however, it is necessary to disengage the locking wedge J_2 from the slot in the circumference of the turret. This is accomplished by means of a cam block K_2 held on the flange of drum K which contacts with the pin L_2. This pin, in turn, is fastened to a lever M_2 located in the bed of the machine, which is spring-controlled and holds up the locking wedge J_2 in the manner illustrated in Fig. 14. As the turret retreats, cam K_2 comes into contact with plunger L_2, depressing lever M_2 and pulling down the locking wedge J_2, thus disengaging it from the slot in the turret circumference. Then the turret is indexed by the rod H_2 as previously described. The indexing can be also effected by hand by simply depressing the handle N_2 which has the same action on the locking wedge as the cam block held upon the drum K. The turret can be rotated by hand by means of a handle which fits on shaft J_3.

The turret head, which has two bearings as illustrated, one of which supports the central shaft A_3 and the other the turret J, is mounted on the bed of the machine and can be adjusted to suit various lengths of work and tools held in the turret. This adjustment is effected by means of the screw O_2 which works in a threaded projecting lug cast integral with the base of the turret head casting. The turret is held to the base of the machine by means of bolts as illustrated. A scale P_2, fastened to the base of the machine, and a pointer Q_2, held on the turret-slide, enable the operator to obtain the same setting of the turret head when setting up a job for the second time.

The method of driving and rotating the turret is clearly illustrated in Fig. 12 which shows a section of the driving mechanism located at right angles to the axis of the turret shaft. Power is conveyed to this mechanism from the overhead countershaft through the medium of the pulley N, keyed to the shank of the friction disk L. The method of driving the turret direct or at its fast speed for accomplishing the idle movements of the machine is as follows: The sliding clutch R_2, shown in its neutral position in the illustration, is thrown to the right and contacts with the pulley N. The power is then direct through the sliding clutch to the worm-shaft S_2 and then to the worm-wheel G_2, turret, etc. The sliding clutch is keyed to the worm-shaft and is operated

Machinery

* For work which does not require heavy cuts these sizes of machines can be obtained in the following increased sizes: 3/8–1/2; 3/8–5/8; 5/8–3/4; 5/8–7/8; 5/8–1 1/16; 7/8–1 1/16; 7/8–1 1/4; 7/8–1 3/8; 1 1/4–1 3/8; 1 1/4–1 1/2; 2–2 1/2; 2–2 3/4; 2 1/4–2 3/4; 2 1/4–3 1/4; 2 3/4–3 1/4; 2 3/4–3 3/4; 6 1/4–6 3/4; 7 1/4–7 3/4.

through the bellcrank levers T_2 and U_2, which are actuated by dogs V_2 (see Fig. 15) adjustably mounted on the rear face of the regulating drum.

The method of driving the turret at its slow or cutting speed is as follows: The sliding clutch R_2 is thrown to the left by means of the dogs held on the regulating drum, and contacts with the pinion W_2 which has clutch teeth cut in it similar to those on the sliding clutch. The drive is then through pulley N, friction disk L, roller Y_2, disk M, pinion and gear A_3 and B_3 to the epicyclic train of gears C_3 down to the pinion sleeve W_2 and through the sliding clutch R_2 to the worm D_3. The changing from slow to fast speed can also be effected by pushing in or pulling out handle I_3. This reduction in speed with roll Y_2 in the position shown in Fig. 12 is in a ratio of about 25 to 1.

In order to make clear the manner in which this great reduction in speed is accomplished, it might be well to deal briefly with the train of epicyclic gears, giving especially the data relating to the computations involved. Referring

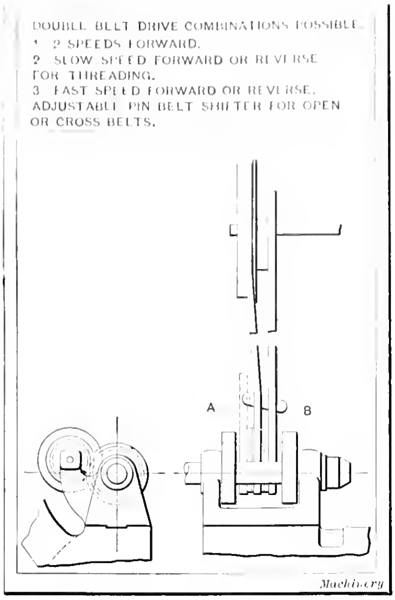

Fig. 16. Standard Double Belt Type of Spindle Drive

This is the speed at which the idle movements of the machine are accomplished.

Now a great variation of speed is obtainable for driving the turret at its cutting speed by the use of the friction disks. The position of the roll between these disks, as was previously explained, is controlled by a regulating drum. In order to make this description clear, it will not be necessary to give any more than three variations of speed, that is when the roll is in the central or neutral position B giving a ratio of 1 to 1, when it is at the extreme outside of the driven disk in position A, and when it is at the outside circumference of the driving disk in position C. As stated, to drive the turret drum at the cutting speed, the clutch R_2 is shifted to the left, engaging with pinion W_2. The drive is then as follows: As pulley N is keyed to the shank of friction disk L, the drive is from pulley N to friction disk L, roller Y_2, disk M, then to pinion A_3, gear B_3, and through the epicyclic gears C_3 and E_3 back to gear W_2 and from there to clutch R_2, shaft S_2 and worm D_3 to worm-wheel G_2.

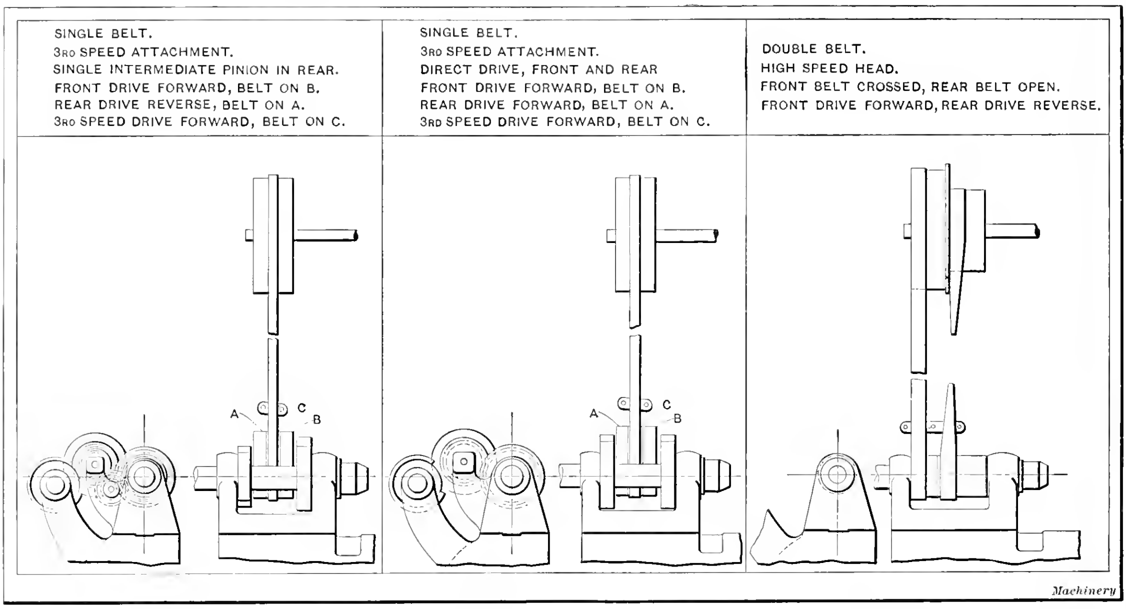

Fig. 17. Third-speed Type of Spindle Drive for Heavy cutting, and High-speed Spindle Drive particularly adapted for Brass Work

to Fig. 18, it will be seen that pulley N, on the 3¼-inch machine, rotates at a constant speed of 630 R. P. M. Then to drive the turret direct, that is at its highest rate of speed, clutch R_2 is thrown to the right and engages with this pulley. The drive is then direct through the clutch to shaft S_2 and from there to the worm D_3 and worm-wheel G_2. Now as pulley N rotates at 630 R. P. M., the shaft S_2 and worm will rotate at the same speed, so that the worm-wheel and the turret drum will be driven at a speed of $630 \div 76$ or about 8.3 R. P. M.

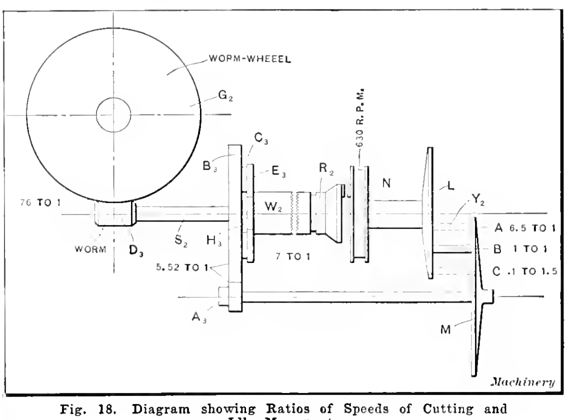

Fig. 18. Diagram showing Ratios of Speeds of Cutting and Idle Movements

Making our calculations with the roll Y_2 in the intermediate position B, giving a speed ratio between the two disks of 1 to 1, we can find the speed of the turret drum in revolutions per minute as follows: With roll Y_2 in the intermediate position, the pinion A_3 will rotate at 630 R. P. M., and the large gear B_3 will rotate at $\frac{630}{5.52}$ or 114 R. P. M., approximately. The next calculation is for the epicyclic train. This can be obtained by using the formula on page 702 of MACHINERY'S

Handbook. Worked out to suit this case it is as follows:

Let S = speed of worm-shaft S_2; then:

$$S = \frac{C_3 \times W_2 - E_3 \times H_3}{C_3 \times W_3}.$$

Assuming the following numbers of teeth in the gears in the epicyclic train to be C_3, 14; E_3, 15; H_3, 16; W_2, 15; we find that the ratio between the speed of gear B_3 and shaft S_2 is

$$\frac{14 \times 15 - 15 \times 16}{14 \times 15} = \frac{30}{210} = \frac{1}{7}.$$

Then as gear B_3 rotates at 114 R. P. M., shaft S_2 will rotate at $\frac{114}{7} = 16.3$ R. P. M., approximately. Then the revolutions of the turret drum with roll Y_2 in position $B = \frac{16.3}{76} = 0.2$ R. P. M., approximately.

With roll Y_2 in position C, the speed of rotation of the turret drum will be $0.2 \times 1.5 = 0.3$ R. P. M., approximately. This is the fastest speed of rotation of the turret drum when driving at the cutting speed. The slowest speed of the turret drum when driving at the cutting speed is when the roll is in position A. Here the speed of the turret will be $\frac{0.2}{6.5} = 0.0308$ R. P. M., approximately.

As previously described, the variation in feed given to the turret and cross-slide tools is accomplished by means of a regulating drum O on which strip cams are held. Fig. 15 shows the action that takes place by shifting one of these cam strips H_3 on the regulating drum. As the cam is shifted, a movement is transmitted to the bellcrank lever Q which has rack teeth cut in its outer end, meshing with teeth in the sliding sleeve R on the rod F_3. This rod is held in a bracket attached to the machine.

Now as a movement is transmitted to the bellcrank lever Q, the sleeve R is moved up and down on the rod, and consequently the position of the roll Y_2 is changed between the two friction disks, thus varying the speed at which the disk M, Fig. 12, is rotated. In order to facilitate set-

ting up the machine on the same job one or more times, a small attachment G_3, as shown in the illustration, has been provided which consists of a pinion running in the rack teeth in the rod F_3. This conveys a movement to the indicator pointer so that the strip cams on the regulating drum can be set in the proper position if the job has been taken down and is to be set up again. This data, of course, is put on the operation card that goes with the job.

The position of roll Y_2 between the two disks is controlled, as previously explained, by means of the fulcrum lever that receives its movement from the strip cam on the regulating drum. It is therefore evident that a wide range of feed for the turret and cross-slide tools is easily secured, and the

change in the feed of the tools can be accomplished while the machine is in operation. This is a good feature, especially when setting up a job for the first time. After a job has once been set up, the position of the pointer, as shown in Fig. 15, is indicated on a card and the operator in setting this job up again simply shifts the cams until the pointer comes to the required point on the indicating dial. The regulating drum is driven from the turret shaft by the pinion P, Fig. 13, meshing with teeth cut in the rim of the drum.

Construction and Operation of the Cross-slide

On the Cleveland automatic screw machine, as regularly equipped, the cross-slide for holding both the rear and front cutting tools consists of one casting, but a double cross-slide can be supplied when desired. The cross-slide is actuated by means of a fulcrum lever T (Fig. 13), which derives motion from cams K_3 on the drum U carried on the rear shaft E. The flange of this drum is numbered so that the position of the various cams can be recorded on a lay-out card to facilitate resetting the work. As shown in Fig. 11, the cross-slide is provided with an adjustable stop-screw so that accurately formed work can be obtained. It is also provided with adjustable gibs to compensate for wear. The position of the cross-slide relative to the axis of the spindle is controlled by regulating nuts on the connecting-rod fastened to the rear of the slide.

Spindle Capacities and Spindle Drives

Table I gives a list of spindle capacities of the various sizes of Cleveland automatics, for handling round, hexagon and square stock. In this table the sizes for hexagon and square stock are only given to the nearest 1/32 inch corresponding to the diameters of the round bar stock. This, of course, is close enough for all practical purposes. It will be noticed under the column "size of machine in inches" that there are a number of machines having two different spindle capacities. The meaning of this is (referring now to the 5/8—3/4 size) that the machine is the same in both, except for the spindle, which is bored on the enlarged size to take 3/4-inch instead of 5/8-inch bars. This enables work on which there is no extremely heavy cutting to be accomplished to be turned out much more rapidly than it could be on a larger sized machine, because the idle movements take less time.

In order to make the Cleveland automatic adaptable for brass, iron and steel work, it is necessary to provide a variety of spindle drives. Figs. 16, 17 and 19 show the different types of spindle drives that have been devised for handling a large variety of work. Fig. 16 shows the standard drive. Fig. 17 shows what is known as the third-speed attachment; two combinations of this attachment are illustrated, while the last view shows the type of drive particularly adapted to brass work and similar materials.

A detail and sectional view of this third-speed drive is shown in Fig. 19, where its construction can be clearly seen. This attachment is contained within the spindle driving pulleys on the back-shaft of the spindle head. Its purpose is to provide a slow and very powerful speed to the spindle for heavy thread cutting or work of a similar nature, requiring great power in the spindle. The result is obtained by shifting the belt to the center pulley A which brings into play the set of hardened steel epicyclic gears B. To accomplish this, the sliding clutch C is engaged with the gear D, and as the clutch slides upon a square shaft and cannot revolve it causes the gears B to rotate around the fixed gear D, thus driving gear E at a very powerful speed. Gear E is securely keyed to the sleeve pinion F which meshes directly into the front spindle gear of the machine.

When the third-speed drive is not in use, the clutch C is moved out of engagement, allowing the entire train of epicyclic gears to be free upon the loose center pulley A. The clutch C is moved along the shaft G by means of the rod H controlled by a cam I, shown in the end view. This cam moves the rod to the left for disengaging the clutch and the spring J moves the clutch to the right for engaging it, when the roll K drops off the end of the cam. There are two frictions M which serve to keep the center loose pulley A driving at the same speed as the pulley N, when the third speed is not engaged, so that the planetary pinions will not rotate on the stud at this time. The cam I is adjustable around the cam-shaft and is clamped into any desired position by the screw O and stud. The lubrication of the entire third-speed attachment with the exception of the planetary pinions is secured by means of a sight-feed oil-cup, while the planetary pinions are lubricated through the oil-hole extending to the rim of the center pulley A. The connection between the rod H and the cam I is link L which carries the cam-stud and roll K.

Principal Dimensions of Turret, Cross-slides and Miscellaneous Data

Tables II and III and the illustrations accompanying them give all the data pertaining to the turret and cross-slides on the various sizes of Cleveland automatics. By referring to the illustrations, it will be seen that the cross-slide on the various sizes of machines is provided with from one to three slots for holding cross-slide working tools. These are furnished in order to enable the tools to be held in the most convenient position in relation to the work. It is obvious, of course, that on the larger sizes of machines a greater range of positions is necessary than on the smaller sizes. This data will not only be of value to the operator when setting up the machine but will also be of use to designers when devising special tools or the attachments for use on this type of machine.

Principal Dimensions and Set-up Plan

The principal dimensions, capacities, etc., of the various sizes of Cleveland automatic screw machines are given in Table IV. The diagram accompanying this table shows how the Cleveland should be set up to economize on floor space, and in the lower part of this table are given the revolutions of the countershaft when driven from the main lineshaft at the speed recommended.

* * *

METHODS OF STANDARDIZATION BY ENGINEERING SOCIETIES

The ground covered by many societies in standardizing engineering details overlaps in many cases, and it has often occurred that different societies have adopted conflicting standards. It would, therefore, be desirable if some understanding could be arrived at between the societies in order to prevent duplication of work. Prof. F. B. Crocker, of the Crocker-Wheeler Co., Ampere, N. J., has prepared a statement on this subject, from which the following paragraphs are abstracted. Professor Crocker is president of the Electric Power Club and has also been a member of the standardization committee of the American Institute of Electrical Engineers; he is, therefore, in a position to write authoritatively on this subject. Owing to the fact that he is especially interested in electrical work, reference is made particularly to standards in the electrical engineering field, but of course the rules and methods laid down are equally applicable to the standardization work done by any engineering body or society.

Fundamentally there are three broad divisions of standardization—scientific, technical and industrial. As true examples of scientific standards, we have the resistivity and temperature coefficient of copper. A proper matter for technical standardizing is the safe temperature limits of the various kinds of insulating material. As clear cases of industrial standardization may be cited the shaft diameters and speeds of different types and sizes of electric motors. A scientific problem should be handled by the U. S. Bureau of Standards or the American Physical Society. A technical electrical matter should be decided by the American Institute of Electrical Engineers, and an industrial electrical question properly belongs to the National Electric Light Association or the Electric Power Club.

The best way to solve the problems of standardization is not by conferences between a number of bodies acting jointly on the various subjects. Of course cooperation is very desirable in some cases, but in dealing with many matters it is unnecessary. Standardization should be carried on in accordance with the following general scheme: First, each organization should have definite jurisdiction, within which it has full authority; second, each organization should confine its action as far as possible within its own jurisdiction; third, when questions arise that are on the border, or when the authority and interest of two or more organizations overlap, then a conference between the interested parties should be held.

In order to determine jurisdiction, the following plan of procedure may be adopted: When any organization considers it desirable that something should be standardized, its secretary communicates that fact to the secretaries of the other bodies likely to be interested in the same subject. Communication between the standards committees is not sufficient, because there may be several in one society and they may change from year to year. In most cases, from the nature of the particular matter involved, it is clear that it properly belongs to a certain organization, and the others will accordingly acquiesce. In other instances, it is evident that a question is on the boundary between two bodies and they will therefore agree to cooperate in acting upon it. When there is doubt or difference of opinion as to jurisdiction that cannot be settled by correspondence between the parties interested, then the case may be referred to an arbitrator, for example, the director of the U. S. Bureau of Standards, or the president of one of the national engineering societies not interested. The arbitrator merely decides which body or bodies shall have jurisdiction over that subject. The actual standards are determined by this body or bodies.

On account of the very rapid differentiating and specializing in electrical science, technology and industry it would seem that some general plan is needed for present and future standardization. In some cases it is quite evident that a certain body should have sole authority over a certain subject. For example, an organization of men who devote themselves to a particular subject should be able to determine standards for it most correctly and most quickly. Special subjects should be dealt with by those who live with them, so to speak, and devote their thoughts and efforts to them.

In all matters affecting standards it is of the utmost importance to give them very careful consideration. It is much better to have no standard than to have an ill-advised one or to have different standards for the same thing. It is difficult to rectify mistakes of this kind. In looking back over the history of electrical standardization, we see that the tendency has been to standardize too quickly, too often and too much. There have been dozens of wire gages, for example, and electrical books in the English language may use the American, Birmingham or the Standard British gages, each materially different from the other two. Many technical terms have also been introduced that were absolutely unnecessary. Experience, therefore, indicates that we should be conservative in establishing standards. This is another reason why each organization should limit its action to those matters which it best understands; thus fewer mistakes are likely to be made. All standardization committees should be careful not to rush in where angels fear to tread. It is surely a mistake for any organization to reach out and attempt to standardize in any field that does not clearly belong to it. Each organization already has far more that is unquestionably within its province than it can possibly cover, and new ground is being rapidly opened up.

A great deal of trouble is caused to manufacturers and users of machine tools by the varying types, sizes and speeds of electric motors employed to drive them. Hence, the standardizing of motor dimensions for machine tool drive is very desirable. It is solely an industrial matter that should be dealt with by the Electric Power Club and the National Machine Tool Builders' Association acting jointly. Neither the American Institute of Electrical Engineers nor the American Society of Mechanical Engineers should have anything to do with it, because it is clearly outside of their jurisdiction. As a matter of fact, it has been considered by committees of both these bodies. Little has been accomplished, however, because it was thought necessary to consult all four organizations, and everybody's business is nobody's business.

* * *

A German contemporary states that a method has been invented by means of which aluminum may be dissolved so that it may be spread cold over any dry surface and applied like paint with a brush. The appearance of aluminum so deposited is like that of a dull silver coating. It is claimed that this coating is an excellent preventative for rust, that it is durable and resists heat well, and that it can be used as a good substitute for tin-plating.

SPECIAL HOB-TOOTH SHAPES*

METHODS OF DESIGNING AND MAKING SPECIAL HOBS FOR GEARS, RATCHET WHEELS, SPLINED SHAFTS, ETC.

BY JOHN EDGAR†

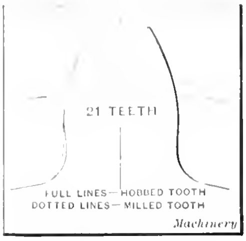

Fig. 1. Comparison between Hobbed and Milled Gear Teeth

There is always an objection to changing existing methods in shop practice when the change necessitates discarding established standards and valuable tools and fixtures. Whether such a change will be profitable or not is a question that requires a close study of the conditions in each case. When the change means an improvement in the quality of the product, the cost of the tools and fixtures should, of course, be a secondary consideration. When the question is mainly one of quantity, the problem must be solved on a cost basis only.

Another factor to be considered, however, is that of interchangeability. This is a most important item in the case of a product in connection with which renewals are constantly being made. Many improvements in design and in methods of manufacture are sacrificed in deference to the demands for interchangeability. In the case of gears, interchangeability is supposed to be rigidly adhered to, but while we have a standard which is supposed to produce interchangeable gears, we have so many variations of the standard, due to the secret forms established by different manufacturers of cutters, that it is necessary in many cases to adhere to one make of tools if interchangeability is to be maintained in any degree. Many manufacturers have installed the hobbing machine in the desire to reduce the cost of gearing, only to encounter the non-interchangeability of the product of the hobbing machine with the milled tooth gear; this has been the cause of turning many against the hobbing machine, through no fault of the process itself.

Variations from the True Involute Tooth Shape

The form of the standard tooth, as adopted by the cutter manufacturers, is not the true involute, but an improvised form built around the involute as a basis. The deviation from the involute is necessary for several reasons: 1. The inability of the formed milling cutter to mill an undercut tooth. 2. The necessary alteration in the form of the point of the mating tooth caused by the fullness of the milled tooth below the pitch line. 3. The desire to make the contact

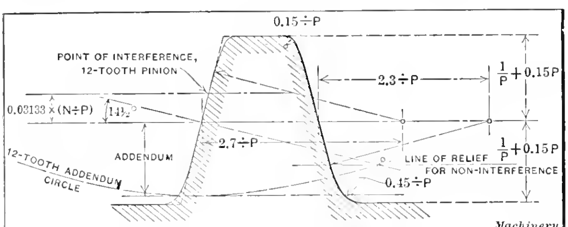

Fig. 2. Hob Tooth designed to generate the Approximate Shape of a 14½-degree Involute Milled Tooth

of the approach as gradual as possible by a slight easing off of the form at the point of the tooth; this provides against the slight variation in the form of the tooth due to irregularities in the division of the space and to the elasticity of the material. 4. The interference in gears with thirty-two teeth or less when in mesh with those of a greater number of teeth. As the 14½ degree formed gear-cutters are based on the twelve-tooth pinion with radial flanks, a rack tooth to mesh with this radial flank tooth can be made with the straight sides extending only to a point 0.376 inch outward from the pitch line in a rack of one diametral pitch. The remainder of the tooth must be eased off from this point outward, sufficiently to clear the radial flank of the pinion tooth. This rounding off of the rack tooth may be made by using the cycloidal curve from the interference point, with a rolling circle of a diameter equal to that of the twelve-tooth pinion. A circular arc tangent to the tooth side, drawn from a center on the pitch line at the point of intersection of the normal to the tooth side at the point of interference, will be a near approximation to the cycloidal curve.

The hobs used extensively today are not made to produce teeth in any near approximation to the shape produced by the milling cutter. The only correction that is made, in many cases, is to make the teeth of the hob a trifle fuller at the base or root to ease the approach; even this is done only in a few instances. The difference between the hobbed tooth and that produced by milling is seen in Fig. 1. The hobbed tooth is shown in full; this shape was traced from an actual hobbed tooth, photographed and enlarged. The gear had twenty-one teeth. The hob used was corrected for the "thinning" of the tooth at the point, but in a gear of this diameter the effect would not show to any great extent. The dotted lines are drawn from actual milled tooth curves and show the difference between the two forms of teeth. Attention is called to the fullness of the milled tooth at the root, and the thinning of the tooth at the point. The difference would be greater in the case of a twelve-tooth pinion.

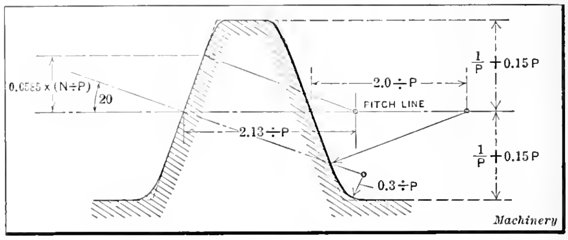

Fig. 3. Hob Tooth for generating a 20-degree Involute Milled Tooth

The filling-in of the flank of the tooth is not done to any rule based on a proportion to the number of teeth in the gear. The curve selected is made to fill in the space at the root to just clear the corrected rack tooth. Neither is the thinning of the tooth at the point proportional to the diameter in the sense that the curve of the hobbed tooth is. Each form of the cutter system is made and varied to the extent necessary for smooth action, and the curves of the entire system cannot be produced by the hobbing process with a single hob. To accurately reproduce the form of the milled tooth, a special hob would be necessary for each number of teeth. However, a close approximation may be obtained, within a narrow range of teeth, with a hob generated from a milled tooth. This is being done in the automobile industry with good results. The necessity for interchangeability makes the duplication of the milled tooth imperative when the originals were made with the formed cutter, and the introduction of the hobbing machine, in such cases, depends on the successful duplication of these forms. It is no exceptional thing to see the hobbing process used in conjunction with the automatic gear-cutter in the production of interchangeable transmission and timing gears. The shapes produced by the standard sets of cutters, from a rack to a twelve-tooth pinion, cannot, however, be generated by a single hob, because the shapes are only an approximation of the correct curve. The gears mentioned above as being successfully hobbed are, therefore, when milled, cut with special cutters for each number of teeth, as in this way only can a curve of correct shape be obtained.

As stated above, most hobs are of the straight-sided shape, and the tooth hobbed is of pure involute form. In gears

* For previous articles on this and kindred subjects see MACHINERY, March, 1914, "Hobbing vs. Milling of Gears"; July, 1912, "Hobs for Spur and Spiral Gears," and also articles there referred to.

† Address: 61 Bruce Ave., Windsor, Ont., Canada.

of less than thirty-two teeth, the flank is undercut to a considerable extent. This undercutting does not involve any incorrect action in the rolling of the gears, but in the case of the twelve-tooth gear, for example, the involute is cut away at the base line close to the pitch line, giving but a line contact at a point which is subjected to heavy wear. This eventually develops backlash. The teeth of the gears also come into action with a degree of pressure that is continuous throughout the time of contact; this results in a hammering which in time develops into a humming noise.

Special Hobs for Gear Teeth

To overcome these objections a hob tooth may be developed to generate a curve which will closely resemble that of the formed tooth. Such a hob tooth is shown in Fig. 2. Theoretically, the correction for interference or undercutting should begin at a point located above the pitch line a distance as determined for a twelve-tooth pinion by the expression:

$$0.03133 \times \frac{N}{P}$$

in which N = number of teeth in the smallest gear to be hobbed;

P = diametral pitch of gear.

However, to begin the correction for interference at this point would reduce the length of the true involute and result in too full a tooth, causing noisy gears. Therefore, a compromise is made and the correction is obtained for a minimum of twenty-one teeth. To compensate for the extra fullness of the tooth at the root, the point of the tooth is thinned down in proportion, and this is done by leaving the tooth of the hob full below the pitch line by striking an arc from a center on the pitch line, and also employing a large fillet having a radius equal to $0.45 \div P$ (see Fig. 2). It will be noticed that the radius of the arc at the top of the hob tooth is smaller than the radius at the bottom of the hob tooth. This will thin the tooth of the gear in excess of the amount necessary to clear the flank, easing the action and eliminating the hammering effect due to the theoretical contact. It will be seen from the illustration that the thinning of the teeth does not affect the twelve-tooth gear to any appreciable extent, but is gradually increased with the number of teeth. The fact that a twelve-tooth gear will mesh without interference at the point of the teeth makes the thinning unnecessary; besides, the small pinions are usually the drivers.

Fig. 3 shows a twenty-degree hob tooth with standard addendum and corrections for non-interference. The curve

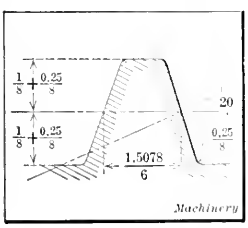

Fig 4. Hob Tooth for a 6/8 Pitch Fellows System Stub Gear Tooth

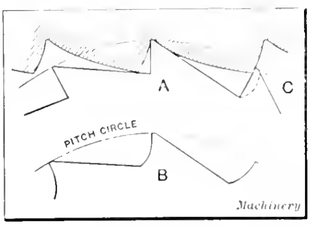

Fig. 5. Diagram showing how Hob may be used for generating Ordinary Ratchet Teeth

of the tooth begins at a point 0.702 inch from the pitch line, in the case of a one diametral pitch tooth, and is based on non-interference with all teeth from twelve teeth up.

Fig. 4 shows the shape of the hob tooth to reproduce the stub teeth of the gears generated on the Fellows gear shaper. The particular tooth in the figure is a 6/8 pitch tooth, and the proportions are given in terms of the pitch numbers so as to be easily applied to the other pitches; thus the height of the tooth above the pitch line is stated as: $1/6 + \frac{0.25}{8}$ where 8 is the addendum number of the pitch designation.

The shape of the rack or hob tooth to roll with the gears produced by the gear shaper should be generated from the cutter used. The Fellows cutters have perfect involutes above the base line, with radial flanks, so that the hob tooth would be straight only a distance from the pitch line equal to $0.0585 \times N \div P$, where N is the number of teeth in the cutter; in most cases the cutter would have more than seventeen teeth and the hob tooth would be straight-sided to the point. In this system the radial flank of cutters with more than seventeen teeth does not affect the shape of the face of the tooth, as the involute portion of the cutter tooth generates a pure involute. The straight side of the hob tooth should extend to the root in such cases.

To reproduce gears of some standard the exact shape of which is not known, the hob-tooth shape can be easily generated from the gear tooth on the milling machine, as will be explained in a subsequent part of this article.

Applications of the Hobbing Process

The hobbing process is not limited to the production of gears, but can be used to generate teeth of almost any shape, such as the teeth of ratchets, milling cutters, reamers with equally spaced teeth, chucking drills, multiple splined shafts

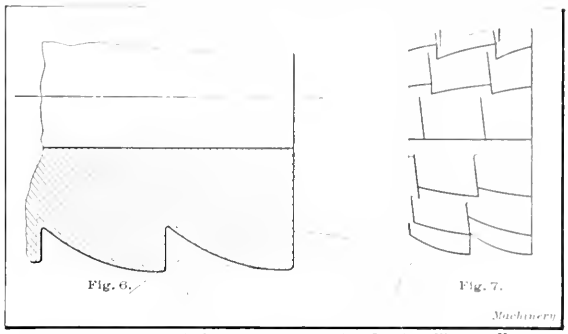

Fig. 6. Type of Hob for generating Ratchet Teeth. Fig. 7. View showing the Relief in the Hob for generating Ratchet Teeth

for automobile transmissions, cams, sprockets, etc. Fig. 5 shows the shape of hob tooth to generate the teeth of ratchets. There is no shape of tooth that will generate the radial teeth of ratchets of the type shown at A; the nearest that can be obtained is the modified shape at B with the filleted root. Should the tooth of the hob be made straight and normal to the axis of the hob, the tooth produced would be undercut as shown at C.

The shape shown is generated from a 12-tooth radial ratchet and would produce a nearer approach to the radial form in ratchets of a larger number of teeth. The back of the teeth would be concave instead of straight in the case of larger numbers of teeth. A good compromise would be to make the back of the hob tooth straighter, the shape being obtained by generating from a ratchet of, say, forty-eight teeth. The back of the teeth of ratchets of a smaller number of teeth would then be convex in shape. Hobs of this kind have been used successfully in hobbing milling cutters, a single hob covering a limited range of sizes. The difficulty in having a hob cover a wide range of cutter sizes is the fact that the pitch of the teeth is not constant, as in the case of gearing. When making cutters in quantities, the cost of the hob is soon covered by the saving in the manufacture of the cutters over the cost of milling. In the case of spiral cutters, the angle can be altered to make it possible to make the hob cover a greater range of sizes. The hobbing process is especially adapted to the making of spiral milling cutters.

The form of hob shown in Fig. 6 is a cross between a hob and a formed milling cutter, and can be employed profitably in the milling of radial teeth by the hobbing process. The form is made with a normal face and is generated back as in the case just shown. The hob is set so as to be all on one side of the center of the blank being cut, as shown. The radial face of the tooth is formed with the face of the hob tooth acting as a fly-cutter, the form of the face being a reproduction of the face of the last hob tooth, which is set radial with the axis of the blank. The fronts of the hob teeth are relieved on the sides; this can be done by using the combined side and radial relief cams, or, if that combination is not available, the side relief can be given as a separate operation. The latter will cause a widening of the top of the tooth as the hob wears back in sharpening. Fig.

7 shows a view of the hob. The convex shape of the generated form of the hob tooth will have the same effect on the shape of the back of the tooth as stated above in the case of the generated hob. This portion of the tooth cannot be made to act as a fly-tool, as it cannot be set on the radial line and must generate the form by a regular generating action.

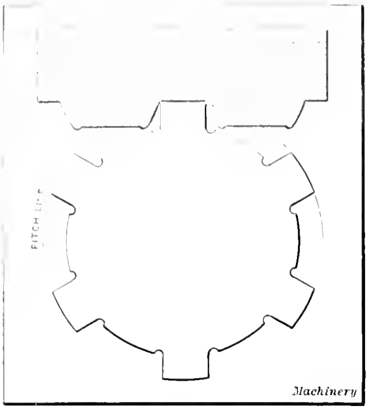

Fig. 8. Hob Tooth for generating a Six-spline Shaft

A form of hob that can be used to advantage in the automobile industry is that for forming the splines on the transmission shaft. This shaft commonly has six splines, as shown in Fig. 8. The face of the splines or teeth have a negative rake, being set ahead of the radial line, and for that reason can be formed with the hob if the depth and thickness are not too great in proportion to the diameter. In the illustration the proportion is six to one, and the hob form is such as to give a very close approximation to the desired form; however, if the shafts are to be used as left by the hob, that is, without grinding, it would be well to make the broach by the same process to insure a duplication of shape in the keyways in the gears. In all these special forms the pitch is taken from the outside of the blank; if taken inside of this point, the hob tooth, if radial, would have to be undercut, which is not practical.

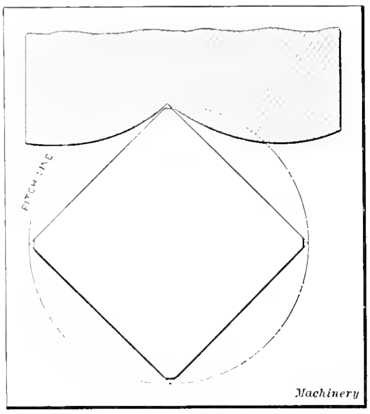

Fig. 9. Hob Tooth Shape for generating Squares

In Fig. 9 is shown another shape that could be used to advantage for hobbing squares. Hobs for this purpose could be used in squaring the ends of such shafts as, for instance, the ends of milling machine feed-screws, cross-screws, and the elevating shafts. If there is a job that is handled to disadvantage on the milling machine, it is the squaring of these shafts and screws. A similar hob could be developed for the hobbing of hexagons and other polygon shapes on the ends of shafts, or for the heads of bolts.

The great disadvantage of the hobbing of the shapes just mentioned is the low number of "teeth" or divisions, which necessitates a rapid travel of the index gear and high ratio gears to give the proper spacing, and also the long lead of the hobs. The latter is not so objectionable in the case of the small squares and hexagons generally used, as the lead in most cases can be lower than one inch.

The examples given do not exhaust the field for the hobbing process, but give an array of cases which are out of the ordinary and show the application of the process to other than the ordinary work of gear-cutting. The shapes have been laid out on the drawing-board in each instance, but a far more accurate way to obtain them is by generating them on the milling machine. This generating process is in reality a duplication of the hobbing process, but in generating the tooth shape for the hob the process is reversed, that is, the shape to be generated by the hob is used in generating the hob-tooth shape.

Generating Hob-tooth Shapes

In Fig. 10 is shown a milling machine set up for generating the hob-tooth templet. This is done on the universal milling machine, or on the plain milling machine if the screw can be connected up with the worm of the dividing head, as in milling spiral work. The spindle of the dividing head is set vertical, and the master gear or templet of the shape it is desired to produce by hobbing is mounted on an arbor in the spindle. In making the master templets, care should be taken to produce the correct shape and to be sure that the shape is true with the hole; if the templet is not true, the shape generated will not be accurate, of course.

[The gearing connecting the feed-screw and the dividing-head must be for a lead equal to the circumference of the pitch circle of the gear from which the hob templet is generated.—EDITOR.]

To provide a rest on which the tool templet to be laid out may be clamped, a parallel is bolted to the outer arbor support so as to be horizontal and parallel with the milling machine table and at right angles to the machine spindle. The rest may also be in the form of an angle plate clamped to the face of the column, but the former type is the most desirable, as it brings the work in a more accessible position.

The blank templet should be a piece of sheet steel about one-sixteenth inch thick, one edge of which should be straight and true and the surfaces smooth and bright. The surface to be laid out can be given a coat of copper solution, or, still better, varnished so that the lines may be etched deeper, as the handling in working out the shape tends to obliterate the shallow lines in the thin copper coat. This blank templet can then be clamped to the rest in a convenient position. There must be plenty of room for the travel of the gear, so as to obtain the proper amount of "roll" to generate the shape desired. The true edge of the plate should be parallel with the rest and the direction of the movement of the milling machine table. Adjust the knee vertically so that the plate will come up under the gear on the dividing head so as to just clear it; the saddle can then be adjusted across to bring the edge of the plate in line with the end of a tooth in the gear when the center line of the tooth is about at right angles to the axis of the feed-screw as shown in Fig. 11. In this way the templet is set to the proper position for depth. The backlash should be taken up by turning the screw in the direction in which it is to be used.

Now select a tooth space *A*, Fig. 11, as the one to be used in the scribing operation, and run the point of a slim, sharp scriber along the outline of the tooth space, scratching the line on the plate; then move the table about one-half turn of the lead-screw and scribe another line, and repeat the operation until the table has been moved through a length equal to three times the circular pitch. When this has been done the lines on the templet will resemble that in Fig. 12. The lines should now be etched in and the plate polished.

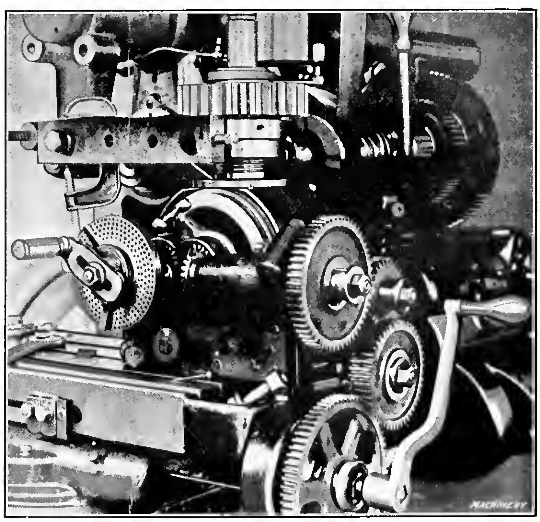

Fig. 10. Milling Machine set up for laying out the Shape of a Hob Tooth

The combined lines on the plate will be seen to describe the rack tooth shape of the hob teeth in a clear-cut manner, if the operation has been carefully carried out. If the gear tooth from which the lines were taken is theoretically correct, the sides of the outline on the plate will be straight a greater portion of the way from the point of the tooth to the edge of the plate; the lines diverge from the straight line at a point near the edge of the plate, as shown by the dotted lines in Fig. 12. This point will be found to be, in the case of the 14½-degree tooth, at a distance from the pitch line of $0.0313 \times N \div P$, where N is the number of teeth in the gear and P the diametral pitch. If the hob to

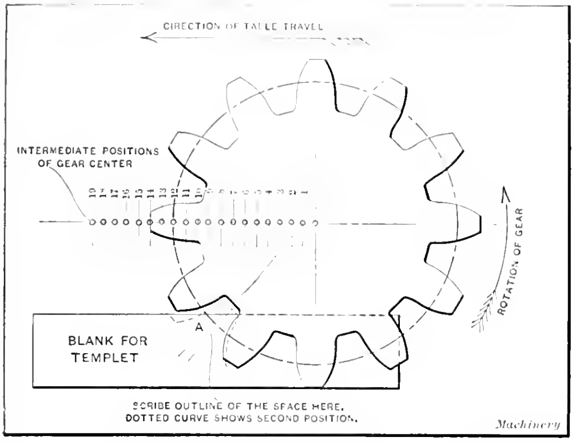

Fig. 11. View showing the Relative Position of Gear and Templet

be made from this form is to be used for N teeth or less, the shape of the templet will be correct, but if the hob is to cut gears of a larger number of teeth, the straight portion of the tooth must be carried down to the edge of the plate in order that the teeth of the larger gears will not be cut away too much at the points.

In making a templet in this way for any other shape than for gears, it should be cut to the lines on the plate, as no correction can be intelligently made in those cases. Some success has been made in the layout of templets for a hob tooth for gears of a limited range of teeth by using the space below the pitch line of the smallest gear in the set and the space above the pitch line of the largest gear in the set as the shape in generating the hob tooth templet. This is of value in generating a hob-tooth shape to reproduce a set of gears milled with formed cutters. However, the best and easiest method is to take the smallest gear in the set as the one from which to generate, and prolong the straight portion of the hob tooth to the edge of the plate, easing the side at A, to point the teeth slightly. The teeth of the hob are generally made with an extra clearance at the bottom as shown. This is a matter on which authorities differ, some preferring to have the hob cut the top of the teeth, to make the teeth of standard length if the blanks should be over size; however, the general practice is to make the tooth the same length both above and below the pitch line as in Figs. 2 and 3.

If the form is for a generated gear and results in the straight-sided tool in Fig. 12, all that is necessary is to measure the angle and make a thread tool that will cut a thread of this section. Should the shape turn out to be a compound of curves, as will be the case in reproducing the milled tooth, the templet should be filed out to the lines, making a female gage to which a planing tool is made, the planing tool being a duplicate of the hob-tooth shape. The threading tool is planed up with this tool. In making the thread tool, it is not usual to make it of female shape, that is, like the templet, but pointed as usual, planing the sides with the opposite sides of the planing tool. The proper corrections should be made in the thread tool to correspond to the angle of the thread, and the setting of the tool and the fluting of the hob, whether it is gashed parallel to the axis or normal to the thread helix.

A master planing tool can be made in the following manner, without the use of the scribed line templet. It is necessary to have a universal milling attachment for the milling machine. The spindle of the attachment is set in the horizontal position with the axis parallel with the direction of the table movement. A fly-tool holder is then placed in the spindle, in which the blank planing tool is to be held. This tool should be roughly formed to the shape to which it is to be finished. The top of the tool should be radial, that is, it should be in the plane of the center of the spindle. The gear or other master templet that it is desired to duplicate by hobbing must be hardened and ground to a cutting edge on one face, preferably the top face when mounted in the spindle of the dividing head, so that the pressure of the cut will be downward. The knee should be adjusted to bring the ground face of the gear to the level of the center of the spindle of the attachment. The dividing head and the table screw are connected in the same way as previously described, but in this case the power feed can be used and the saddle can be fed in to depth as needed, care being taken to use the power feed, in generating the tool, only in one direction, as the backlash in the gears and screw will throw the tool and dividing head out of relative position if used in the opposite direction. As many cuts can be taken as required to obtain a tool of the correct shape.

If the tool is to be used in making more than one threading tool, as might be the case in many instances, the planing tool can be made in the shape of a circular tool which can be ground indefinitely without losing the shape. In this case the fly-tool holder would give place to the standard milling machine arbor. This method is the most accurate way of making the master planing tool, and where the universal milling attachment is available, it should be used where accurate results are desired. It eliminates the human element and the amount of skill required in making the master templet. The inaccuracy of the machine is the only element that is likely to cause error.

One point that is likely to cause difficulty is the relation of the generated tool shape to the thread shape, as it appears in the normal section of the hob tooth. The simple fact is that the master tool shape, as generated by the direct method of making the master planing tool, or the shape as outlined on the hob tooth templet in the first method, is

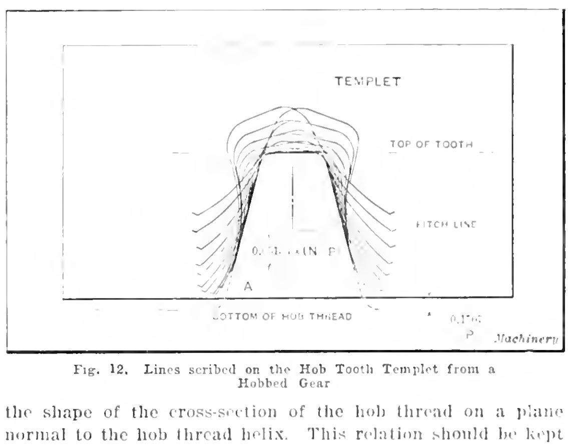

Fig. 12. Lines scribed on the Hob Tooth Templet from a Hobbed Gear

the shape of the cross-section of the hob thread on a plane normal to the hob thread helix. This relation should be kept in mind throughout the process of making the tools and hob. This statement also clears any haziness regarding the question of the lead, as in single-threaded hobs this must be such that the normal pitch of the thread is equal to the circular pitch of the teeth hobbed. In the case of hobs of small thread angles, the normal and axial leads are practically the same, and may be treated as such in cases where the angle is less than 2 degrees and the pitch less than ½ inch; an error of more than 0.00025 inch should not be exceeded in any case. The effect of the error is apparent in the case of a 6 diametral pitch hob 3 inches in diameter, when the axial lead is taken as the circular pitch of the teeth, as it results in an error of more than one-half degree in the pressure angle of the hobbed tooth. Only in extreme cases should the angle of the hob thread be more than ten degrees.

WHY A MAN IS PROMOTED

Anyone who has worked in a machine shop is familiar with expressions such as this: "They made him foreman of the tool-room and yet he is not much of a toolmaker. Why, he couldn't turn out the kind of work that Jim Higgins can do; he couldn't begin to touch it." Thus his fellow-workers judge the new foreman's ability as foreman only from the point of view of his manual skill, forgetting entirely that a good foreman must have other qualifications besides skill in his trade. To be a good toolmaker is very desirable for a tool-room foreman, but it by no means follows that every good toolmaker will make a good foreman. In fact, the most skillful toolmakers are likely to make the least successful foremen, for the reason that their development has been altogether along lines of skill in their trade, and other qualifications have remained dormant. A foreman should have executive ability, good judgment, a knowledge of men, and tact; and if he has a fair proportion of these qualifications, he can get along with a comparatively meager toolmaking ability. He is not supposed to *make* the tools; he is supposed to know *how* to make them, and it is a curious fact that people whose hands are not very skilled in doing certain work often possess the ability to tell others how to do it.

The same also holds true in regard to positions above that of foreman. The superintendent need not always be a man versed in all the details of the operations performed in the shop. The more he knows about the details the better, of course, but if his foremen are of the right type, they should be depended upon to look after details. His work should be of a general supervisory and advisory character. He should not be burdened with detail, but should be left free to get a good perspective view of the work in the whole factory; to see that all the departments work in cooperation; that harmonious relations exist; that the methods used are the most modern; that nothing is permitted to get into a rut; that causes for friction between employer and employe are adjusted; that the capacity of the plant is suited to the demands on it; that there is no waste of labor due to inefficient methods; and that systems are not being worked for system's sake. If he is able to look after all of these things efficiently, he will make a pretty good superintendent, even if he should happen to lack information on some of the details relating to the work in camming up an automatic screw machine.

STANDARDIZING ENGINEERING DATA

The confusion that exists in the engineering trades, due to the lack of a standard for straight pipe taps, has caused much trouble to firms making and using taps and dies for producing this class of threads. The various manufacturers of dies and taps each have tables by which these tools are made, and taps, dies and gages bought from different manufacturers differ slightly in their diametral dimensions. In one case a manufacturer threaded three thousand valve stems with dies obtained from one maker, and upon comparing them with a gage obtained from another, found considerable discrepancy in the dimensions.

The American Society of Mechanical Engineers is endeavoring to do some work toward establishing standards, but the methods of doing the work so far adopted are inadequate to produce the results which the engineering world has a right to expect from an association of its reputation. To accomplish the desired results the society should concentrate more on work looking toward standardization of engineering data; there is no field in which more useful work can be done. It is hardly possible, however, for a large engineering society to carry out work of this kind simply by forming committees of members who receive no compensation for their work and give only their spare time to it. Such work must be carried forward in a systematic manner by picked men who are paid for their time, and the society would be warranted in using a portion of its funds for this purpose.

We think the watchword of an engineering society should be "efficiency"; but the efficiency of a society is not apparent unless it can point to some constructive and useful work having been performed, not merely by individual members, but by the society as a body.

HOLDING FAST TO THE GOOD

During the past few years there has been much said in regard to the narrow guide on machine tools. The narrow guide is undoubtedly an advantageous feature of machine design, whether applied to machine tools or any other type of machinery requiring slides to move in a rectilinear path with a minimum of friction and wear. The binding action of comparatively short slides in wide guides is well illustrated in the drawers of wide furniture, and someone has referred to it as the "bureau drawer" effect—a very expressive term.

The revival of the narrow guide in American machine tool design—for a revival it is—is an illustration of how valuable ideas are sometimes employed and then discarded for no apparently good reason. They seem to fall out of sight. As an illustration, the Gleason gear planer of the former type was built in 1876 with a narrow guide for the housing, but in later designs this admirable feature was not used. The value of the feature was apparently lost sight of for a number of years, when it was revived in the designs now being built.

It is important to originate and progress, but it is equally important to hold onto that which has been proved good. The principle applies not only to machine building, but to every activity of life.

* * *

THE POLICY OF SECRECY

It is hardly conceivable that there are no standard dimensions for so simple a thing as a nut for a 3/16-inch bolt. Yet it appears that no dimensions for nut diameters smaller than ¼ inch have ever been standardized, and it is practically impossible to obtain from manufacturers of nuts any tables giving dimensions for these sizes. In an endeavor to amplify the data we have published relative to standard dimensions of bolts and nuts, we tried to obtain from a number of manufacturers the dimensions used in making this class of nuts; but in all instances the replies were evasive, and we were unable to obtain a list of dimensions for small nuts, although tens of thousands are manufactured annually, and the manufacturers must have some tables or data from which to work. Of course, there is no generally recognized standard for these small machine details, but if manufacturers were not so reluctant above giving out information when secrecy cannot be of the slightest advantage, it would be possible to establish a standard.

Our readers frequently write us asking why we have not published information on this or that subject. To most of these inquiries we must answer that the manufacturers, even of articles which can be bought in the open market and measured, on account of some narrow policy, refuse to give out information which will make it possible to place on record the required data.

SOME POSSIBILITIES OF MOVING PICTURES

The general possibilities of moving pictures in the industries have been discussed in MACHINERY from time to time, but being a fruitful field we shall undoubtedly have occasion to refer to them frequently in the future. Like many other inventions, the moving picture has been applied to uses not thought of by the originators. The spread of the moving picture theater has been astonishing, and nearly every small town has at least one in operation. The capital investment in these enterprises and in the manufacture of films and machines is enormous. The large profit in the business makes possible more rapid developments than in other lines.

One interesting development is showing the pictures of lost men and women on the screen of theaters all over the country. If these persons are alive the probability of identification is greatly multiplied as compared with the means commonly used. Another development is the dissemination of pictorial news which is shown to thousands, thus spreading knowledge of places, men, historical pageants and notable events more vividly than can be done by the newspapers.

The uses that will be made of moving pictures in the machinery industry have hardly been touched, although their application in marketing machinery is beginning to be appreciated by some manufacturers. That they will become a most important factor in marketing many products is evident to those who have studied the subject.

An aspect of the moving picture which has received little attention so far is the possibility of making drawings "alive." The drawing of a machine can be understood only by a mechanically trained mind, and to one who is not familiar with mechanical drawing an ordinary blueprint means little. Even the trained mechanic experiences some difficulty in imagining all the relations of the parts when in operation, especially if the movements are at all complicated.

The moving picture affords the means of building machinery in the drafting-room—machinery that will "run" and show the functions of the various parts. To secure such results means making many drawings, sufficient to illustrate a complete cycle as observed from any desired viewpoint. Moving pictures requiring several thousand drawings to illustrate the humorous conceptions of famous caricaturists have been successfully produced, the illusion being perfect.

The moving picture has been applied lately to the demonstration of automatic machinery before the patent courts. Few jurors are mechanical men, and it is difficult for them to grasp the principles of operation of automatic machinery, such as is used for making shoes, for example. Recently the moving picture of an automatic shoe machine in full operation was made use of to illustrate its action to a court with great success.

The value of moving pictures is limited as yet in teaching trades, and it is difficult to show clearly the operations of machines on account of intervening parts. In the latter case, the natural position of an operator at work, between his machine and the camera, also interferes with the photographer. In automatic machine work opaque objects may sometimes be replaced by glass parts through which the other parts can be photographed. The operation of pumps for students studying physics and some other operations have been shown in this way, and undoubtedly other developments will be worked out to facilitate the use of moving pictures for such purposes.

To the scientific manager, the possibility of doing experimental work on paper instead of using costly iron and steel will appeal strongly. It will be done cheaper, quicker and more quietly; and if successful, the films will be useful as a means of demonstrating the action to prospective buyers.

STEEL DRIVING BELTS

In a paper on steel-belt power transmission read before the Textile Institute of Manchester, England, February 24, the following information, not previously published, is contained.

A great many of the Lancashire textile mills that in the past have used rope drives are now equipped with steel driving belts. One of the most important advantages of the steel driving belt is the small percentage of loss of power in the power transmission. It has been thought, in general, that steel belts could be used only for comparatively light powers, but, at the present time, there are steel belt drives installed transmitting all the way from 10 to 3650 horsepower. The steel belts—manufactured by the Eloesser Kraftband Gesellschaft, Charlottenburg, Germany—are made from a charcoal steel hardened by a process which is kept secret by the manufacturers. The finished material has a tensile strength of 190,000 pounds per square inch. Owing to its great strength, the belt never need be stretched above its elastic limit, and, hence, the length of the belt is constant and no subsequent adjustment is required. The thickness of the belts varies, but never exceeds 0.040 inch. The widths used at present vary from 1½ to 8 inches, according to the working conditions and the maximum horsepower to be transmitted.

The ends of the belt are joined by a steel joint, so designed that it can be bent to the shape of the pulley when passing around it. The rims of the pulleys in present-day installations are covered with a layer of canvas to which is glued thin sheets of cork that are in contact with the steel belt.

During comparative tests carried out in Germany, and officially confirmed by the German government, it was found that a mill using five rope drives consumed 342 horsepower. When these drives were changed to steel belts the horsepower required was 318. In another case, where rope driving required 643 horsepower, steel belt drives, under similar conditions, consumed but 581 horsepower. At an English spinning mill the average power required with rope drives during a period of two weeks was 1020 horsepower, while with steel belts it was not more than 900 horsepower. Smaller installations have shown even a greater proportion of saving in the power losses.

The following details are given of the comparative cost of steel belting, leather belts and ropes, and also of the comparative size of steel belts required to replace cotton rope drives. In a case where 300 horsepower was transmitted at 250 revolutions per minute, the total cost of a rope drive installation was $1200. With leather belts the cost of installation would be practically the same, while with steel belts the total cost would not be more than $900. It is further stated that the power loss with rope drives would be 6 per cent; with leather belts, 4 per cent; and with steel belts, only ½ per cent. A steel belt 8 inches wide will take the place of eight cotton ropes 2 inches in diameter, or of a double leather belt 22 inches in width. In other instances, an 8-inch belt has been used to replace ten 2-inch ropes, and four 6-inch steel belts have been used to replace twenty-two 2-inch ropes, the horsepower required in the latter case being 900. Experiments made at the Charlottenburg Technical Institute, Germany, indicate that the coefficient of friction between the steel belts and the covered pulley is 0.27. A considerable number of rolling mills have adopted steel-belt drives in Germany.

While there is the advantage that the weight of steel belts is only about one-sixth of the weight of leather belts or ropes suitable for transmitting the same power, and while there seems to be no practical limit to the speed at which they can be run, there are also some disadvantages. So far, it has not been found feasible to use steel belts with fast and loose pulleys on account of the difficulty of shifting; neither are they adapted for cross belts where the distance between the centers of the pulleys is less than eighty times the width of the belt. They are not suitable to be run over very small pulleys on account of the severe bending stresses set up in the steel. In Great Britain this belt is handled by the Power Pulley Co., Ltd., Manchester. This concern claims excellent results from the installation in large cotton mills in the Manchester district.

BORING AND REAMING AUTOMOBILE ENGINE CYLINDERS

The method of machining automobile engine cylinders varies to a considerable extent throughout the automobile industry. In some plants they are rough-bored in a cylinder boring machine and finished by grinding. This is considered by many manufacturers to be the most practical method of finishing a cylinder that has a blind end. However, on engine cylinders of the T-head type where boring-bars having leaders can be used, the method of finishing the bore by boring and reaming is quite generally used. The Sterling Motor Co., Detroit, Mich., uses a Beaman & Smith cylinder boring machine, as illustrated in Fig. 1, and completes the cylinder bores in this machine by boring and reaming.

The bore is machined to the correct size in three cuts. A roughing cut, as shown in the set-up in Fig. 2, is first taken. Boring-bars having leaders that are guided by bushings in the lower part of the jig carry Kelly boring cutters, a better and closer view of which appears in Fig. 3. In the first cut, about 1/4 inch is removed from the diameter of the cylinder

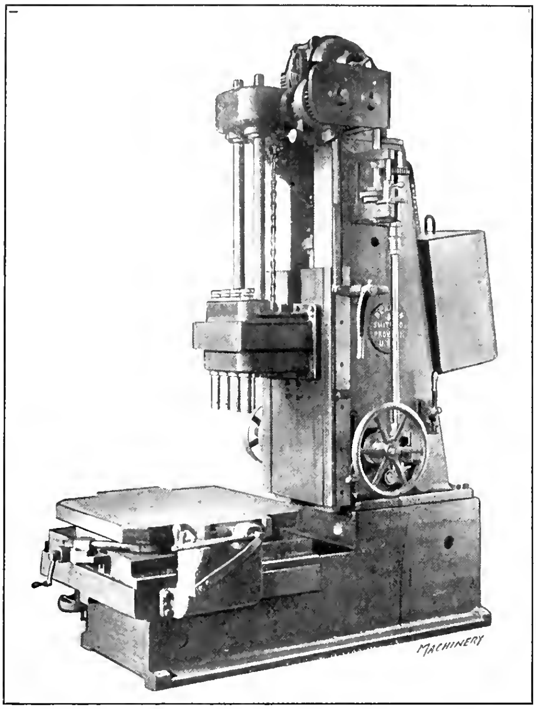

Fig. 1. Beaman & Smith Cylinder Boring Machine used for boring and reaming Engine Cylinders

bore; then the cylinders are annealed, after which they are brought back to the cylinder boring machine and two cuts taken, a finish-boring and a reaming cut. For the final boring and reaming operation a Kelly combination boring and reaming tool is used. This tool is arranged with the boring tool located ahead of the reamer, but set back to leave about 0.010 inch to be removed from the diameter of the cylinder bore by the reamers that follow. It is thus possible to take two cuts in one down travel of the head of the boring machine.

Referring to Fig. 1 it will be seen that the cylinder boring machine has a table of square section on which the work-holding fixture is held. This table is provided with two indexing points, so that a fixture which is capable of handling two pieces of work at the same time can be operated very economically. Fig. 2 shows a closer view of the fixture and gives a good idea of its construction. It will be seen that two castings are held in the fixture by means of swinging clamping straps, which also retain screws for holding the top portion of the cylinder rigidly in position. By having a table that can be indexed, it is possible to be operating the machine while removing and loading the other station on the fixture, so that the machine is kept in practically continuous

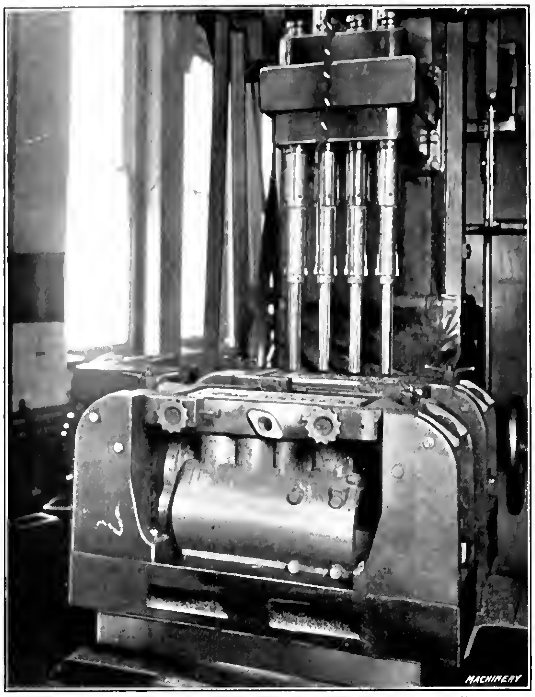

Fig. 2. Type of Fixture used in the Plant of the Sterling Motor Co., Detroit, Mich., for holding Four Cylinder Castings while boring and reaming

operation. This provides a very economical means of operating and greatly increases production. The finished dimensions of the cylinder illustrated are 2 3/4 inches diameter by 6 3/4 inches depth of bore, and a production of forty completed castings or 160 cylinder bores is obtained in ten hours.

The lock-gate sills of the Panama Canal are all made from "greenheart," which is a large tree found in the dense jungles of northern South America, especially in British Guiana. The wood will bear, without crushing, a weight of six tons to the square inch, and will remain sound 100 years under water; it is immune to the attacks of the salt water teredo.

GAS AND OIL FIRED FURNACES FOR HEATING STEEL

TYPES OF FURNACES USED, AND IMPORTANT FEATURES OF THEIR CONSTRUCTION

BY E. F. LAKE*

IN the last decade many improvements have been made in furnaces in which steel is heated, to obtain greater accuracy and uniformity in the temperatures. Only a few years ago any temperature that was above that at which steel would harden and below that at which it would become burnt was considered good enough. In most steels this would cover a range of something like 300 degrees F. Recent investigation, however, has shown that only a few degrees of variation in temperature between these two points makes considerable difference in the hardness, the elastic limit, the reduction of area, or the longevity of steel, as shown by fatigue tests. For instance, to heat steel 50 degrees above the transformation or critical point, or the point at which it should be quenched for hardening, shows a loss of something like 15 per cent in these physical properties; and greater variations show correspondingly greater losses. Thus, while large furnaces formerly had a variation of some 50 to 100 degrees in different parts of the heating chamber, the modern furnace must be so designed that the temperature will not vary more than 10 degrees between any two places, when the furnaces are operated at temperatures that are between 1400 and 1800 degrees F.

The interior construction of the furnaces has, therefore, been changed; appliances for pre-heating the fuel have been devised; gas and oil burners have been improved; automatic heat control instruments have been attached; and heat measuring instruments of various kinds have been brought into use to register and record the temperatures. Other improvements have also been made to reduce the fuel consumption; considerable study has been devoted to this part of furnace design.

The consumption of fuels has been studied by the Bureau of Mines, at Washington, D. C. One of the things conclusively proved is that a solid wall is better than a hollow wall, especially if the air space is near the outer side of the furnace. The general belief has been that air spaces built into the walls of a furnace would greatly reduce the amount of heat that was dissipated through the walls. The investigation mentioned proved, however, that while heat would travel slowly through air, because it is a poor conductor, the heat would readily leap the air space by radiation, and thus a considerable percentage was lost that could have been saved if the air space had been filled with some solid non-conductor of heat.

These results caused the Industrial Furnace Co., of Detroit, to design and build furnaces in the manner shown in Fig. 1. In these *A* is the cast-iron shell or outer wall of the furnace; *B* is mineral wool, or asbestos, used as a heat-ing insulator; its thickness varies from 2 to 4 inches according to the size of the furnace; *C* is the inner fire-brick wall of the furnace; and *D*, the fire-brick floor. The burners are located at *E*, and the arrow heads show the direction in which the flames and hot gases circulate. After passing through the heating chamber and giving up their heat, the spent gases pass through the vents *V*. At *F* is a sliding door that is typical of such furnaces, and at *G* the peep-hole in the door, while *H* is a shelf in front of the furnace.

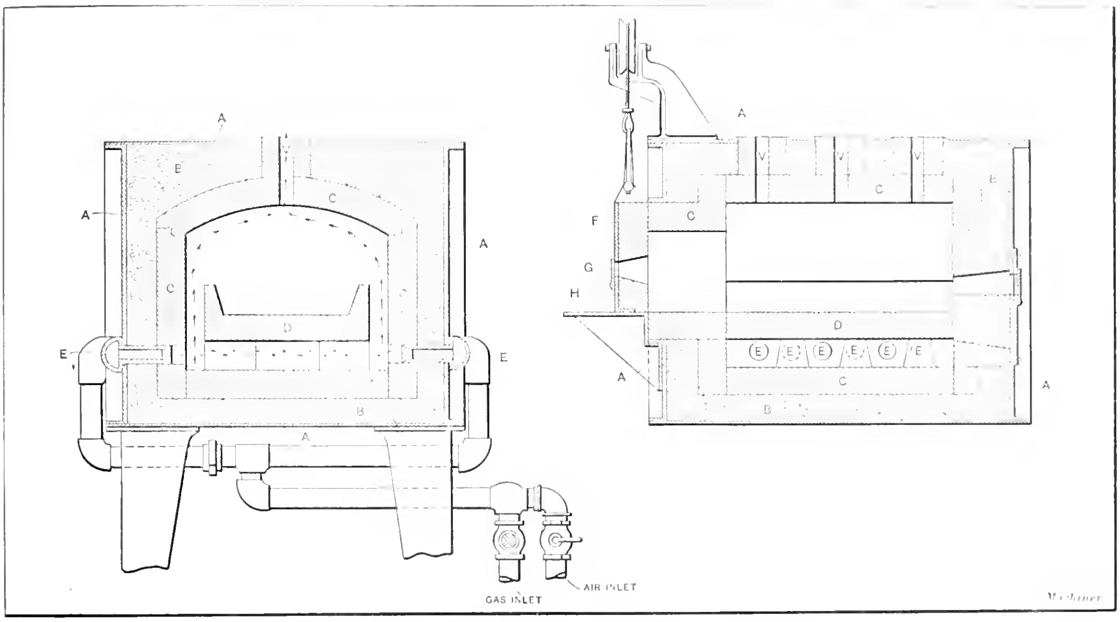

Fig. 1. Heating Furnace heavily lined with Asbestos to retain the Heat

Another method of economizing fuel is shown in Fig. 2. Here the Industrial Furnace Co. has taken two furnaces, similar to the one shown in Fig. 1, and provided a conduit connecting the side of one with the bottom of the other. This conduit is lined with asbestos and fire-brick, the same as the furnace, and can be taken off at any time, so that the furnaces may be used as separate units. In this twin furnace harrow springs are inserted in furnace *I*, to the left, and heated to the correct hardening temperature which is here maintained. After the gases have done their work in furnace *I*, they pass through conduit *J* to furnace *K*, at the right, and heat this to the correct temperature for drawing the temper of the springs. Thus the heat from the fuel is used the second time before it is allowed to escape to the atmosphere. In long furnaces several conduits are necessary to distribute the heat and make the temperature uniform in all parts of the heating chamber. The conduits should then be provided with dampers, so that the heat can easily be controlled. With only one conduit, however, the temperature within the heating chamber of the tempering furnace can be controlled by opening and closing the vent hole.

The same principle has been used by the Garrett-Tilley Furnace Co., of New York, in a three-chambered furnace,

* Consulting Metallurgist, 412 Pennsylvania Ave., Detroit, Mich.

each part of which is maintained at a different temperature. This is built in a single unit as shown in Fig. 3; that is, the three different heating chambers are built inside of one furnace shell. In one instance this type of furnace has been used for manufacturing leaf springs. In that case, the heating chamber *L* is used to heat the spring plates to the fabricating heat, which is about 1800 degrees F. When taken from this fire the plates are bent to the correct shape to fit the leaf below, on which they have their bearing. After that they are inserted in the middle furnace or heating chamber *M*, to be heated to the hardening temperature, which is around 1500 degrees F. When heated to this temperature they are taken from furnace *M* and quenched in oil. After that they are inserted in the furnace or heating chamber *N*, and heated to the drawing temperature, which is about 750 degrees F. This allows an accurate control of the temperature in the three separate heating chambers, and each is maintained all day at its respective temperature of 1800, 1500, and 750 degrees F. In this case fuel oil is used for heating the furnace, and pyrometers are used to measure the heat in each oven, so that the temperature can be kept at the correct point.

The heating chambers in this furnace are about six feet in length, and it is especially designed to give a uniform temperature in all parts. On the test run the variation between any two places in each of the heating chambers was shown to be less than 10 degrees. This accuracy was obtained by overfiring and passing the heat through a honeycombed arch over the heating chamber, as shown by the sectional view at *O* in furnace *L*. This arch separates the combustion chamber *W* from the heating chamber *L*. The burners are located at *S* and the flames enter the furnace at *T* where they strike a baffle plate *R*. This distributes them to both sides of the heating chamber. After filling the heating chamber, the hot gases pass through the openings in the honeycombed arch, as shown at *U*, and heat the oven in which the work is placed. The spent gases then leave the heating chamber through ports *P*, pass underneath the floor of the furnace and up through the vents *V*. Thus the top, sides and bottom of the heating chamber are kept at the same temperature throughout its entire length. This over-fired principle has been applied to furnaces with a single heating chamber as well as to those that have two and three heating chambers, and has proved very successful.

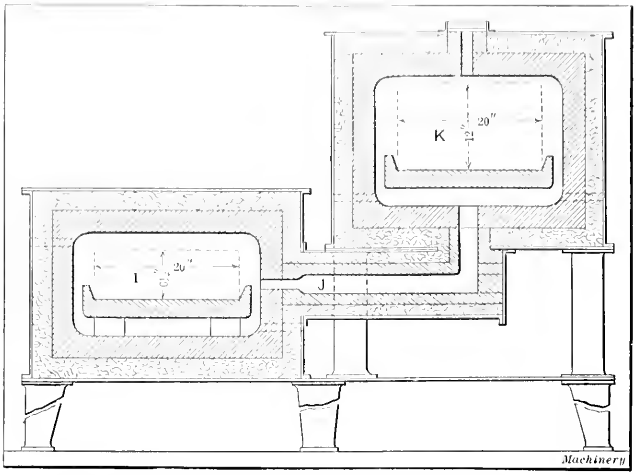

Fig. 2. Twin Furnace connected with a Conduit in order to make Use of the Heated Combustion Gases Twice

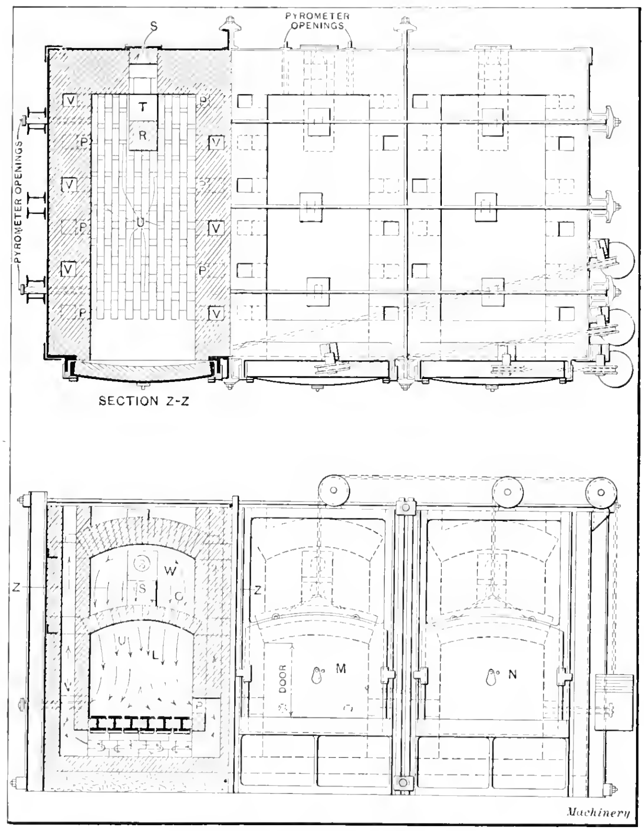

Fig. 3. Over-fired Furnace containing Three Heating Chambers arranged for Accurate Heat Control

Still another improvement in oil fired furnaces was recently patented by Walter S. Rockwell of the Rockwell Co., New York. This is shown in Fig. 4. It consists of a pipe coil through which the air is passed and pre-heated before it reaches the burners, where it is mixed with the fuel oil. This pre-heating coil *A* is located in front of the furnace, directly over door *B*, where it receives the heat which comes through the opening in which the work is inserted into the furnace. The plate *C* in front of the coil serves the purpose of protecting the furnace operator from the heat which comes through door opening *B*. One of these furnaces has been used by the Detroit-Timken Axle Co. for some time; it is claimed that the fuel consumption has been reduced by more than twenty-five per cent over that of furnaces that do not pre-heat the air. All or part of the waste gases can be made to pass through the door opening instead of through vents, and thus pre-heat the air to any desired degree.

The air for combustion enters the coil, under pressure from a pump, through pipe *D*, which is provided with valve *E* to regulate this pressure, so that the air and fuel oil will have the proper mixture. The heated air leaves the coil through pipes *F* and enters burners *H*, where it is mixed with the fuel oil which flows to the burners through pipes *I*, its rate of flow being controlled by valves *K*. The blast of hot gases then passes from burners *H* into heating chamber *L* to raise it to the correct temperature, and out through door *B* to heat the air in coil *A*.

Oil and gas fired furnaces are a great improvement over those that are fired with coal and coke, as with the latter it is impossible to keep the temperature in the furnace at a given point, and much of the heat is lost through the chimney which must be provided to carry away the smoke and gases. A large part of the furnace operator's time is taken up in shoveling in the coal or coke and carrying away the

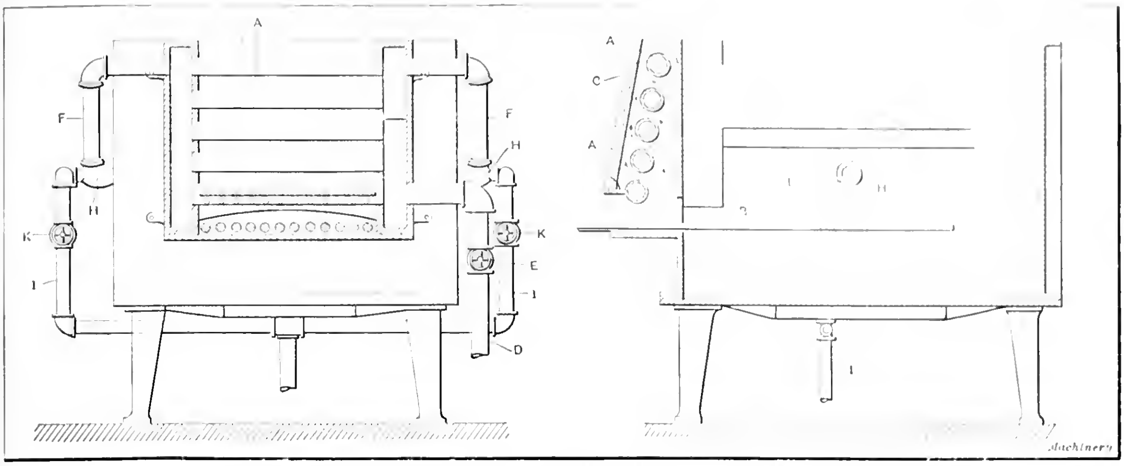

Fig. 4. Recently developed Type of Oil-burning Furnace in which the Air is pre-heated

ashes, while the dust and dirt that accumulates from these operations is, to say the least, very disagreeable. Then again the steels heated in such furnaces are more liable to oxidize and scale, and to absorb some of the sulphur or other injurious elements that arise from the combustion. It is a well known fact that steel absorbs such impurities more readily when heated to the high temperatures required for hardening, forging and welding. For these reasons, furnaces using liquid fuels or gas have improved the quality of metal heated in them, effected a considerable saving in fuel consumption, and saved time by allowing the operator to give more of his attention to the heating of the metal. They have also effected a big improvement in the cleanliness of rooms in which furnaces are located.

When gas and oil furnaces were first installed, a 50-degree variation in the temperature during a day's run or in different parts of the furnace was considered quite good performance, but recent improvements have brought this to a point where a 10-degree variation is all that is allowed in high-class furnaces. This has made it possible to heat-treat steels at more accurate predetermined temperatures, and thus give them greater strength and resistance to fatigue.

One of the greatest improvements that has been made for controlling the heat in the gas furnace is the temperature control instrument that is manufactured and attached to furnaces by the American Gas Furnace Co. This automatically increases and reduces the amount of gas and air that enters the burners, and hence raises and lowers the flame that enters the furnace. It is operated by a mechanism that is attached to the pyrometer. By means of a diaphragm this mechanism raises and lowers a sleeve containing gas and air ports, and thus increases or reduces the size of the port openings. With this instrument the heat inside the furnace can be kept within five degrees of the point at which the instrument is set, and the temperature can be maintained within this narrow limit as long as the gas and air blast keeps flowing into the furnace. The oil-burning furnace must be regulated by an adjustment of the oil and air valves by the furnace operator, as no instrument has yet been perfected that will do this automatically. Several individuals are working on this problem, however, and seem to have arrived at a solution. Thus it will probably be but a short time before a similar instrument will be devised for automatically controlling the temperatures in furnaces using oil for fuel.

Many improvements have also been made in oil- and gas-burning furnaces that heat liquid baths for raising the temperature of steel to the hardening temperatures. One of the improvements made in an oil-burning furnace is shown in Fig. 5. This was designed by W. S. Quigley of the Quigley

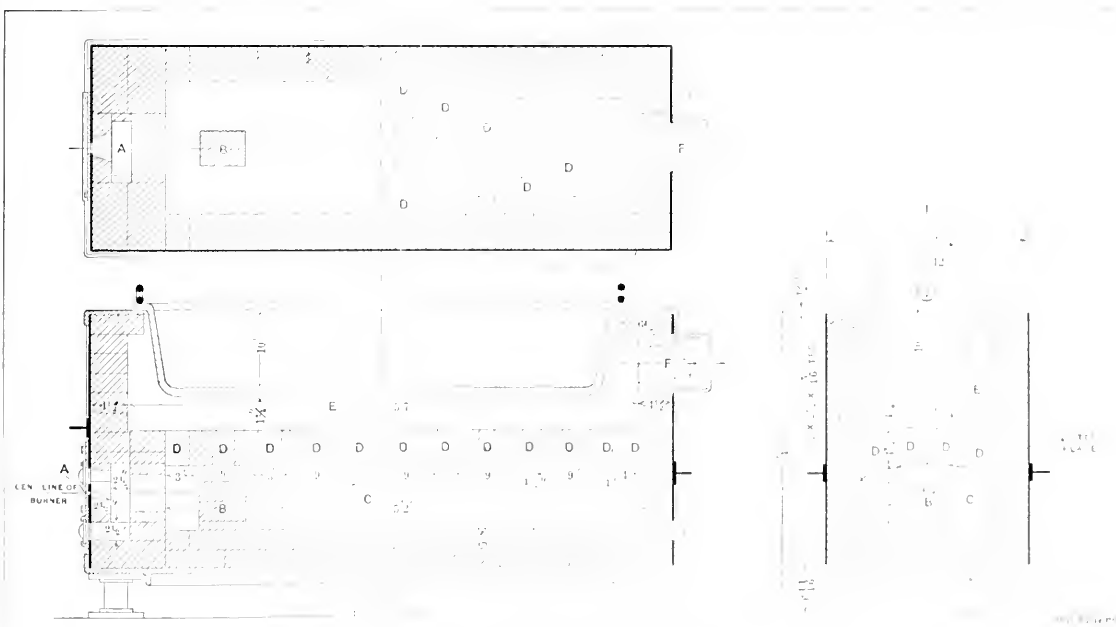

Fig. 5. Furnace for heating Liquid Bath

Furnace & Foundry Co. and uses a honeycombed arch similar to that shown in Fig. 3. The arch is used underneath a lead pot to separate the combustion chamber from the heating chamber and more evenly distribute the heat underneath the entire length of a five-foot lead pot. The flames from the burner enter opening *A* and strike the baffle plate *B* where they are broken up and distributed to both sides of combustion chamber *C*. The hot gases then pass through honeycombed openings *D* into heating chamber *E* and the spent gases leave the furnace through vent *F*. Salt hardening and tempering bath furnaces are finding more users every day,

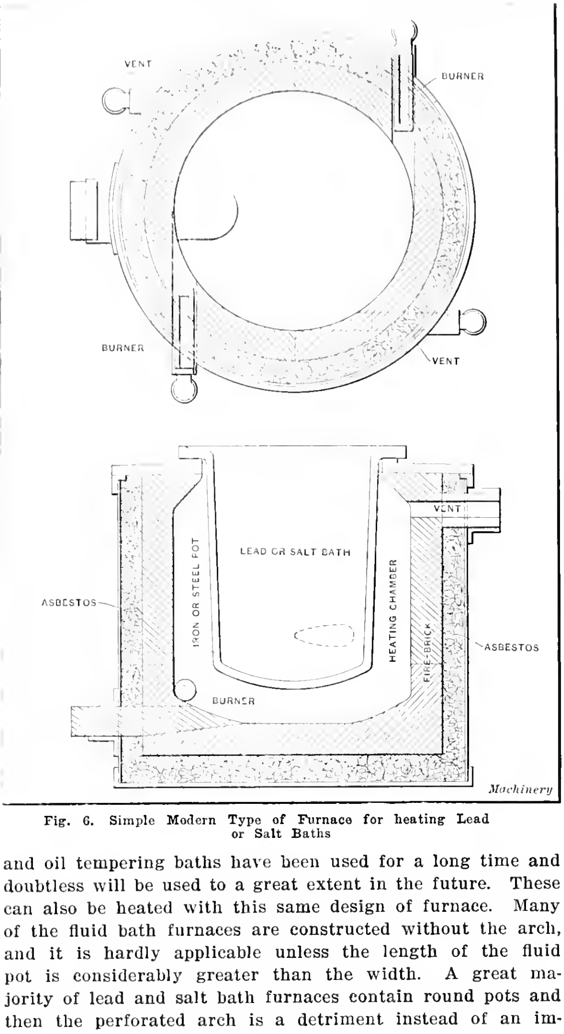

Fig. 6. Simple Modern Type of Furnace for heating Lead or Salt Baths

and oil tempering baths have been used for a long time and doubtless will be used to a great extent in the future. These can also be heated with this same design of furnace. Many of the fluid bath furnaces are constructed without the arch, and it is hardly applicable unless the length of the fluid pot is considerably greater than the width. A great majority of lead and salt bath furnaces contain round pots and then the perforated arch is a detriment instead of an improvement. This type of furnace is shown in Fig. 6.

LIMITS FOR THE TOOL DEPARTMENT

BY C. KNOWLES*

The tool department in any shop should be put on a commercial basis, *i. e.*, rate of production as well as quality of the work should be considered. It is often said that a toolmaker always uses the slowest speed and feed on his machine. This is not true in many cases, but it is a fact that much time is wasted by working too accurately. It is impossible for a toolmaker in a large shop to know much about the part for which he is making tools; therefore, he has no knowledge of conditions on which to form an opinion of the accuracy that is required. The foreman and inspector who have a great number of jobs to look after are even worse off in this respect. Of course, these men could make inquiries and thus obtain a knowledge of the fundamental facts of each case, but this would mean additional time and expense to charge against the department. The result is that many tool departments establish a standard of their own, which is too accurate for some jobs and not accurate enough for others.

* Address: 77 Cheswick Road, Edgewood, R. I.

The proper time to decide on the allowable limits for each tool is at the time it is designed. In planning tools for the manufacture of a given part, the designer should thoroughly investigate the relation of this part to other members of the machine and specify the limit of accuracy accordingly. For example, if the work is a bracket with screw and dowel-pin holes and two bearings for shafts carrying gears in mesh, the following conditions will have to be met. The screw and dowel-pin holes must match the holes in the piece to which the bracket is secured. The designer knows that the stock screws used in the shop are a certain amount small, and that it is the custom to drill dowel-pin holes under size and ream them with the two parts in position. Thus he realizes that the jigs for the two parts do not have to be exactly right, but can vary from each other by the amount that the screws are smaller than the screw holes. The bearing holes for the shafts must not be too short on the center distance, as standard gears would bind under such conditions. On ordinary work, however, if the center distance is a trifle long, the resulting backlash will do no harm. The principal reason for making a jig is to provide interchangeability, and if a considerable number of the parts are to be manufactured, the cost of production will also be reduced. Accuracy is required in the jig for this purpose and it can only be made in a well equipped toolmaking department.

In many cases the jig is used because of the convenience with which it enables the work to be handled, thus reducing production costs. When interchangeability of parts is not a factor, scale measurements would be close enough and the jig could be made by an ordinary workman using manufacturing machines. In order to design tools intelligently, the designer must know all of these conditions, and his work is not complete unless he specifies the allowance limits or permissible variation from standard dimensions in each case. All locating points, studs and bushings, center distances and other dimensions, which, for any reason must be held close, should be given the widest limit that is consistent with the work that is to be produced by the tool. In all cases it should be borne in mind that the last 0.00025 inch means delay and expense. This recommendation in regard to the allowable variations from specified dimensions should be used on gages, cutting tools and all other classes of tool work.

Knowing the accuracy to which each tool must be finished, the tool-room foreman can lay out his work with the view of securing the greatest possible economy. The accurate work can be given to the men best qualified to handle it and these men can be assigned to the best machines in the tool-room. Similarly, the lower grade of work can be given to the less expert mechanics and these men can be given the use of manufacturing machines which can be forced with the view of increasing production. In many cases when the tool department is rushed, this low-grade work can be turned over to the manufacturing department with very satisfactory results. It is often necessary to duplicate a tool which was made at some previous time, and if the proper limits are recorded on the drawing, this can be done without measuring or referring to the old tool in any way.

The recommendations given in this article may be briefly summarized as follows: By having properly established and recorded limits we are able to obtain greater efficiency in the tool-room. Delays caused by investigations made by the foreman or workmen are avoided. The provision of exact information in regard to each tool makes it possible for the work of the tool-room to be put through more rapidly. The tools are adapted in both quality and accuracy for the work for which they are intended and economy is effected by giving the high-grade work to highly skilled mechanics, and less accurate work to men of more meager experience. The work is classified so that, if necessary, work which does not demand a high degree of accuracy may be sent out to the manufacturing departments. Tools may be made in duplicate or existing tools may be matched without involving the expense and delay caused by measuring tools already made.

AUTOMATIC INDEXING FIXTURE FOR CUTTING INTERNAL RATCHET GEARS

BY ALFRED SPANGENBERG*

In considering the design of fixtures for machining small parts in quantities, the introduction of automatic features will often effect a large saving in the cost per piece by cutting down the time between cuts. This applies particularly where the operations involve frequent indexing of the work, since the elimination of hand indexing, with the consequent starting and stopping of the machine, will effect a further economy in labor by enabling the operator to run two machines, thereby securing a material reduction in the cost per piece.

This principle is well illustrated in the accompanying illustrations, which show an automatic indexing fixture for cutting small internal ratchet gears on a Brown & Sharpe No. 3 milling machine equipped with a commercial slotting attachment. The fixture is in use at the Pond Works of the Niles-Bement-Pond Co., Plainfield, N. J. The ratchet gear *A* to be machined has thirty-two internal teeth of 1-inch face width by 1/16 inch depth, while the bore of the hole is 2¾ inches in diameter. A number of other sized gears are cut on this fixture by substituting indexing wheels *B* having the required number of teeth. As will be seen from Fig. 2, the fixture proper consists of a suitable bed-plate *C* that forms a bearing for stud *D*, to which is secured the indexing dial bearing *E*. Rigidity of the index wheel and its bearing *E* against the pressure of the cut is secured by a finished seat of ample diameter on casting *C*.

The index wheel and its members *D* and *E* are free to revolve on the bed-plate *C*, but to prevent over-travel during

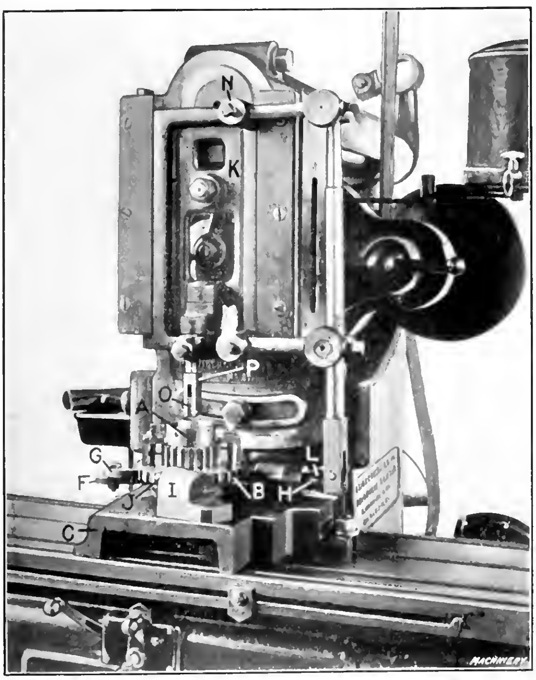

Fig. 1. Automatic Indexing Fixture in Position on Brown & Sharpe Milling Machine

the operation of indexing, a light tension is secured by means of a lock-nut and spring washer carried on the lower end of stud *D*, which imposes an additional friction between the under surface of the bearing *E* and the finished surface of the bed casting. The bearing *E* is turned on its periphery to fit the bore of the rocker *F* which carries a pawl *G* and the link connection to the spring plunger *H*. Cast integral with the bed-plate is a bearing *I* for the dial locating plunger *J* which is operated by a suitable spring contained within the bearing. Power for the automatic indexing is derived from the slotting attachment ram *K*, Fig. 1, to which the pawl *L* is attached by means of supporting rods.

In operation, the stroke of the ram is set to over-travel about one inch above the teeth in the work. This permits pawl *L*, during the over-travel on its upward stroke, to engage plunger *H*, the indexing being effected by means of the rocker *F* and its mechanism. The pawl *L* is hinged as shown, so that no indexing takes place during the downward stroke of the tool. The function of plunger *J* is to locate and hold the index dial *B* during the cutting stroke. Dotted lines at *M*, Fig. 2, show the normal position of plunger *J* against the index dial. The feeding only takes place upon the completion of each revolution of the work. The feeding of the work in to the tool is accomplished by moving the milling machine

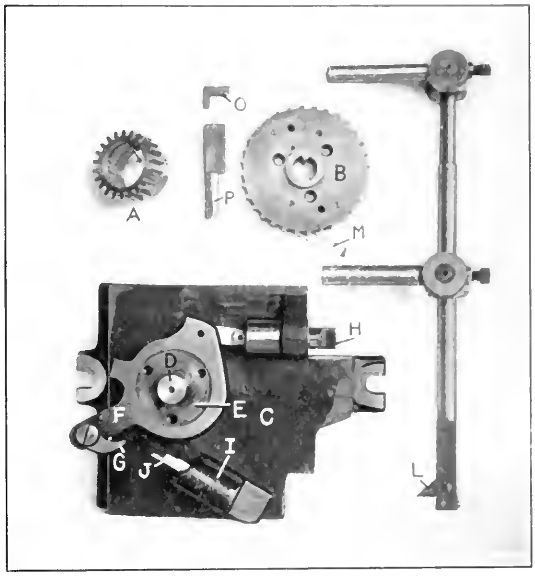

Fig. 2. Details of Fixture illustrated in Fig. 1

table crosswise by hand. At the start, the depth of cut is set at about 0.050 inch and this is gradually decreased at each revolution of the work until the final depth is reached, which requires three revolutions, because each successive cut is heavier.

As was previously stated, ratchet gears of several sizes having different numbers of teeth are cut on this fixture. Consequently, the rocker mechanism must be adjustable in its movement. This is provided for by a horizontal adjustment of the pawl-carrying arms in the studs *N*. The method of centering and clamping the work is made clear by a study of the illustrations. To provide relief for the cutter during its return stroke, the cutter *O* is made L-shaped and is hinged in its holder *P*. The tool-holder is drilled to receive a spring that presses against the heel of the cutter and so keeps it in its normal position.

Previous to the introduction of the fixture described in this article, the ratchet gears in question were cut on a regular slotting machine, using a somewhat similar fixture except that the indexing was accomplished by hand. This method produced about five finished ratchet gears per hour, while with the new method the output averages about twenty-five per hour—an increase of production of 500 per cent. The external gear teeth in these ratchet gears are, of course, previously finished in a regular gear-cutting machine.

* * *

Plans have been filed with the Bureau of Buildings, New York City, for an office building which will be 894 feet high. The structure is proposed to be built on the block bordered by Broadway, Eighth Ave., 57th and 58th Sts., and to be fifty-one stories high. The design is to follow the Gothic style. The building is to be built by the Pan-American State Association, and the tower will be surmounted by an allegorical figure representing the association. The estimated cost is $12,500,000.

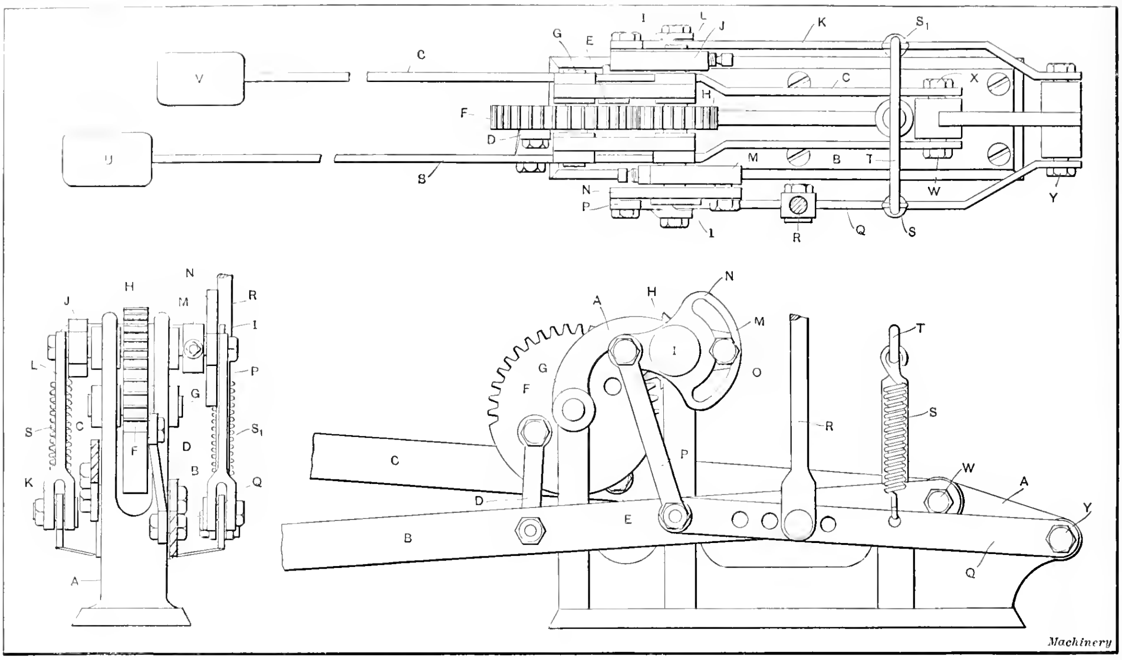
DUPLEX SAFETY TRIPPING DEVICE

BY JAMES H. RODGERS*

The cause of a great number of crippled hands of men employed in the iron or sheet-metal working trades can be traced to the power press, where the starting and stopping depends entirely upon the operator. The starting of a large majority of the different makes of power presses is by depressing the well known form of foot treadle located below the bed of the machine, which releases the latch that holds the clutch out of gear and allows the crankshaft to make one revolution. As soon as the press is in action the foot must be lifted or removed from the treadle to allow the latch to return to its former position. In nine cases out of ten, when an accident takes place, the operator will say that the press "repeated." This may or may not be true; but if the press did repeat, it was due largely—if not entirely—to a lack of caution displayed by the person operating it.

When an operator removes his foot from the treadle each time he trips the press, it requires double the number of movements to perform his work, and where from 10,000 to 30,000 operations a day are performed it involves considerable muscular action in the operator's leg and foot. Where an operator does not remove his foot from the treadle, but allows it to return after releasing the press, he must retain considerable tension upon the muscles of his limb in order to prevent the depression of the operating treadle before the proper time. Now, one not familiar with the operation of power presses has only to imagine what effect this muscular strain would have on a person who is practically holding the weight of his leg up for from seven to ten hours a day. Another objectionable feature of the method of tripping with an ordinary treadle, and one that is deserving of censure, is the custom of a large number of press operators of allowing the treadle to rise just far enough for the latch to operate the clutch-pin. The writer has seen cases where operators allow only one-eighth inch contact when there should be one-half inch. An observer can readily see that this perilous condition of affairs neither facilitates the operation nor increases the rapidity of action. But it does make it possible for the operator, when placing work in position, to unintentionally depress his foot sufficiently to trip the press, owing to his carelessness in not allowing the latch to return to its proper position. It is this condition more than any other that causes the majority of power press accidents.

The accompanying illustration shows a duplex safety tripping device which reduces to a minimum the number of accidents traceable to the carelessness of the operator. In this illustration, *A* is the frame casting that is secured to the floor below the press. Fulcrumed at *W* and *X* are the two treadle levers *B* and *C* which extend to the front of the machine in the ordinary manner. The links *D* and *E* connect the treadles *B* and *C* with the gear *F* at diametrically opposed points. The shaft *G* on which gear *F* is mounted rotates through an angle of about 60 degrees. Meshing with gear *F* and carried by the shaft *I* is the pinion *H*, and secured to the left-hand end of shaft *I* is the crank *J* which is connected to the lever *K* by the link *L*. On the opposite end of the shaft *I*, and secured to it, is another crank *M*. Outside the crank *M* and free to rotate is the slotted disk *N*, which is held in position by the head on the shaft *I* and the stud *O*. The link *P* connects the disk *N* with the auxiliary treadle lever *Q* which is fulcrumed at *Y*. The trip-rod *R* is secured to the auxiliary treadle lever *Q* in the ordinary manner. The teepost *T* carries the two springs *S* and S_1, which makes the action of the mechanism positive after the operator has tripped the press.



Duplex Safety Tripping Device for a Power Press

The foot is placed on the foot-rest *V* and pressed downward, lowering the treadle lever *C* and through the link *E*, rotating gear *F* in a clockwise direction. This causes the pinion *H* and the two cranks *J* and *M* to rotate in the opposite or counterclockwise direction. When the crank *M* has rotated through an angle of from 60 to 90 degrees, governed by the length of the slot in the disk *N*, the stud *O* comes into contact with the end of the slot and begins to rotate the disk *N*. Through the link *P*, auxiliary treadle lever *Q* and trip-rod *R*, the latch is released by the continued downward pressure of the operator's foot and then carried back to position to stop the press after the crankshaft has made one revolution. By lowering the other treadle *U* (which by the above action has been raised ready for the next operation) the movement of the mechanism is again performed in the opposite direction but with the same results. Every time either treadle is pushed down the press is released and automatically locked after making one revolution.

It will be seen from the illustration that the cranks *J* and *M* will have passed the center before the latch releases the clutch, and as the spring S_1 is under greater tension than the other spring *S*, the mechanism will perform the movement independent of the operator. The muscular tension on an operator's limb will, therefore, be reduced to a minimum.

* Address: 350 Dundurn St., S., Hamilton, Ont., Canada.

STEAM POWER PLANT PIPING DETAILS*—8

THE DESIGN AND ERECTION OF EXPANSION BENDS

BY WILLIAM F. FISCHER†

IN previous numbers of MACHINERY, rules and tables were presented from which to estimate the amount of expansion and contraction to be cared for in a steam main of a given length conveying steam at a given pressure. Having determined the amount of expansion to be cared for, the designer should next decide upon the most suitable method of compensation. For low-pressure steam and exhaust mains, expansion joints of any suitable standard make may be used to take up or relieve the strains on the piping system (see MACHINERY, November, 1913), but for high-pressure steam mains, it is customary and advisable to use expansion pipe bends made up of full-weight or extra-heavy steel or wrought-iron pipe. When the steam main is of considerable length it is advisable to divide the expansion between different sections of the piping system, anchor the main rigidly at a point near the middle of each section, and provide an expansion bend in each section, as mentioned and illustrated in a previous number of MACHINERY. Having decided upon the location of the expansion bends, the next question to be determined is the type of bend to be used and its dimensions. The exact amount of expansion that can be taken care of by a wrought-iron or steel pipe bend of given dimensions is a matter of some uncertainty. Distortion of a pipe bend beyond a certain stage throws very heavy bending strains on the pipe joints and outer fibers of the material from which the bend is made. Before excessive bending strains are reached, however, expansion bends, if properly proportioned and suited to the conditions, will prove as flexible as most other methods of caring for expansion and contraction, and will be found much safer in operation. The amount of expansion that can be taken care of by an expansion bend of wrought-iron or steel pipe depends upon the shape of the bend, the mean radius of the bend, the outside diameter of the pipe from which the bend is made, and the amount of straight pipe allowed between the arcs or curved portions of the bend.

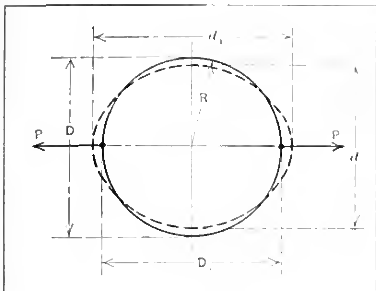


Fig. 61. Deflection in Ring due to Forces P

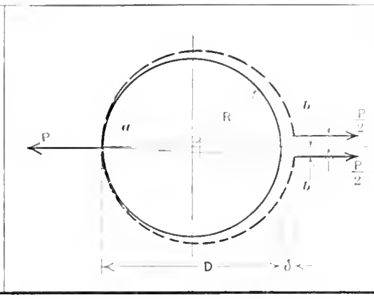

Fig. 62. Diagram used in deriving Formulas

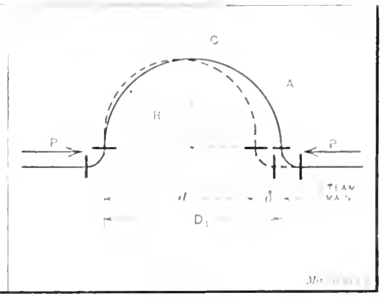

Fig. 63. U-pipe Bend strained by Expansion

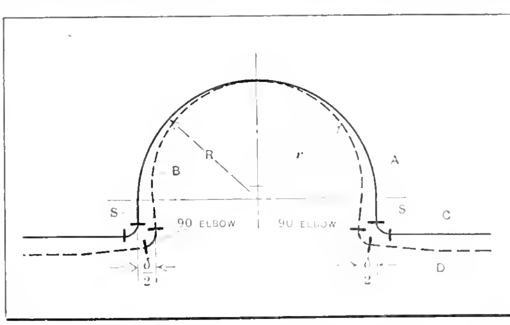

Fig. 64. Single U-expansion Bend connected to 90-degree Elbows

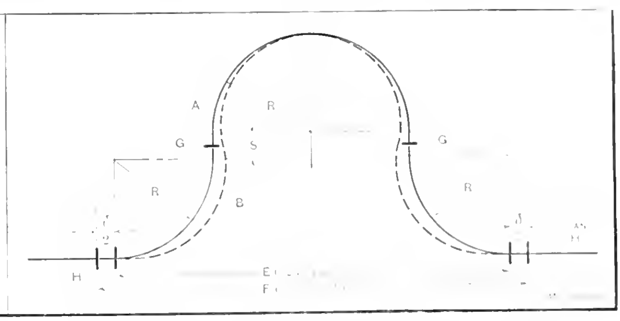

Fig. 65. Expansion Bend that reduces Bending Stress in Main

Practical data relating to the design of expansion bends is rather scarce. The writer has no excuse to offer in presenting the following approximate rules, formulas and tables relating to the design of expansion bends, other than the fact that they will be found well on the safe side for each case considered and that they are to be used as a guide in determining proportions rather than as hard and fast rules. In making up a steel or wrought iron pipe bend, it is necessary to provide a short length of straight pipe at each end where the flanges connect to the bend. It is also advisable to allow a short length of straight pipe between the arcs or curved portions of a bend, especially where the curve is reversed in direction as at S in Figs. 65 and 66. These short lengths of straight pipe will be found to increase the flexibility of the bend, but as it would greatly complicate the formulas, rules and tables, if taken into account, the writer has ignored its effect altogether and only considered the curved portions of the bend in each case. In preparing the formulas and tables for U-shaped expansion bends, the writer used the following rules and formulas for figuring the deflection of circular rings when acted upon by two equal and opposite forces.* Fig. 61 indicates a circular ring of mean radius R acted upon by two equal and opposite forces P. The dotted lines show the form the ring assumes under stress, D and D_1 being the mean vertical and horizontal diameters of the ring before the forces P are applied, and d and d_1 the mean vertical and horizontal diameters after the forces are applied. If we consider the ring to be cut at b and divide P into two equal parts, as indicated in Fig. 62, all motions may be considered to take place about the point a. In this case, the dotted lines show the form each half of the ring will assume under the action of the forces P and $\frac{P}{2}$, D being the original mean diameter of the ring and δ the deflection of the ring when cut and loaded as shown.

Let δ = horizontal deflection of ring in inches.
P = concentrated load, in pounds, acting upon ring;
R = mean radius of ring in inches;
E = modulus of elasticity of the material in ring,
I = moment of inertia of a cross-section of ring,
π = 3.1416.

† Address: 3959 Fulton Ave., Woodhaven, N. Y.

* See [illegible]

Then, according to Professor Hudson:

$$\delta = \frac{P\pi R^3}{4EI} \tag{11}$$

$$M_b = \frac{PR}{\pi} \tag{12}$$

where M_b = maximum bending moment on ring, in inch-pounds, due to concentrated load P.

In any segment of the ring, the external forces acting on the ring will be held in equilibrium by the internal, or resisting forces acting upon the segment at its two ends. Therefore, in order that the ring may be of sufficient strength, the resisting moment, M_r, in inch-pounds, due to the internal stresses at any section of the ring, should equal the bending moment, M_b, in inch-pounds at that section, due to the external forces. Therefore:

$$M_b = M_r \tag{13}$$

where M_b = maximum bending moment in inch-pounds;
M_r = corresponding resisting moment in inch-pounds.

From Formula (12) we find that $M_b = \frac{PR}{\pi}$. We also know that the resisting moment for a beam of any cross-section is:

$$M_r = \frac{fI}{y}. \tag{14}$$

where f = allowable fiber stress in pounds per square inch;
I = moment of inertia of a cross-section of the beam;
y = distance, in inches, from the neutral axis of beam to outermost fibers.

Therefore, if we substitute the above values in Formula (13) we have:

$$M_b = M_r \text{ or } \frac{PR}{\pi} = \frac{fI}{y}. \tag{15}$$

By transposing in (15) we get:

$$P = \frac{fI\pi}{Ry}. \tag{16}$$

Now if we substitute $\frac{fI\pi}{Ry}$ for P in Formula (11), we have:

$$\delta = P \times \frac{\pi R^3}{4EI} = \frac{fI\pi}{Ry} \times \frac{\pi R^3}{4EI}$$

$$\delta = \frac{f\pi^2 R^2}{4Ey}. \tag{17}$$

This formula gives the deflection δ of the ring in terms of the fiber stress f. See Figs. 61 and 62.

Formulas for Deflection of U-shaped Expansion Bends

In applying the above formulas to expansion bends, the writer assumes the conditions shown in Fig. 63, *i. e.*, a U-shaped expansion bend A, of radius R, acted upon by two equal and opposite forces P. These forces act in the direction of the arrows when the bend is caring for expansion in a steam main, and in the opposite direction when the bend is caring for contraction in a main. It should be noted that the expansion bend A is acted upon by two equal and opposite forces P, while each half of the split ring in Fig. 62 is loaded only one-half as much, being acted upon by two equal and opposite forces $\frac{P}{2}$. Therefore, in order to apply Formula (11) to expansion bends as shown in Fig. 63, the writer has multiplied the formula as it stands, by 2, as follows:

$$\delta = 2 \times \frac{P\pi R^3}{4EI} = \frac{P\pi R^3}{2EI}. \tag{18}$$

Formula (18) is not yet in the desired form for expansion bends, however, for the following reasons: In the case under consideration, the equal and opposite forces P cause the bend to deflect an amount δ. In the case of an expansion bend serving a steam main, however, the force P is unknown and would have to be determined before applying Formula (18). For example, when the steam main (Fig. 63) expands, it lengthens an amount δ, thereby causing the expansion bend A to deflect and close up an equal amount, as shown by the dotted lines. As the force of expansion is practically irresistible, we know that the bend must give sufficiently to take up the expansion in that particular section of the piping system served by the bend. Therefore it is not necessary to compute the magnitude of the thrust P due to expansion of the steam main, but rather to compute the unit fiber stress

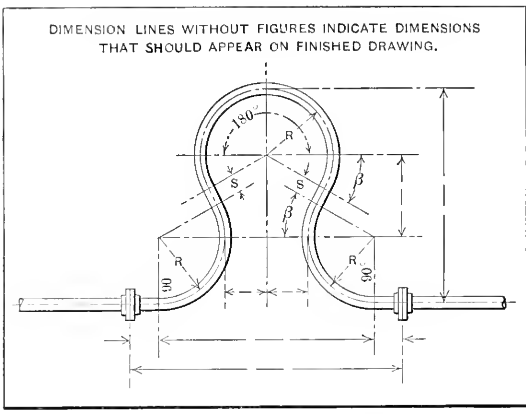

Fig. 66. Double Offset Expansion Bend

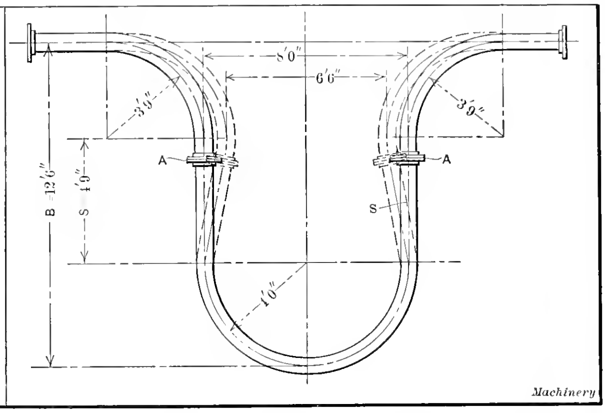

Fig. 67. Kellogg Improved Expansion Bend

f in pounds per square inch in the outer fibers of the material of the bend, due to the bend deflecting an amount δ. From Formula (17) we found $\delta = \frac{f\pi^2 R^2}{4Ey}$, which is the deflection of a ring in terms of the unit fiber stress f. Therefore, if we multiply by 2, we get for the deflection of an expansion bend in terms of the unit fiber stress f:

$$\delta = 2 \times \frac{f\pi^2 R^2}{4Ey} = \frac{f\pi^2 R^2}{2Ey}. \tag{19}$$

Substituting 9.87 for π^2 and transposing gives:

$$\delta = \frac{\pi^2 f R^2}{2Ey} = \frac{9.87 f R^2}{2Ey} = 5 \times \frac{fR^2}{Ey} \tag{20}$$

$$f = \frac{Ey\delta}{5R^2} \tag{21}$$

$$R = \sqrt{\frac{\delta E y}{5f}}. \tag{22}$$

Formulas (20), (21) and (22) are in the final form desired for U-shaped expansion bends—as shown in Figs. 63 and 64. For mild steel and wrought-iron pipe, the modulus of elasticity E may be taken as 29,000,000, in which case Formula (20) may be further simplified as follows:

For an allowable unit fiber stress f = 12,000 pounds per square inch:

$$\delta = \frac{5 \times 12{,}000}{29{,}000{,}000} \times \frac{R^2}{y} = 0.0021\,\frac{R^2}{y} \tag{23}$$

For an allowable unit fiber stress $f = 15{,}000$ pounds per square inch

$$\delta = \frac{5 \times 15{,}000}{29{,}000{,}000} \times \frac{R^2}{y} = 0.0026\,\frac{R^2}{y}. \qquad (24)$$

For an allowable unit fiber stress $f = 18{,}000$ pounds per square inch

$$\delta = \frac{5 \times 18{,}000}{29{,}000{,}000} \times \frac{R^2}{y} = 0.0031\,\frac{R^2}{y} \qquad (25)$$

and for an allowable unit fiber stress $f = 20{,}000$ pounds per square inch

$$\delta = \frac{5 \times 20{,}000}{29{,}000{,}000} \times \frac{R^2}{y} = 0.00345\,\frac{R^2}{y}. \qquad (26)$$

Formulas (23) to (26), inclusive, were used by the writer in estimating the values of δ in Tables X to XIII inclusive.

Formulas (20) to (26), inclusive, may be applied to U-shaped expansion bends as illustrated in Figs. 63 and 64, where the short lengths of straight pipe at each end of the bend are not considered. Values of y, for the different standard sized pipes will be found in the fifth column of Table IX, and in the sixth column of this table will be found values of the moment of inertia I, to be used in connection with Formula (18) in cases where the concentrated load P is known. To illustrate the use of Formulas (20), (21) and (22), and Tables IX to XIII the following examples are given:

Example 1:—The expansion δ of a 6-inch steam main is found by calculation to be 1.44 inch and it is desired to care for this expansion by installing a 6-inch U-bend as illustrated in Fig. 63. To what radius should the bend be curved in order that the extreme fiber stress f on the material of the bend will not exceed 12,000 pounds per square inch? By Formula (22) we find that the value of the radius is:

$$R = \sqrt{\frac{\delta E y}{5f}}. \qquad (22)$$

From the above:

$\delta = 1.44$ inch;

$E = 29{,}000{,}000$;

$f = 12{,}000$ pounds per square inch;

$y = 3.3125$ (see Table IX).

Substituting these values in Formula (22) gives:

$$R = \sqrt{\frac{1.44 \times 29{,}000{,}000 \times 3.3125}{5 \times 12{,}000}} = \sqrt{2305.5} = 48 \text{ inches}$$

This will be found to check with Table X. Under 6-inch pipe and opposite 48-inch radius will be found $\delta = 1.44$, the expansion cared for by a 6-inch U-bend at a fiber stress of 12,000 pounds per square inch.

Example 2:—It is desired to estimate the unit fiber stress f on the material of the 6-inch U-bend if curved to a radius of 42 inches instead of 48 inches, all other conditions being the same as in Example 1. By Formula (21), we find that $f = \frac{Ey\delta}{5R^2}$ and with $R = 42$ inches:

$$f = \frac{29{,}000{,}000 \times 3.3125 \times 1.44}{5 \times 42 \times 42} = \frac{138{,}330{,}000}{8820} = 15{,}680 \text{ pounds}$$

per square inch.

As a check on this result consult Table XI. Under 6-inch pipe and opposite 42-inch radius will be found 1.39 inch, the expansion cared for by a 6-inch U-bend of 42-inch radius, at a fiber stress of 15,000 pounds per square inch. The same bend when caring for 1.44 inch expansion is subjected to a fiber stress of 15,680 pounds per square inch, as per Example 2.

Example 3:—As an example showing the use of the tables assume the following conditions: The expansion of an 8-inch steam main is found by calculation to be 1.65 inch $= \delta$. To what radius should an 8-inch U-bend be curved in order to care for this expansion without stressing the material of the bend beyond 12,000 pounds per square inch? Table X gives the expansion cared for by U-bends of different sizes of pipe bent to various radii. Under the column headed 8-inch pipe, 1.65 is found to lie between 1.40 with a corresponding radius of 54 inches, and 1.73 with a corresponding radius of 60 inches. To determine the radius required to care for 1.65 inch expansion, proceed as follows:

Let e = expansion to be cared for = 1.65 inch;

X = radius required for this expansion;

δ = next lowest known deflection (from table);

R = radius corresponding to known deflection (from table).

Then, as the deflection of a U-bend (or the expansion cared for) varies as the square of the radius—see Formula (20)—we have:

$$X^2 = \frac{R^2 \times e}{\delta} \text{ or } X = \sqrt{\frac{R^2 \times e}{\delta}}$$

The expansion e to be cared for = 1.65 inch and the next lowest known deflection from table = 1.40 inch, with the corresponding radius R = 54 inches. The required radius X is then found to be:

$$X = \sqrt{\frac{54^2 \times 1.65}{1.40}} = \sqrt{\frac{4811.4}{1.40}} = \sqrt{3437} = 58.63 \text{ inches—say } 59$$

inches. These results may be checked by Formula (22)

$$R = \sqrt{\frac{\delta E y}{5f}} \qquad (22)$$

where $E = 29{,}000{,}000$;

$f = 12{,}000$ pounds per square inch;

$\delta = 1.65$ inch;

y = for an 8-inch pipe 4.3125. (See Table IX.)

Substituting these values in Formula (22) gives:

$$R = \sqrt{\frac{1.65 \times 29{,}000{,}000 \times 4.3125}{5 \times 12{,}000}} = \sqrt{3439} = 59 \text{ inches approximately.}$$

When designing expansion bends, it is not advisable to allow much over 15,000 pounds per square inch for the fiber stress f on the material of the bend, as the material has already been strained to some extent in heating and curving the bend to the required form. Fig. 64 illustrates the action of a single U-shaped expansion bend as used in connection with two 90-degree elbows for taking care of expansion and contraction in a steam main. The full lines A and C show the position of the bend and part of the steam main before steam is turned into the piping system, and the dotted lines B show the approximate position of the bend when caring for expansion after steam is turned into the piping system. As the 90-degree, cast-iron elbows at each end of the bend make a very rigid connection at this point, a more or less severe bending strain is thrown on the steam main at D as the bend deflects in caring for the expansion of the main. Increasing the length of straight pipe at each end of the bend, as at S in Fig. 64, tends to increase the strain at this point to some extent because the bending moment increases with any increase of length S. For this reason it is advis-

Machinery

* This table applies to U-bends as shown in Figs. 63 and 64. For 90-degree bends of same radius, divide above values by 2. For bends of the form shown in Fig. 65, multiply above values by 2. For bends of the form shown in Fig. 66, multiply above values by 2½.

$$\delta_1 = 2 \times \frac{5fR^2}{Ey} = 10 \times \frac{fR^2}{Ey}. \qquad (26)$$

Transposing in Formula (26):

$$f = \frac{Ey\delta_1}{10R^2} \qquad (27)$$

$$R = \sqrt{\frac{\delta_1 Ey}{10f}} \qquad (28)$$

where δ_1 = expansion in inches, cared for by bends;
f = allowable unit fiber stress in pounds per square inch;
R = mean radius of bend in inches;
E = modulus of elasticity of material;
y = outside diameter of pipe ÷ 2 (see Table IX).

In the preceding formula the length of straight pipe at S is not considered.

able to increase the radius of the bend rather than to increase the length of straight pipe at each end of the bend to obtain the same results.

The use of expansion bends of the form shown in Figs. 65 and 66 does away with the bending action on the steam main as the strain at this point (D, Fig. 64) is then taken care of by the reverse curve of the bend, as indicated in Fig. 65 by the dotted lines. In the latter illustration, the full lines A show the position of the bend when the steam main is cold and dotted lines B show the position of the bend when caring for expansion, in which case the bend is caused to deflect or close up an amount $\delta = F - E$, where dimension F is the original length of the bend, and dimension E is the length of the bend when caring for expansion. Very large bends of this form may be made in one piece if so desired (omitting flanges G) by welding two or more pieces of pipe together. This is now being done successfully by several of the large manufacturers of piping materials. The bend shown in Fig. 65 is made of three pieces of pipe as indicated, with flanges at the points G. In order to prevent the pipe from buckling and to insure a more perfect bend, it is always advisable to allow a short length of pipe between reverse curves, as shown at S. Expansion bends of this form will take care of at least twice as much expansion as the single U-bend shown in Figs. 63 and 64, as the bending action is distributed over twice the length of curved pipe. Therefore, in estimating the amount of expansion cared for by a bend of this type, the values for δ, as given in Tables X to XIII, inclusive, should be multiplied by 2.

Formulas for Expansion cared for by Bends of the Type shown in Fig. 65

In order to apply Formula (20) to expansion bends of the type shown in Fig. 65, it is necessary to multiply by 2, in which case we have:

Expansion cared for by Bends of the Type shown in Fig. 66

Fig. 66 shows a "double offset expansion bend." When considerable expansion is to be cared for this is the best form of bend to use. Where the angle β is not made less than 22½ degrees, bends of this type will care for at least 2½ times as much expansion as the single U-bend illustrated in Figs. 63 and 64, as in this case the bending action is distributed over 2½ times the length of curved pipe. Therefore, in estimating the amount of expansion cared for by bends of this type, the values of δ given in Tables X to XIII, inclusive, should be multiplied by 2.5. In making up bends of this type, it is always advisable to allow a short length of straight pipe (at least equivalent to the outside diameter of the pipe from which the bend is made) between reverse curves, as shown at S. It should be understood that any increase in the length of straight pipe at S (Figs. 65 and 66) will add to the flexibility of the bend. In order to apply Formula (20) to ex-

* This table applies to U-bends as shown in Figs. 63 and 64. For 90-degree bends of same radius, divide above values by 2. For bends of the form shown in Fig. 65, multiply above values by 2. For bends of the form shown in Fig. 66, multiply above values by 2½.

pansion bends of the type shown in Fig. 66, we must multiply by 2.5, in which case we have:

$$\delta_2 = 2.5 \times \frac{5fR^2}{Ey} = 12.5 \times \frac{fR^2}{Ey}. \quad (29)$$

Transposing in Formula (29) we get:

$$f = \frac{Ey\delta_2}{12.5 \times R^2} \quad (30)$$

$$R = \sqrt{\frac{\delta_2 Ey}{12.5f}} \quad (31)$$

where δ_2 = expansion in inches cared for by expansion bends of the type shown in Fig. 66; f, R, E and y are the same as in the previous case.

In the preceding formula, the length of straight pipe at S (Fig. 66) is not considered, and it is further assumed that angle β is not made less than 22½ degrees when making up the bend in the pipe shop.

Expansion cared for by a Six-inch Bend in Actual Service

A study of Fig. 67 will give the reader some idea of the amount of expansion that can be taken care of by a flexible pipe bend when properly made and installed. This expansion bend was made up of two right-angle or square bends, curved to a mean radius of 45 inches; and one U-bend curved to a mean radius of 48 inches, that is approximately eight times the diameter of the pipe from which the bend was made. A length of straight pipe, 4 feet 9 inches long, was allowed between the curved portions of the bend, as shown at S, making the center-to-center dimension of the bend 12 feet 6 inches, as shown at B. These expansion bends were made by the M. W. Kellogg Co., of Jersey City, N. J., and installed in a steam main in the yards of the Delaware, Lackawanna & Western R. R. at Hoboken, N. J. The bend was carefully measured after erection, when cold, and again after steam at 150 pounds gage pressure was turned into the 6-inch main. The full lines show the position and dimensions of the bend taken after erection, and the dotted lines show the position of the bend when caring for the expansion. The expansion of the 6-inch steam main caused the bend to close up, or deflect about 18 inches, without causing leakage at any of the pipe joints or without unduly straining the connections. Although the flanged joints A received most of the strain, due to the severe bending action at these points, the joints, upon careful inspection, showed no signs of weakness or failure. The steam main in which this bend was installed was equipped throughout with what is known as the "Kellogg improved Van Stone joint" with rolled steel flanges. When designing the bend, the long length of straight pipe was allowed at S (Fig. 67) in order to make the bend more flexible. On a bend of this type any increase in the length S adds greatly to the flexibility of the bend when caring for expansion or contraction. As far as the writer knows, no attempt was made to ascertain the unit fiber stress f due to the contraction of the bend, but from all indications the bend was not unduly strained at any time. As this bend has been in use for a number of years without giving trouble of any kind, it may be safely used as a guide in determining the dimensions and proportions of expansion bends for similar service. Expansion bends should never be curved to a radius of less than six times the diameter of the pipe from which the bend is made, and when greater flexibility is desired the radius of the bend should be increased as much as the conditions will allow.

* This table applies to U-bends as shown in Figs. 63 and 64. For 90-degree bends of same radius, divide above values by 2. For bends of the form shown in Fig. 65, multiply above values by 2. For bends of the form shown in Fig. 66, multiply above values by 2½.

Erecting Expansion Bends

If one-half the calculated amount of expansion in a steam main is allowed for when cutting the pipe to length, as mentioned in a preceding installment of this article, the steam fitter, when erecting the piping system, should stretch or spring the expansion bends sufficiently to make up the connections in the main without the use of filler pieces, or "Dutch-

men," as they are called. After steam is turned into the main, the expansion removes the cold strain put on the bend by the steam fitter and in this way the bend is strained only half as much as it would be if no allowance were made in the length of the main when cutting the pipes. In all cases where one-half the expansion is allowed for in the length of the main, the expansion bends shown in the illustrations Figs. 63 to 66, inclusive, will care for twice as much expansion as calculated by aid of the formulas and tables presented in this article, or what amounts to the same thing, an expansion bend should be designed to take care of only half the calculated amount of expansion, as half has already been allowed for in the length of the main.

CAUSE OF "ALLIGATOR SKIN" EFFECT ON DRAWN SHEET METAL

The peculiar mottled effect on the drawn sheet metal cup shown in the accompanying illustration is known in the sheet metal industry as "alligator skin." This marking is noticeable only when the metal is drawn or stretched to a considerable extent, as in the formation of a deep cup. There have been many reasons given for this effect.

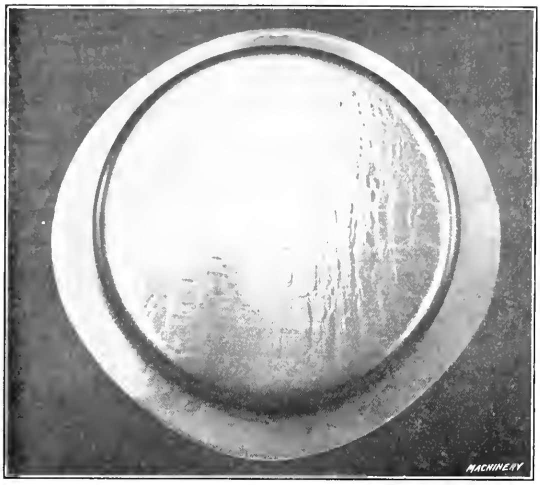

Illustration showing "Alligator Skin" Effect on a Cup drawn from Strip Steel that has a "Skin Hard" Surface

In producing cold-rolled strip steel, the material is annealed previous to the last rolling operation, so as to eliminate brittleness as much as possible. The last rolling operation serves to brighten the metal and bring it to the correct thickness. For some work, however, it is necessary to secure a grade of sheet metal known as "skin hard." This cold-rolled strip steel has a comparatively hard surface, and when the skin is not too deep produces bright and nicely finished cold-drawn work. However, it is much more difficult to work than the softer grades of steel, and is used only when a hardened surface on the material is desired. It is when "skin hard" strip metal is being drawn up that the "alligator skin" effect is produced. If the metal, after annealing, is reduced too much in thickness in the final rolling operation, a hard surface is formed on the exterior which is much tougher than the interior. Then when the metal, in being worked up to the desired shape, is drawn to a considerable extent, the interior or center portion of the cup draws much more than the outer surface; hence the outer surface, or hard skin, pulls apart, as it will not stretch anywhere nearly as much as the inside. This leaves a peculiar looking surface slightly depressed in those portions where the skin has broken away. In this particular cup which was drawn up from 0.037 inch sheet steel to a depth of 1½ inch and a diameter of 3 5/16 inches, the partings of the skin vary from 1/16 to 3/32 inch in width in those portions where the metal has broken away to the greatest extent. It will be noticed in looking closely at this illustration that the markings are much finer at certain points than others. This, no doubt, was due to imperfect alignment of the die and punch, which caused the metal to be drawn more on one side than on the other; consequently, the markings vary around the bottom of the cup.

It might be mentioned here that this "alligator skin" effect very seldom appears on soft sheet steel but is quite often present on "skin hard" steel. Manufacturers often find that this "skin hard" metal comes mixed up with soft stock, indicating that the rolling mill is at fault in allowing too much reduction in the final rolling operation. There is no possible way of eliminating this defect in the metal after it starts to appear. Of course "skin hard" metal can be drawn without producing this "alligator skin" effect if it is not reduced too much in thickness nor stretched to a considerable extent, but it cannot be removed by stamping or redrawing if it has once appeared. D. T. H.

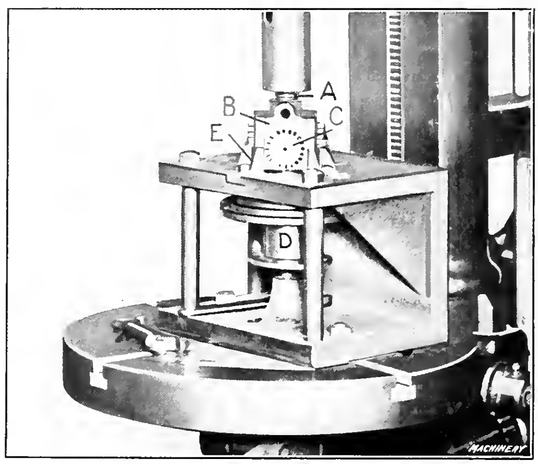
INTERNAL MILLING ON DIFFERENTIAL GEAR CASES

For finishing the four inside faces of a differential gear housing, the New Process Gear Corporation of Syracuse, N. Y., uses the device shown on the drill press spindle in the illustration. The casting for the housing is first put through the different lathe operations, and then comes to the drill press for the finishing of the four internal panels that act as side supports for the bevel pinions of the differential mechanism. The housing is held in the jig shown on the table of the drill press, and the milling fixture is held in the spindle of the drill press. The milling fixture is held and driven by arbor *A*, about which is the square framework *B* which supports the four milling cutters *C*. These milling cutters are mounted on short shafts extending through the faces of frame *B*. On the inner ends of these four shafts are bevel pinions, in turn driven by a central bevel gear on the lower end of spindle *A*. The outer ends of the shafts or studs do not extend beyond the cutter faces. When the spindle is lowered so that the cutters enter the differential housing casting *D*, the corners of the frame *B* are engaged by brackets *E* and prevent the frame from turning. Continued down feeding permits the revolving cutters to finish the four faces. The amount of metal to be removed is about 1/32 inch from each face, and the principal work that has to be done is the sizing and finishing of the four faces. This method of milling takes care of what would otherwise be a troublesome job. C. L. L.



Fixture for Internal Milling on a Differential Gear-case

* * *

In the industries today, the one fundamental demand is for cooperation. There are men of rare technical knowledge, ripe experience and sterling honesty who have been total failures because they were always in a turmoil. They threw sand in the wheels of progress. Tact is the lubricant without which no efficient transmission of cooperative energy can be achieved.—*J. M. Eaton in the Journal of the Worcester Polytechnic Institute.*

LOADING AND "CLIPPING" CARTRIDGES*

TOOLS AND METHODS IN USE AT THE FRANKFORD ARSENAL

BY DOUGLAS T. HAMILTON†

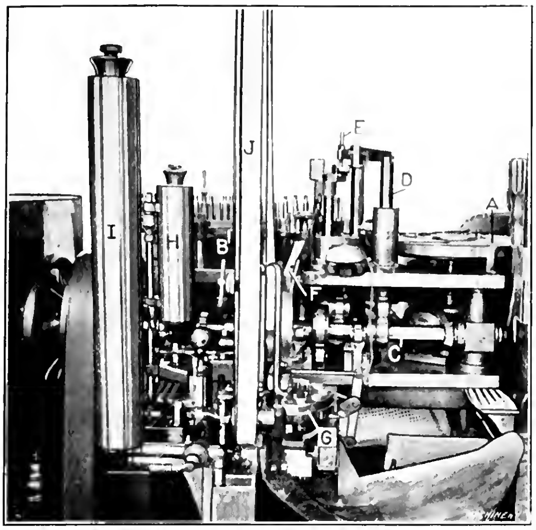


Fig. 1. Priming and waterproofing 0.30-Caliber Cartridge Cases

In the March number of MACHINERY the development of 0.30-caliber cartridge cases from the sheet to the finished shell was described. The operations taken up were blanking, cupping, drawing and trimming. The heading of these cases has been described in a previous article (see the April, 1911, number of MACHINERY), so it will be unnecessary to go into this subject here. The method of priming 0.30-caliber cartridge cases in the Frankford Arsenal is different from that described in the article mentioned, so we will start from the priming of the cartridge, or in other words, placing the detonating cap in the head of the cartridge case.

Priming—Inserting the Detonating Cap

The head of the cartridge case, when being formed in the heading machine, is provided with a pocket, which is made by a teat on the end of the heading bunter. This pocket is approximately the same size—slightly smaller—than the diameter of the primer, and the inserting of the primer in this pocket is called priming. It is accomplished in the machine shown in Fig. 1. The primers are located, fifty or more at a time, on the dial *A* by the operator, and the shells are located on the dial *B* as illustrated. Both the dials are rotated, dial *A* being driven at a constant speed, while dial *B* is indexed by means of a ratchet dial in the usual manner. Over dial *A* is a spring that constantly vibrates, due to the friction of the dial rotating under it, so that the primers are agitated and gradually pass into a narrow channel, one at a time. As the shell reaches the priming point, a primer is carried out by a finger, held in line with the pocket in the shell, and then a punch operated from a cam-shaft forces the primer into the pocket. At the same time that the primer is being inserted the cam on shaft *C* operates plunger *D*, which through a fulcrumed lever actuates a padded punch *E* that holds the shells down while the primer is being inserted. After the primer is inserted, a finger knocks the shell from the dial down the chute *F*. From this chute it is deposited in a dial *G* which is also of the ratchet type.

The dial *G* is used as a medium for holding the shells while the mouth and primer end is being lacquered or waterproofed. The lacquer is held in tanks *H* and *I*, one tank supplying lacquer to a swab that enters into the mouth of the shell, whereas the other supplies lacquer to the swab that lacquers the primer and head of the shell. These swabs, of course, are operated in opposite directions, one going into the mouth of the shell and the other coming up against the head. Then as the dial indexes around, a ribbon *J* rotated on pulleys passes across the head of the shell and wipes the surplus lacquer from the head. The shell then drops out of the dial and is deposited in a box under the machine. The lacquer used for waterproofing the mouth and head of the shell is composed of shellac cut with alcohol and resin. The cartridge case is waterproofed so that it cannot become non-explosive if it should be dropped into water. The shellac that is applied is distributed around the rim of the primer and

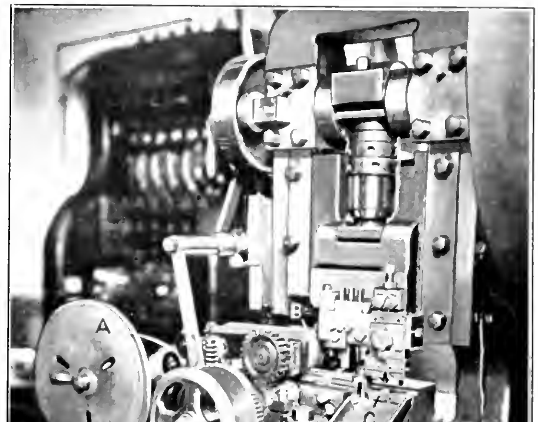

Fig. 3. A Machine used for making the Springs used in Cartridge Clips

Fig. 2. Inserting the Powder and Bullets and crimping—loading 0.30-Caliber Cartridges

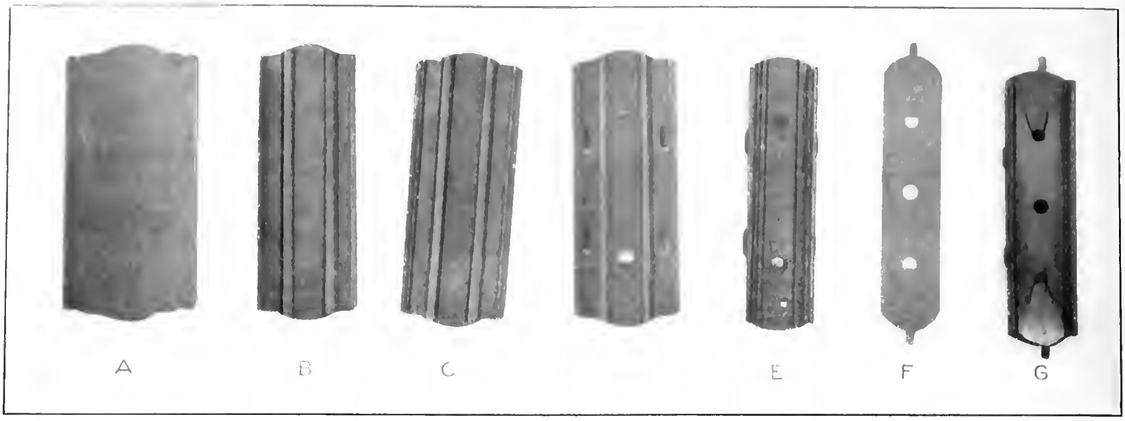

Fig. 4. Evolution of the Cartridge Clip that is used for holding Five 0.30-Caliber Cartridges

provides a protective coating. The lacquer deposited in the mouth of the shell after the nickel jacket bullet has been inserted serves the same purpose.

Loading

After the primers have been inserted in the cartridge cases, they are ready for loading. This consists in inserting the correct charge of powder and the bullet in the case, and then crimping the bullet into place. The cases are held in the box *A*, Fig. 2, from which they are removed by the operator and placed on a dial of the plain type. This dial carries the shells to the ratchet dial *B*, which, in turn, is indexed and presents the shells mouth up to the various loading containers and punches. The first action on the shell is to set it down properly. This is accomplished by a spring punch. Then the proper powder charge is inserted. The powder is held in the funnel-shaped container *C* and is removed from it by a slide operated by a crank motion. This slide comprises a small container that carries the correct charge of powder and deposits it in the shell in which it is packed by means of a punch. Then as the shell indexes around to the next position, a second charge of powder is inserted.

At the time that the operator is placing shells on the plain dial, he is also placing nickel jacketed bullets in the dial *D* with the points up. This dial is also of the ratchet type and after the powder has been put into the shell it is transferred from dial *B* to a position under dial *D*. Then a punch operated from a cam-shaft under the machine comes down on top of the bullet and inserts it in the shell. As the shell indexes to the next position, a crimping device turns in the top edge, holding the bullet in position. It is then ejected from the machine loaded.

Making Cartridge Clips

The device for quickly inserting cartridges in the magazine of a 0.30-caliber rifle consists of a clip which holds five cartridges sufficiently tight to prevent them from falling out. As soon as the clip is placed over the breech and the top cartridge pressed, they are ejected and pass into the magazine. The clips are thrown away after they have been emptied, so it is absolutely necessary that they be made very cheaply and at the same time in such a manner that they will not fail to perform their function. The main body of the clip is made from a sheet of brass stock about 0.021 inch thick by 2 7/16 inches wide. The sequence of operations necessary to complete this clip is illustrated from *A* to *G* in Fig. 4, and the machine for making the body of the clip is shown in Figs. 5 and 6.

Referring now to Fig. 5, which shows a front view of the press, the strip stock is held on a roll located at the right-hand end of the machine. The stock is fed into the machine by the ordinary type of feeding rolls, and the first operation is to cut out a blank as illustrated at *A* in Fig. 4. This is accomplished by the punch and die *B*, see Fig. 6. The blank is then ejected from the die and carried on to the next punch and die *D* and *E* by means of a transfer slide *C* similar to that employed in a multiple plunger press, that receives its motion from a crank mechanism at the left-hand end of the machine. The next operation, performed by the punch *D* and die *E*, is to form two ribs in the center of the blank, and turn up the two edges as shown at *B* in Fig. 4. The formed blank is then ejected and the transfer arrangement carries it on to the next operation, where punch and die *F* and *G* crimp the two outer edges into the condition shown at *C*. The edges of the blank are flattened down and at the same time turned up a distance about 3/64 inch above the top surface of the blank. The blank is then ejected from the die and is carried forward over die *H*. As punch *I* descends it forces the blank out of the transfer fingers and into the die *H*. This operation forms four projections which are shown at *D* in Fig. 4 that act as retainers for the spring to be inserted in later. The next punch and die *J* and *K* draw up the sides of the clip into box shape as shown at *E*. Then as the blank is passed on to the last punch and die *L* and *M* it is slightly curved and is ejected from the machine by a crank mechanism *N*, Fig. 5, which actuates the last die. This sequence of operations is carried on entirely automatically,

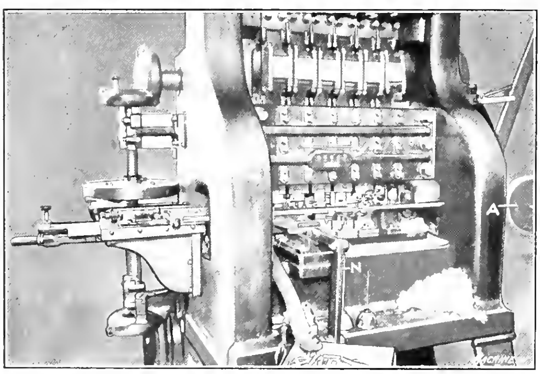

Fig. 5. The Cartridge Clip Machine—A Special Machine that completes the Body of the Clip in Six Distinct Operations

Fig. 7. Assembling the Spring in the Cartridge Clip

Fig. 8. Inspecting and weighing 0.30-Caliber Cartridges

and, in fact, the machine will run without any attention whatever until the roll has been exhausted. The operator then starts up the machine and the sequence of operations continues.

Making the Spring for the Cartridge Clip

In order to hold the cartridge in place in the clip, a curved flat spring *F*, Fig. 4, is used. This spring, which is made from a sheet of half hard brass stock 0.510 inch wide by 0.010 inch thick, is blanked out and bent to shape in the press shown in Fig. 3. The stock is held on a roll *A* shown to the left of the machine, and is drawn in by a pair of ordinary feeding rolls *B* operated by a ratchet mechanism receiving power from the crankshaft of the machine. The first operation is to cut off a strip to the required length, form the ends and pierce the three holes. This blank, by means of a carrier, is then transferred to the punch and die *C*. Here the blank is bent up into a curved shape and the spring prongs at each end are formed, after which it is ejected. These prongs are used in assembling the clips for holding the spring in place; they catch on a projection formed in the base of the clip. This machine is also entirely automatic in its operation, and when it is started will run until the roll of stock has been exhausted.

Assembling the Spring in the Cartridge Clip

The assembling of the springs in the cartridge clip is accomplished in the small bench machine shown in Fig. 7. The operator places the clip in a nest, then inserts the spring in a slide which carries it forward and inserts it in the clip. The spring is held on this slide and is pushed into the clip automatically by the prongs which fit into the raised catches in the clip. The clip is carried forward into the assembling position by another slide, which works beside the spring inserting plunger, and operates a carrier *D*.

In order to show the working mechanism of this machine, the top lid or plate that covers the mechanism has been removed, and is shown to the right of the illustration. The clip is inserted through the hole *A*, and the spring in the hole *B*. When the operator pulls the handle *C*, the slide advances carrying the spring and assembles it in the clip. After assembling, the clip is ejected from the machine and drops into a box placed beneath it. The assembled clip appears at *G* in Fig. 1.

Gaging, Weighing and Inspecting Loaded Cartridges

Before locating the cartridges in the clip, they are inspected, gaged and weighed. These three operations are all accomplished in one machine, which is shown in Fig. 8. The dies held in the dial *A* in which the cartridges are placed by the operator act as a gage for the body of the cartridge; that is, the contour of the holes in these dies is similar to the chamber of the rifle. As the dial passes around, the cartridges are carried beneath an electrically operated plunger which inspects them to see that each one has a primer in it. Should a cartridge be encountered that has no primer, this punch drops down into the pocket and breaks the electric circuit, which causes a bell to ring, thus notifying the operator that a cartridge with no primer has passed. When the primer is located upside down, the same action takes place.

The weighing of the cartridge is accomplished in a unique and interesting manner. As the dial *A* passes around, the cartridge is lifted up and caught by the ejector *B*. This transfers the cartridges to the scoops *C* which are carried on the weighing dial *D*. The weighing is done by balances *E* in which the cartridges are deposited by the scoops *C*. The bullet comes up to a stop in these balances and a wire hook attached to the balance catches on the wire *F* when the cartridge carries the correct charge of powder and dumps the cartridge into the box *G*. When the charge of powder in the cartridge is light the hook on the weighing balance *E* rides up over wire *F*, but as the dial passes around still further the hook catches on a wire located higher than wire *F*, and dumps the cartridge into the light charge box. It is therefore evident that cartridges which are light in weight pass the first box, but cannot go completely around, as they are ejected by the second wire, thus making certain of dumping the weighing balance and throwing the cartridge out. This mechanism successfully eliminates all light charge cartridges, and keeps them uniform in shooting quality.

Inserting Cartridges in the Clips

The machine used for inserting the cartridges in the clips is shown in Figs. 9 and 10. A dial *A*, which accommodates

Fig. 9. Cartridge Clipping Machine—assembling the Cartridges in the Clip

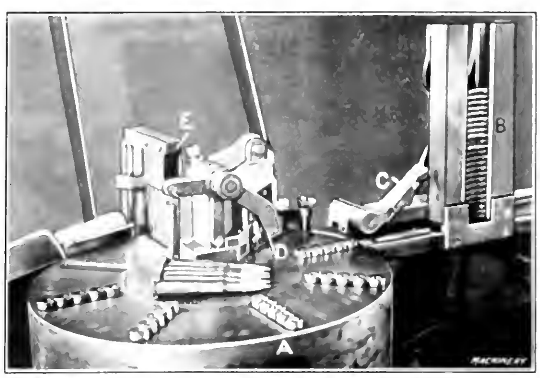

Fig. 10. A Closer View of the Machine shown in Fig. 9, illustrating the Operating Mechanism

five cartridges in a row, carries the cartridges around to where the clip is inserted over them. This dial is rotated by means of a crank motion, pawl and ratchet in the ordinary manner, the ratchet dial being located beneath the dial carrying the cartridges. The assembled clips are placed in the proper position in the magazine *B* by an operator; two operators are engaged in keeping the cartridge dial full. The clip is carried out from the bottom of the magazine by means of a carrier operated by an eccentric shaft, and is located over the five cartridges in the dial *A*. The "latch" *C* which is shown thrown back in the illustration runs under a roller held in bellcrank *D* and seats the clip properly on the heads of the cartridges. The dial then indexes to the next position, where a bending tool comes into action and bends down the prong projections on the ends of the spring in the clip, thus preventing the cartridges from dropping out. As the dial then indexes around to the next position, the cartridges that have been inserted in the clips are picked up out of the dial by means of a swinging transferring arm that drops them in a box. 65,000 of these cartridges are inserted in the clips per day of eight hours. Fig. 10 shows a closer view of the machine illustrated in Fig. 9, and gives a better view of its construction and operation. Here it will be seen that the ejecting or work-removing fixture is composed of two pieces of sheet steel, spring tempered, which grip the clip by the lower surface.

FROM THE CELLAR UP*

When a small boy, not yet in my "teens," I sought and obtained employment in an old Connecticut "hame" factory. I had visions of wealth that I would gain from my industry, and entered the employ of an old-time contractor, who, among other things, did the polishing of the metal work on hames. He used wooden wheels covered with leather and coated with glue and emery. A large part of my work was to "wash" or soak off the glue and emery from the worn wheels preparatory to re-coating.

I wish it were possible to show a photograph of the place and the facilities—a low, dark cellar, among rats and mice, where never a ray of sunlight entered. A small leak in the old waterwheel flume furnished the water supply. I had to hold the wheels and turn them gradually so that the coating of glue and emery might soak away. It was a tedious and ambition-killing process for a boy—holding one wheel at a time and slowly turning it to bring all parts of the circumference under the stream.

I can recall how injured my feelings were when I believed I was competent to perform the skillful mechanical work up in the shop above, and how I planned various protests, the language of which I readjusted from hour to hour, that it might be convincing when the auspicious moment for its utterance should arrive.

At last the injustice of my treatment became so great in my mind, and the foolishness and wastefulness of such labor so plain to me, that the invention of a machine for doing the soaking automatically kept rising uppermost in my brain, until I forgot my eloquent protest and fell to studying out the great invention. I forgot all about the fact that I was slowly turning in my hands the wheel that was soaking. I forgot all about the darkness and loneliness of my workshop in the mental visions of the machine that was to wash a dozen or more wheels in the time that I was washing one, and was to do this while I was employed at more useful and more interesting work above.

At last, when my vision was complete, full of hope and visions of progress, I summoned up my courage to explain it all to my employer. Alas! I did not know that I was then to learn my first lesson in opposition to progress. My employer laughed and several others with him. The impossibility of washing a dozen wheels at once and without labor was too clear to them to admit a doubt. Little did I realize then that this opposition was only the beginning of what my life should encounter in the introduction of new designs and processes. Little did I then understand that all progress must be made in the face of opposition from those who, it would be natural to suppose, would be most interested in it.

I then also learned my first lesson in false economics. I was informed that if such a machine could be made to work, I would be out of a job. I replied that I could be employed at some of the more interesting work in the shop. I was informed that there would then be no work for someone else. They were too much for me then, but I could not get over the belief that, with the washing machine in operation, I could be more profitable and my work more interesting. I was crestfallen. My invention was turned down by my employer. I was laughed at. I stole away quietly and waded in the pool under the waterwheel that was then still for the noon hour.

Time and change have wrought their wonders since then. The old "hame shop" is gone. A fire destroyed it years after, and the place where I worked, alone in the darkness, is now uncovered to the sunlight and the wild flowers bloom there. Fifty years have passed since then, and my washing machine has become a reality. Today there are many of these machines in use, and no boys are washing buffing wheels by hand.

In view of this, the facts I would impress upon young men are: First: That while the first struggles determine it afar off, final success in life comes not at the beginning of life, when one is young, but only after years of hard, patient work. Second: To succeed as a leader and creator of useful things, that help the world to a higher and better life, whether it be the designing and invention of machinery, methods, ideas or changes in any form, one must always encounter the opposition of both high and low, the educated and the ignorant. Third: The greatest reward comes by the way of one's own inner consciousness of having accomplished something to help the very world that has opposed him. For it is true that few men who really create the ideas and improvements that make the world better, receive frank recognition from those that their efforts have helped most.

* Abstract of an address delivered before the Boys' Vocational Club, Worcester, Mass., by Charles H. Norton.

LOAD CAPACITY OF BALL BEARINGS

In a lecture recently delivered before the Institution of Automobile Engineers (Great Britain), Prof. John Goodman, of Leeds University, dealt with the design of ball bearings. The lecturer has given the subject considerable attention for the past fifteen years, during which time he has conducted many experiments on this type of bearings. One result of his investigations has led to the establishment of the following formula which gives the maximum working load in pounds to be allowed for any given ball bearing:

$$\frac{Kmd^3}{ND + Cd}$$

where

m = the number of balls in the bearing;
d = the diameter of the balls in inches;
N = revolutions per minute;
D = diameter of ball race, taken from the point of contact of the ball with the outer race (for a thrust bearing D = the diameter taken from the centers of the balls).

The constants C and K are as follows:

For thrust bearings:

	C	K	
Flat races	200	500,000	
Hollow races	200	1,000,000	when the radius of the race is about twice that of the ball;
		1,250,000	when the radius of the race is about 9/16 that of the ball.

For journal bearings:

	C	K	
Flat races	2000	1,000,000	
Hollow races	2000	2,000,000	when the radius of the race is about twice that of the ball;
		2,500,000	when the radius of the race is about 9/16 that of the ball.

THE INSIDE OF THE MAGNETIC CHUCK—2

CHUCKS FOR VARIOUS PURPOSES AND PRINCIPLES OF DESIGN

BY HERBERT L. THOMPSON*

THE chuck shown in Fig. 8 is a simple rotary chuck for use in the lathe. Soft Swedish iron should be used in its construction, and if well made it will hold strongly enough for grinding, light drilling, boring and facing on such work as master plate blanks or sub-press dies. If provided with tapped holes in the face, it becomes what might be called a semi-magnetic faceplate which is very convenient for any work that must be indicated for location. The piece to be machined is held on the chuck by the magnetism and tapped with a soft hammer until located, after which clamping straps are applied so that severe machining operations can be performed. The general shape of the magnetic circuit in this chuck is similar to that of the one in Fig. 5, though, of course, this chuck is cylindrical while the one in Fig. 5 is rectangular; but the single coil and enclosing iron carry out the same idea. The hub, base and core are one piece, while the cover *A* comprises the outside magnetic circuit, both poles, the gap and filler. The cover *A* is pressed onto the shoulder of the base at *B*, and held in position by the screw *C*, which must bring the center pole piece and the end of the core into close contact at the same time that the rim of the cover completely engages the shoulder at *B*. The gap line is shown square, and the anchor spots *E* are milled into the edges of both pole pieces to retain the filler alloy. It will be noticed that the polar gap is wider at *F* than it is on the active face of the chuck; this is to increase the magnetic resistance of the gap, and prevent the magnetic current returning across the inner side of the gap as far as possible. This widening of the gap on the unused side of the poles is good practice with any chuck, and will materially increase the holding power of the chucking surface.

The coil for this chuck is not form wound. Being adapted for attachment to the lathe spindle, it is a simple matter to wind the coil directly onto the paper insulating sleeve *G* on the core *H*. The paper washer *I* prevents the wire in the coil from coming in contact with the base of the chuck; and the fiber washer *J*, which must be glued to sleeve *G*, holds the winding in place until the cover is attached. As a rotary chuck must revolve, it is impossible to attach it to the electric supply in as simple a manner as could be used for any kind of a stationary chuck. Some kind of moving contact must be provided, and nothing could be much simpler nor more efficient than the brushes and collecting rings shown in the illustration. The piece *K* is a fiber bushing bored to press snugly onto the hub of the chuck, and shouldered at each end to accommodate the two brass rings *L* and *M*. At diametrically opposite sides of the bushing *K* are milled the channels *O* and *P*, through which the ends of the coil wires are brought for attachment to their respective rings. The fiber bushings *Q* and *R* are provided to insulate the wires where they pass through the base of the chuck. The service wires are attached under the heads of the binding screws *S* and *T*, and current enters the coil through the brass brush *U*, the ring *M* and the wire through bushing *Q*. It leaves by the wire through the bushing *R*, the ring *L* and the brush *V*, after passing through the coil. The fiber base *W* may be of very different shape, and can be attached to the bed or the headstock of the lathe, depending upon which is most convenient.

Winding a Rotary Magnetic Chuck

To wind this chuck, it is necessary to remove the cover and have the insulating washers and sleeve in place with the glue dry. A short piece of single strand lamp cord is soldered into a hole through the ring *M* and passed through the bushing *Q*. The other end of the lamp cord is then firmly soldered to the end of the magnet wire of which the coil will be made. The reason for using the lamp cord is to provide a strong lead to the inside wire of the coil, as a slight slipping of the ring would probably break the frail magnet wire, which would make it necessary to entirely unwind the coil for repairs. For the same reason the lamp cord should be left as loose as possible, as a little slack may be necessary later on if the cord should become disconnected from the ring. The soldered connection between the magnet wire and the cord should be taped to insulate it from the rest of the wire, and the lamp cord should have at least one turn about the core to prevent any outside pull from bringing a strain directly upon the end of the magnet wire.

Magnet wire is always sold on a wooden spool, and this greatly facilitates the winding of coils in the lathe. A piece of half-inch rod should be fastened in a horizontal position, so that the wire spool can revolve freely upon it. After taping the junction of the lamp cord and magnet wire, the first few turns of the wire should be wound while turning the lathe by hand, so that the wire will bind the core and not slip when the speed is increased. The lathe can now be started by power, and the operator should feed the wire to the core as evenly as possible, in the same way that an old fashioned sewing machine bobbin is wound. It is far from necessary to lay each layer of wire exactly even, but it must be borne in mind that it is very advantageous to have as much wire as possible in the available space. For this reason, the coil should be revolved with considerable speed, and care should be used to prevent too much crossing of the successive convolutions. The winding should be continued until the wire is even with the opening in the bushing *R*, after which it is cut and passed through the bushing to be soldered into a slot in the edge of the ring *L*. No lamp cord is used on this terminal, as a break could easily be found and remedied without unwinding, and one turn of wire from the coil is sufficient to repair any break. After all connections are made, the coil should be wound with a layer of friction tape to prevent unevenness in the winding, and to keep centrifugal force from causing the wire to touch the inside of the cover and short-circuit the coil when the chuck is running.

If the chuck shown in Fig. 8 is wound for service on a voltage as low as twenty or lower, it is possible to simplify the construction to some extent by using the frame of the chuck and lathe as one of the electric terminals. Instead of using the ring *M* and brush *U*, the inside coil-end is simply fastened under a screw head anywhere on the iron part of the chuck, and the service wire that would be attached at binding screw *T* can be fastened under any screw head on the lathe. This arrangement brings the lathe and chuck into the electric circuit, and for this reason would be extremely dangerous on the higher voltages; but as a severe shock is impossible on twenty volts, it is here permissible and a real economy. The brushes and rings should always be kept clean, and especially free from chips or soldering acid, as either will be apt to short-circuit the chuck. A guard or shield of some kind protecting the rings and brushes is desirable if the voltage is high, as even 110 volts is unpleasant to handle with perspiring hands. It is a good idea to paint the exposed electrical connections with asphaltum, as a measure of insulation, but of course, this cannot be applied to the rings and under sides of the brushes.

Magnetic Lathe Chuck for Severe Service

For lathe work of a kind requiring fairly severe machining, it is possible to secure excellent results by the use of a chuck like that shown in Fig. 9. This differs from all the previous chucks in that it is strictly multipolar, having six independent cores and coils of alternate polarity, each attached to its own individual pole piece. A chuck of this description has many advantages over one provided with any form of bi-polar magnet, but is so much more expensive to make that it would be extravagant to use it on any work that

* Address: 287 Commonwealth Ave., Elgin, Ill.

could be handled on the cheaper and less complicated forms previously described. For master plate and fine die work, such as is commonly done on the bench lathe faceplate, this chuck is ideal. It will hold very strongly, and will give absolutely accurate results because there is no distortion due to clamping, as is invariably the case to some extent with the ordinary faceplate. Needless to say, it will save an enormous amount of time in setting up and locating.

If one considered the expense of making this chuck entirely of Swedish iron too great, the base *A* and enclosing frame *B* could be made of gray iron to good advantage, but in any case it is necessary to machine every part all over and very accurately. The cores *C* and the pole pieces *D* should be made of Swedish iron, and as they are by far the most important part of the magnetic circuits, the gray iron base will have but slight influence upon the holding power. The center piece *E* is a brass bushing provided with a tapered hole to hold a center pin for master plate work. It is threaded into the polar face of the chuck so that the tapers can be driven in or out without danger of dislodging the bushing. The cores *C* are firmly pressed into the holes in the base of the chuck, and it is very essential that these holes should be carefully indexed and bored, to insure a nice running poise for the finished chuck. The pole pieces *D* should all be made exactly alike, special care being taken to have the screw hole very accurately located. As the filler alloy is quite a factor in the strength of the polar face of this chuck, anchor spots similar to those illustrated at *E* in Fig. 8 should be milled into the edges of both the pole pieces and the enclosing frame. To apply the filler to this chuck, it is necessary to completely assemble the iron parts, locating the pole pieces with reference to the frame and each other as carefully as possible. The whole chuck can now be laid on its polar face while the molten alloy is poured in from the back through the threaded hole *F*. This binds the seven pieces of iron composing the cover together, so that the pole piece screws now hold the frame in place as well.

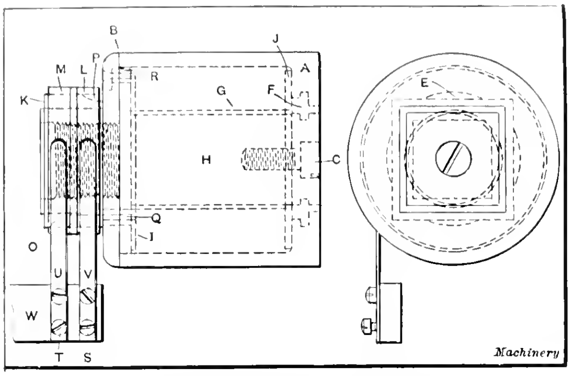

Fig. 8. A Semi-magnetic Chuck for Use on the Lathe

The coils for this chuck may be form wound, or they might be wound on separate wooden or paper spools, but in any case the finished coils must weigh the same. In connecting them up it is important for the electric current to pass around each in alternate directions, as shown in the illustration. In a multipolar magnet there are a number of separate magnetic circuits, and to secure the best results adjacent poles should always have alternate polarity. If a piece of work were laid across a gap between two poles of like polarity, it would be repelled instead of attracted; but if it also covered part of even one pole of opposite polarity, the attraction would become intense from all three. For this reason it is wise to make small sized pole pieces, so that very small work will be able to cover part at least of several of them. This is one of the excellencies of this chuck; it has a gap of intricate shape, but not of undue length for each pole piece, and it is possible for a small piece of work at the center to cover part of all six of the pole pieces. A magnetic circuit is also established if work is laid across the gap between the frame *B* and any of the poles; this is a valuable feature, as it makes the whole face of the chuck active. Its worth would be appreciated by anyone who finds it necessary to counterpoise a faceplate job on this chuck. What was said about the rings, brushes and terminal connections of the chuck in Fig. 8 applies equally to this case, as they are identical for any rotary chuck. The bushings *G* and *H* in Fig. 9 serve the same purpose that those shown at *Q* and *R* do for the chuck in Fig. 8, and as all of the coils in Fig. 9 are connected in series, there are but the same two terminals, though there are six coils.

Fig. 10 represents a multipolar chuck somewhat similar to that in Fig. 9, but made for use on the planer or milling machine. It is considerably easier to make than the chuck illustrated in Fig. 9, because it is not necessary to poise it. Gray iron can be used entirely in its construction, or the cores and pole pieces may be composed of Swedish iron to some advantage if exceptional holding power is desired. If made of gray iron only ten pieces are necessary, while if Swedish iron is used for the cores and pole pieces, it will take eighteen pieces of iron all told. This chuck differs from the one in Fig. 9 in that the frame *A* of the top plate extends between each pole piece, so that each pole is separated from its neighbor by two thicknesses of filler and a section of the frame. This adds something to the magnetic resistance of the gaps, and as the frame is active to work that is in contact with any one of the poles and to thin pieces that cover any number of poles, there is some advantage in this construction.

A chuck of this kind is particularly adapted for general tool work when large and small pieces of various shapes are to be held. It will hold extremely thin pieces better than any other kind of magnet would, and the active surface of the chuck face is so well distributed that work can be held upon any part of it. This chuck will stand the roughest kind of use, and being entirely iron bound, neither water nor oil will harm it if well made. It can be made in various shapes and sizes to accommodate special work, and though it is more expensive than some of the simpler shapes, it will also hold some forms of work for operations that would be impossible with a cheaper kind of magnet. Form wound coils can be used on this chuck, and they should be connected in series in such a way that alternate polarity will result in each successive pole. In attaching the coil terminals to the leading-in lamp cord, great care must be exercised to have both connections well taped for insulation; and to prevent accidental pulls on the cord from breaking the magnet wire, a knot should be tied in the cord large enough to prevent its being pulled through the bushing. Care in this particular will prevent frequent trouble from broken connections inside the chuck. This applies to any of the chucks described, as well as the one shown in Fig. 10.

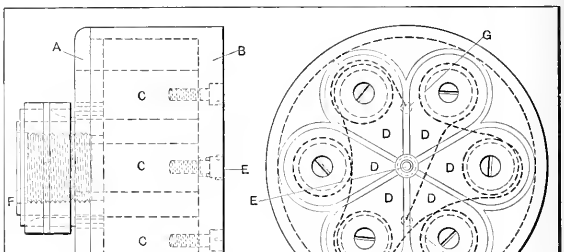

Fig. 9. Multipolar Magnetic Chuck for Heavy Lathe Work

Making Form-wound Coils

For winding the coils of any of these chucks, except the ones shown in Figs. 8 and 9, some kind of form is necessary, and Fig. 11 shows one made of wood that is quite satisfactory. It is about the right shape for the coils of the chuck in Fig. 6, but of course could as well be made any other shape. To use this form, place it between the centers

of the lathe and arrange a small dog or a stud on the face-plate to drive it. Support the spool of supply wire in front of the lathe, as when winding the coil for the chuck in Fig. 8. Insert three or four inches of the magnet wire under guide *A* at *B*, and wind several turns of it about the form, by hand, to prevent slipping. The winding can now be continued by power until the coil is brought to size. After stopping the lathe, and before cutting the wire, the coil should be wound with friction tape on both sides, so that it will retain its shape after being removed from the form. The slots in the form and guides permit this to be done very readily, after which the wire is cut and the form removed from the lathe. The pins *C*, *D*, *E* and *F* are now withdrawn from the guides *A* and *G*, and the coil can be pressed off the form with the guides. The form being tapered somewhat,

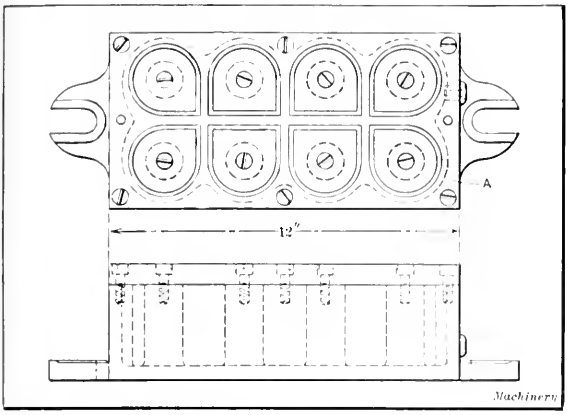

Fig. 10. Multipolar Chuck for Use on the Planer or Milling Machine

allows this to be accomplished quite easily without harming the insulation of the wire. Tape should now be applied to the whole coil until no wire is exposed except at the terminals, which should be left long enough to make connecting an easy matter. If all the coils are always wound in the same way, the terminals will issue from the coil in the same relative positions. This will facilitate connecting, as the direction in which the coil is wound can always be seen at a glance by the position of the terminals. Enameled wire is to be recommended for winding magnetic chuck coils, as it has many advantages over fabric insulation.

Principles used in Designing

In the foregoing descriptions of magnetic chucks, no mention was made of the reasons for the proportions used, nor were any rules given for establishing the size and quantity of wire to employ. These are, of course, matters of the greatest importance, and while experiment will often show opportunities for improvement in any predetermined winding, it is an easy matter to establish at least the size of the wire.

To secure maximum holding power, the cores for any magnet should be at least equal in cross-section to the work to be held. This means that the magnetic circuit should never be constricted to a smaller cross-section than the maximum of that part of the work through which the magnetic current flows when in place on the chuck. In case of a bi-polar chuck having cores on each side of the gap, it would mean one half of the cores. With a single coil chuck it would mean the total cross-section of the one core, and in the case of a multipolar it would mean one half as many of the cores as were actually engaged with the work, though in most cases such chucks are made for general purposes, and the core sizes become more a matter of judgment than of rule. The cross-section of the remainder of the magnetic circuit should exceed this, if weight or size is not an objection, as the lowest possible magnetic resistance is to be desired. Considerable latitude is permissible in the shape of the cores for any magnet. The greatest magnetic effect is obtained from the wire nearest the core, and for this reason a long core which would allow of a great quantity of wire in the first few layers would have this advantage, but as it would have the disadvantage of increased magnetic resistance due to its greater length, no real gain would result. A cylindrical core of a length greater than six or eight times its diameter will leak magnetism badly through the air, and the length can be carried to such extremes that practically all of the current will be absorbed in this way. On the other hand, a core could be so short that there would not be enough room for sufficient wire adjacent to it to magnetize it to any extent. Generally speaking, it is well to make cylindrical cores about twice as long as their diameters, and they should be energized by a coil not larger than three times the diameter of the core. That is, the winding must not be thicker around the core than the core diameter. If a greater cross-section is needed than can be secured by a cylindrical core of correct proportions in the space available, it is advisable to use an oblong shape as in Figs. 5, 6 and 7, and the windings should not be thicker on one side than the smaller diameter of the core.

Weight of the Required Wire

When the iron parts of the chuck are finished, and the size of the coils has been determined, it becomes necessary to discover the proper size of magnet wire to use in the coils to accommodate the voltage of the circuit upon which the chuck will be used. The weight of wire necessary to make one coil must first be found. To do this, pick any large size wire from a table of dimensions of copper wire, which can be found in almost any electrical or mechanical handbook. Find the diameter of the wire from the table, and see how many times the diameter is contained in the length of the core to be wound. This will give the number of turns to one layer, and the thickness of the coil divided by the diameter of the wire will give the number of layers. Multiply the number of layers by the number of turns in one layer and we have the total number of turns. Find the length of one turn of the wire in the middle layer; this will approximate the average length of all the turns, and the total length of the wire on one coil can be found by multiplying the average length of one turn by the number of turns. Having arrived at the total length of the wire, its weight can be found from the table under the heading "Weight and Length." The actual weight of the coil will be about three-fourths of that found, as some allowance must be made for insulation and the crossing of the wires in winding. The weight of a coil of given size will be the same, regardless of the size of the wire

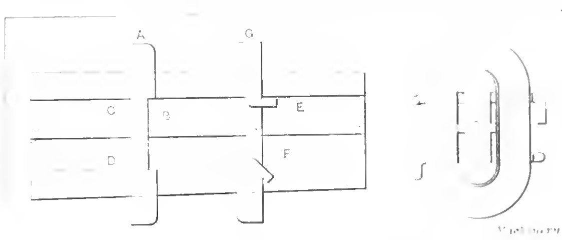

Fig. 11. Form on which the Coils for Electromagnetic Chucks are wound

used, so a haphazard choice of a size for experiment is permissible. Having the weight of one coil, the weight of all of the wire on the chuck can be found by simply multiplying by the number of coils.

The passage of an electric current through a wire is always attended by some heat, and too much current will cause a rise of temperature sufficient to ruin the insulation of the wire. For this reason, the wire to be used on any magnet must be of such size that the quantity required for the coils will have sufficient resistance to prevent the voltage used from forcing more than a safe amount of current through it. Ohm's law states that the current in amperes in any circuit is equal to the number of volts acting on it divided by its resistance in ohms. From this, it is an easy matter to find the amount of current that any voltage will force through the chuck coils after the wire size is established, so that its re-

sistance can be found from the table. Small magnet wire should carry from 1500 to 2000 amperes per square inch of cross-section without undue heating. Knowing the safe carrying capacity of the wire per unit of cross-sectional area, the weight of wire required for the coils and the voltage upon which the chuck is to be used, no further data is required for finding the wire size.

In the "Ohms per pound" column of the wire table, find such a resistance that, when the voltage to be used is divided by it, the result will give a quotient in amperes close to the safe carrying capacity of the wire which it represents. The cross-sectional area of the wire is always given in the table. There will be considerable difference between the results obtained from wire sizes next to each other, and it may not be possible to find a size that will be just right for the size coils in hand. If this is the case it will generally be safe to use the next size larger, because if the coils did heat to some extent, it would be an easy matter to add a few extra layers of wire to the coil, which would bring the resistance up to that required.

WIRE TABLE OF SIZES SUITABLE FOR MAGNETIC CHUCKS

Number B. & S. Gage	Diameter in Inches	Area	Capacity in Amperes	Feet per Pound	Ohms per Pound

Machinery

Method of Determining Wire for a Given Voltage

As an aid in figuring the wire sizes for different voltages the table above is given for the range of sizes most likely to be used in magnetic chuck work; and in addition to the usual data, it includes a "capacity column" in which the safe range of load for each size wire is given. To illustrate the method of finding the wire size for a given voltage, take for example a chuck designed with four coils, the cores of which are to be cylindrical in shape, 1½ inch in diameter and 2½ inches long. Space should be provided for a depth of winding of ¾ inch and this is to be filled with wire of the proper size to accommodate 20 volts. Referring to the wire table, find a wire of rather large size whose diameter will be nearly evenly contained in the depth of the coil winding ¾ inch. No. 15 answers very well in this case, as it has a diameter of 0.057068 inch bare and with the insulating enamel on would come very near to 1/16 inch. This is contained in the winding depth ¾ inch twelve times, so it will take twelve layers of No. 15 wire to complete a coil, and as 1/16 is contained in the core length 2½ inches forty times, there will be that many turns of wire in each layer. If there are twelve layers of forty turns, each coil with contain $12 \times 40 = 480$ turns in all.

As there is to be a depth of wire on the cores of ¾ inch, a turn of wire that lies at half this depth or ⅜ inch from the core will have an average length. This length can be readily found by multiplying the diameter of the turn in question, which is 2¼ inches, by 3.1416. This gives a length for one turn of 7.0686 inches, and multiplied by the number of turns, 480, gives a total length for the No. 15 wire on one coil of 3393 inches, or practically 283 feet. Referring again to the wire table, No. 15 wire is found to run 101.40 feet to the pound, so dividing 283 feet by this value gives approximately 2.8 pounds as the weight of wire of any size that one coil will contain. As the chuck in question has four coils, the total amount of wire required will be 11.2 pounds. Having determined the weight of the wire for the entire chuck, it remains to find a size of wire that will have the correct resistance for the voltage. This resistance must be such that 20 volts will have just sufficient pressure to force the safe carrying capacity of the wire through it. Taking as an experiment the same No. 15 wire, 0.32307 is found in the wire table to be its resistance in ohms for one pound. Multiplying this by 11.2 gives 3.6 ohms as the resistance for the entire chuck. To find the current this will allow to pass, it is only necessary to divide the voltage, 20, by the resistance, 3.6. The result is 5.5 amperes, and as the wire table gives the capacity of No. 15 wire at from 3.8 to 4.8 amperes it is plain that a smaller wire will be needed for this chuck. Taking No. 16 as next choice, 0.51373 is given in the table as its resistance for one pound, or 5.7 ohms for 11.2 pounds. Dividing the 20 volts by this resistance gives 3.5 amperes, which is well within the capacity 3.2–3.8 given in the table for No. 16 wire. Therefore this chuck will require a winding of 11.2 pounds of No. 16 wire, to operate at 20 volts.

If the chuck were to be used on any other voltage, proceed in the same way to find the wire size, but it must be understood that these sizes, as found, can often be improved upon by experiment. For instance, a chuck having oblong cores of large size and a heavy base in close contact with some heavy machine platen could stand a heavier load on its wire than a light weight enclosed chuck for use on a lathe. In the first case, the excess heat would be rapidly carried away by the heavy parts, while in the light chuck it would simply accumulate. Again, some chucks may be made for very short operations with longer idle intervals. In such cases, lighter wire than called for by the load may be employed with good results, as insufficient time will be allowed for dangerous heating. No rule can be given for securing a certain holding down pressure, as conditions vary considerably in every case. A chuck that would hold a 6 by 12 by 2 inch block of iron with a pressure of 200 pounds to the square inch would not hold a piece the size of a dollar with nearly that strength. It can be said, however, that any of the chucks illustrated should hold a flat piece 1 by ½ by 6 inches strongly enough so that a very strong man could not move it with his hands.

It is very unlikely that perfect results are ever secured in winding coils for a certain voltage without some experimenting. The amount of current a coil of a given sized wire will stand varies with different conditions. The shape and size of the coil, the weight and shape of the core, the kind of insulation used and the opportunity given for air circulation are some of the factors in determining the heating properties of any chuck. A mild warmth after the chuck has been in use continually for an hour or so is not objectionable; in fact, this would indicate good results.

Method of Connection to Circuit

For connecting the finished chuck to the current supply, ordinary drop cord is very satisfactory. It should be soldered to the coil terminals and very carefully taped at the splice. Some sort of switch must be provided, preferably one that will allow reversing of the current to demagnetize the chuck when large work is being held, as the temporary residual magnetism is likely to be very strong in a gray iron chuck. A double-pole, double-throw, knife switch fulfills these requirements nicely; such switches are easily obtained and quite inexpensive. There are six binding posts on these switches, two in the center to which the blades are attached, and two at each end into which the blades engage when thrown in either direction. The drop cord from the chuck should be attached to all four of the end poles, each separate conductor being scraped and fastened to one binding post on the near end of the switch, and then brought diagonally across to the post on the extreme opposite end and attached. The service wires enter the binding posts in the center of

the switch—the same ones to which the blades are pivoted. Closing the switch into one pair of the end posts allows current to flow through the chuck coils in one direction, and reversing to the other end changes the current flow to the opposite direction, thus changing the polarity of each pole in the chuck. This cannot be accomplished instantaneously, and it is plain that there must be one point in its progression at which there will be no polarity and consequently no magnetism. If the switch is opened from the second contact at this precise instant, both the chuck and work being held will be found to be completely free from magnetism. Of course in practice one could not hope to perform this operation accurately enough to demagnetize the chuck perfectly each time, but a sufficient reduction in holding power for the easy removal of work can always be accomplished.

Objection to magnetic chucks for milling and planing is often raised by inexperienced people, on account of the chips sticking to the chuck, work and tools. This is largely fallacious, as a moment's consideration would show. Each individual chip in a magnetic current becomes a separate bar magnet, having a polarity the same as the main current. It can stand only lengthwise with the current, and is only attractive to the ends of opposite polarity of its lengthwise standing neighbors. For this reason, chips will always be found standing on end on the chuck, work and tools, except where they cross a polar gap directly. In this position, they are less likely to crowd between the cutter and the work than if lying free, and as their actual attraction to the magnet is very slight, it is scarcely a factor. When the chuck is demagnetized, the chips can be removed more easily than from the average clamping fixture, as there are no clamps, straps, screws nor dogs for them to gather under; and if cast iron is being worked, the workman will appreciate the fact that the dust is all sticking to the chuck where he can carefully remove it with an oily cloth, instead of filling the surrounding atmosphere, his nostrils, lungs and clothes. On tool work that must be closely watched, if the cut is very heavy the accumulation of chips on the cutter may be somewhat of a nuisance, and it will be necessary to remove them from time to time with a bristle brush. Again, where oil is used in working steel, it is often impossible to get good results without brushing off the chips as they are formed. However, it is doubtful if these difficulties are increased to any extent by the magnetism, and the fact that it does not cure them is not a good argument against the magnetic chuck.

It is to be regretted that an alternating current will not operate a magnetic chuck satisfactorily, as this requires a special direct-current dynamo to be driven from the lineshaft in those factories equipped with alternating-current lighting systems. It is often the case, though, that the dynamo can be purchased and installed and the chuck built at less expense than would be necessary in making one clamping fixture for the work in hand. If there are a number of chucks to be supplied with current, the dynamo expense becomes but an item, and the possibility of using a much lower voltage than that supplied for lighting is at times a decided advantage, especially when rotary chucks are to be used. The life of a magnetic chuck is very long, as there are no working parts to wear or become deranged. The active face can be refinished at times to keep it true, and beyond this nothing is needed except possibly a new piece of lamp cord when the old one becomes badly frayed. Magnetic chucks are cheaper to design, build, operate and maintain than most fixtures of any other kind; and though it is true that they cannot be used in a great many cases, still there are so many kinds of work that could be successfully held by them that they are bound to become vastly more popular as their many merits are realized.

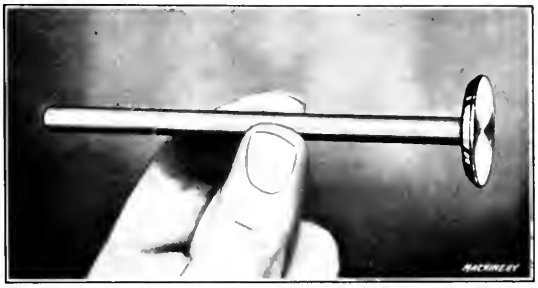
* * *

One of the most dangerous common objects and one frequently seen is a board lying on the floor or ground with nails projecting upward. Many serious accidents have resulted from such obstructions. Workmen stepping on sharp-pointed nails run the risk of puncturing their feet. A wound caused by dirty, rusty nails may cause lockjaw and death.

RAPID WORK ON THE CLEVELAND AUTOMATIC

The illustration shows a gas engine poppet valve 4 1/4 inches long over-all, having a head diameter of 1 1/16 inch, which was made on one of the Cleveland Automatic Machine Co.'s 7/8-inch machines, built for the Fairbanks-Morse Co., of Beloit, Wis., at the rate of 24 an hour, or 2 1/2 minutes each. The forming is a separate operation from the milling of the stem, because two tools cannot work in conjunction with each other on this part.

The valve stem was reduced with a single box-tool equipped with roller supports in one cut. The size of the stock is 1 1/16 inch and the diameter of the stem 1/4 inch. This means that



Gas Engine Poppet Valve produced at the Rate of Twenty-four an Hour on the Cleveland Automatic

the diameter of the stem part is reduced 13/16 inch in one cut. Notwithstanding this great reduction of the diameter the stem is parallel within 0.00025 inch.

This job indicates that the Cleveland roller-rest box-tools are of first-class design, because in removing so much stock in one cut and reducing the stem to such a small diameter it is done with such close approach to exact parallelism. To be able to produce machine parts so accurately and rapidly is indeed a triumph for the automatic machine.

* * *

At the last annual meeting of the Association of German Machine Tool Manufacturers, it was stated that the reaction in the general machine building field, which manifested itself toward the end of last year, had also made itself felt in the machine tool business. The works of the various machine tool builders, however, continue to be fairly busy, although in some branches the business on hand is not sufficient. This is especially true of the works where medium and small machines for general purposes are manufactured, as the demand for this class of machinery has materially diminished. As far as large and special machine tools are concerned, the position is quite favorable, although several works, which as a rule could promise delivery only after several months, are now able to fill orders at short notice. A point of great importance to the makers of large and special machine tools in Germany is that the comprehensive extension to the works of many large concerns, and the extraordinary demands for the equipment required by the railway shops during the last few years, have now come to an end. In the same way, many works manufacturing arms have been equipped during the last few years and new equipment in this line is not required at the present time. Export business has also suffered somewhat, except the export trade to Russia, where, owing to the increased industrial activity which at present manifests itself in that country, the trade conditions are favorable.

It was stated that wages and salaries are on the increase in the machine building trades and that the ever-increasing tax burdens tend to make the cost of production greater. The competition from America and lately from England has also made itself felt in the international market. The discharge of labor has, on the whole, been avoided by the German machine tool builders, but if the trade conditions are not altered within the near future, it will be necessary to somewhat reduce the number of men in the industry. On the whole, the prospects for the present year were considered rather gloomy. It will thus be seen that the present depression in the machine tool trade in the United States is by no means a local condition.

JIGS FOR MACHINING PISTONS

BY I. W. SPRINK*

The jig shown in Fig. 1 is used successfully in cross-drilling pistons. It possesses a few novel features that may be of interest to readers of MACHINERY who have work of a similar nature to perform. In the first place it will be seen that the piston is drilled from both sides and not all the way through from one side, which is the common practice, especially when the work is done on some style of lathe. It is not an easy matter to drill and ream a true hole by starting on one side of the piston, drilling through one boss and then advancing the tool across the opening between the bosses and expecting the tool to get a true start in the second boss.

This jig was made in the following manner to insure accuracy. A block of cast iron was milled square and the large hole rough-bored to within 1/16 inch of size. This block was then milled across one end to receive the stop-bar *A*. After fitting the stop-bar, it was removed and the seat for the clamp-bar *B* was bored by using a fly-cutter in the milling machine. This clamp-bar was a piece of two-inch cold-rolled stock, milled flat to form a little more than a half round. During the succeeding boring and grinding operations the clamp-bar was held to its seat by the two screws *C* which had washers under their heads instead of the springs shown in the illustration. A piece of 0.005-inch stock was placed between the clamp-bar and seat while boring and grinding; this shim was taken out later to allow for a little clearance. After the clamp-bar was fitted and bored, the holes for the hardened bushings *D* were bored and the bushings fitted. These bushings were long enough to reach through the large bore so that they could be ground flush with the inside of the jig.

The jig was next set up on the table of a Heald cylinder grinder and the holes in the bushings ground in line and true to size. The jig was then placed on one side with the bushings in a horizontal plane and the large hole finished to size by grinding. To be sure that the holes in the bushings would be perfectly central with the large bore, an arbor was ground to a snug fit for the bushings and the large hole was gaged from it, measuring from the wall of the large hole to the arbor until both sides were exactly the same. The hole

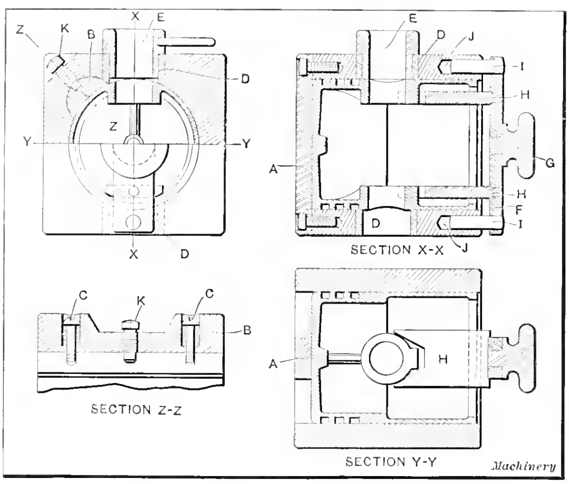


Fig. 1. Jig used for cross-drilling Pistons

was then finished 0.003 inch larger than the piston to be worked on. Two slip bushings *E* were made to fit the bushings in the jig, one for the three-lipped drill and the other for the reamer. The reamer used was 0.0015 inch under size, so that the holes could be finished with a long hand reamer that reached through both holes of the piston.

To locate the piston in the jig so that the bosses would line up with the holes being drilled, the "locater" shown at the open end of the piston was made and used in the following manner. The locater consists of the cross-bar *F*, into which are fitted the knob *G* that is used for a handle, two flat bars *H* with V-slots in the ends, and the two pilot pins *I*. The pilot pins fit into holes *J*, bored in the face of the jig in line with the bushings. In using this locater the piston was first put into the jig and then the locater was pushed in until the V-slots came in contact with the bosses. This put the piston in such a position that the bosses were in line with the drill bushings. After locating, the piston was gripped by the clamp-bar by tightening the set-screw *K*.

In this case the pistons were rough-drilled 3/32 inch under size before turning, so that in this jig it was only necessary to use one drill and reamer. The drilling operations were as follows: The drill bushing was put in and the drill run through one side. The bushing was then taken out, the jig turned over, and the bushing put in the other side, after

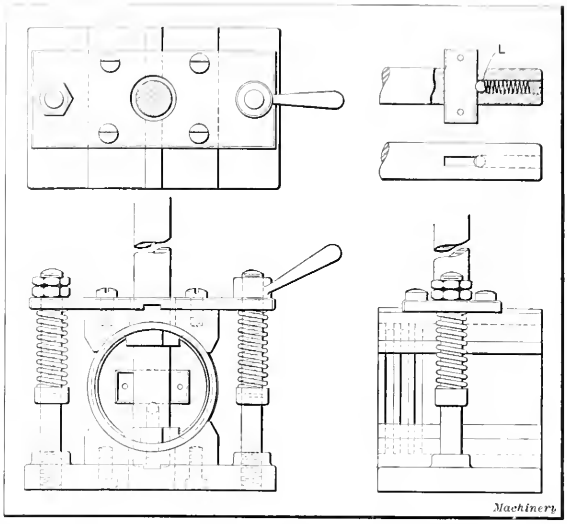

Fig. 2. Jig used for facing the Bosses in Pistons

which the second boss was drilled. The drill bushing was now replaced by the reamer bushing and the hole reamed; the bushing was then taken out, the jig turned over, the bushing replaced and the second hole reamed. It may be well to mention that when using this jig two strips were fastened to the drill press table forming a channel in which the jig could slide and which would also hold the jig in line with the machine spindle.

Jig for Facing Bosses in Pistons

Fig. 2 shows the jig and facing bar used for facing the bosses in the piston after it leaves the cross-drilling jig. It was found advantageous to do this operation in a separate jig because it consisted of top and bottom facing and also because the machine spindle had to be set to a stop. This jig proved to be a very handy and rapid tool. The base and the adjustable top are provided with a pair of jaws bored to the proper size to fit the piston to be worked on. The springs on the upright studs hold the upper or clamping jaw up while the work is being put in or taken out.

In operation, a piston is slipped between the jaws, the facing bar run down through the cross-drilled holes, the cutter fitted into the bar, and the top jaw set by a half turn of the lever handled nut. A novel feature of the facing bar is the manner in which the cutter is held. It will be seen that the cutter has a half round notch in the center of the bottom edge that registers with a steel ball *L* in the center of the cutter slot. A stiff spring holds the ball to its seat in the bar. The cutter is also provided with two holes near each end that are used for pulling it out of the bar with a stout wire hook. It is double edged, so that both bosses can be faced without reversing it or stopping the machine. This method of holding the cutter would not do in the case of a boring tool but for a facing tool it serves very well. Of course the cutter must be a nice fit in the bar. The illustrations are so plain that a detailed description is hardly necessary except to mention that when the facing jig is used it can be clamped to the machine table, while the cross-drilling jig is not clamped, because it is necessary to turn it over and over.

MACHINING AUTOMOBILE WHEEL HUBS ON BARDONS & OLIVER TURRET LATHE

Fig. 1 shows an automobile wheel hub that is made from a malleable casting and is machined in a Bardons & Oliver turret lathe in the plant of the Kelsey Wheel Co., Detroit, Mich. The method of handling this work and the sequence of operations performed upon it are interesting, and no doubt

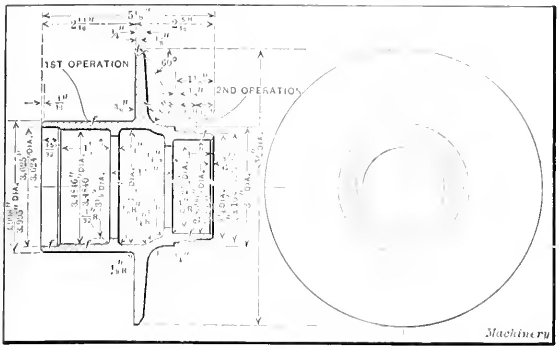

Fig. 1. Automobile Wheel Hub made from a Malleable Iron Casting and machined Complete in 7½ Minutes

will be appreciated by mechanics in general. Fig. 2 shows the machine used, which is a No. 9 Bardons & Oliver turret lathe, and gives a good idea of the tool set-up. Figs. 3 and 4 show diagrams of the tool equipment used for performing the first and second series of operations.

The first series of operations is shown in the plan view Fig. 3. The casting *A* is held in a three-jawed chuck *B*. First tool No. 1 equipped with two cutters rough-faces the flange, while the inner and outer surfaces of the cylindrical part are rough-bored and turned by the combination turning and boring tool No. 2. This tool has, in addition to a regular bar, a bracket or tool-holder projecting above the work and carrying cutters that operate on the top or outer surface of the work. Tools Nos. 3 and 4 come into action next, tool No. 3 finishing the surfaces roughed out by tool No. 2, and tool No. 4 finish-facing the flange and end of the hub. The detailed side view of tool No. 3, which is practically the same as No. 2, shows the arrangement of the cutters *C* and *D*. One of the cutters turns the cylindrical surface of the body of the hub and the other bevels the end of the hub. The hole in the hub is next finished by tool No. 5, which is a stepped reamer that machines the bore and counterbore to the required size within close limits. The surfaces machined by the different tools referred to are indicated by the sectional view *E* of the hub, that shows which tools are used on each surface.

For the second series of operations the position of the automobile hub is reversed; in this case it is held in a spring collet, as shown in the plan view Fig. 4. The finished cylindrical end of the hub is inserted in the split collet *F* which is drawn back into the tapered collet ring by rod *G* operated by the turnstile handle *H*, Fig. 2. This closes the collet tightly around the casting. The first operation is that of facing the side of the flange and end of the hub with tool No. 6, which is held on the cross-slide in the working position shown in the illustration Fig. 4. A broad cutter *H* is used for facing the flange and finishing the large fillet, and the end is faced by a smaller cutter *I*. When these tools have been withdrawn, tool No. 7 is moved up to take the roughing cut from the outside of the cylindrical end (preparatory to cutting a thread) and rough-bore the hole. These same surfaces are then finished by tool No. 8. The arrangement of tools Nos. 7 and 8 is shown by the detailed view. Tool *J* turns the part to be threaded, while tool *K* turns the end beyond the threaded part, and tool *L* bevels the corner or edge.

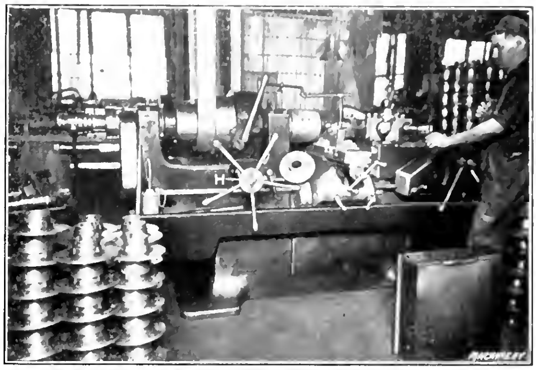

Fig. 2. No. 9 Bardons & Oliver Turret Lathe used for machining Automobile Wheel Hubs

The reaming tool No. 9 is then indexed to the working position for finishing the hole and beveling the outer edge slightly. At the same time the form tool No. 10, held on the rear of the cross-slide, is brought up for beveling the flange to an angle of 60 degrees and turning the outside of the flange

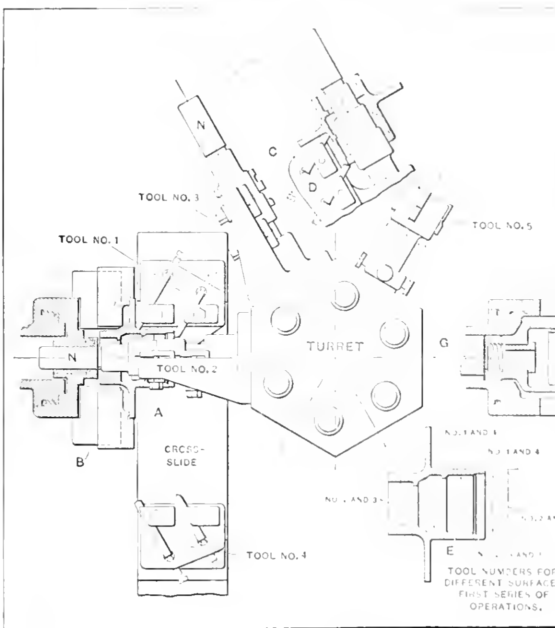

Fig. 3. Diagram showing Layout of Tools for performing First Series of Operations on Automobile Wheel Hubs

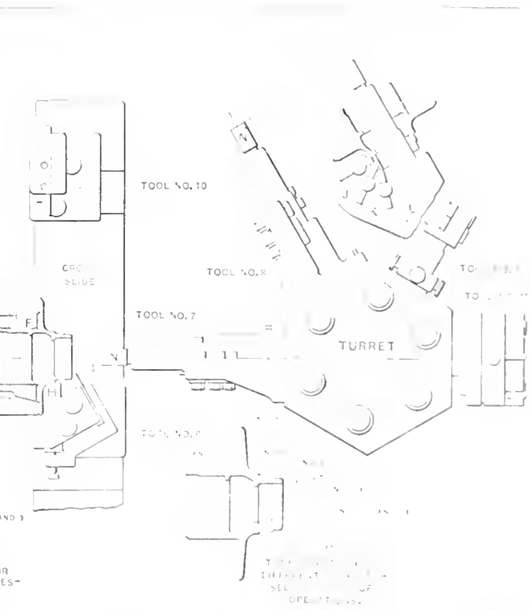

Fig. 4. Diagram of Layout of Tools for performing Second Series of Operations on Automobile Wheel Hubs

to size. The final operation to be accomplished is that of threading the end, which is done with die No. 11. The boring bars of tools Nos. 2, 3, 7 and 8 are all provided with pilots A which enter close fitting bushings held in the spindle to steady the bar while the cuts are being taken—this is a common method of supporting the tools.

The feed of the turret for both the first and second series of operations is 1/27 inch per revolution of the work, and the work is rotated at 60 revolutions per minute for taking the roughing cuts, and 90 revolutions per minute for taking the finishing cuts. The total calculated time for machining one of these castings is about $7\frac{1}{2}$ minutes, which includes the time required for placing the work in the chuck, but a product of 85 to 95 completed hubs is secured in ten hours. The following gives in detail the actual time required for each operation and indicates the ease and rapidity with which this work is handled.

Time for first series of operations on hub: chucking, holding work in a three-jawed chuck—20 seconds;

Tools Nos. 1 and 2: rough-facing, turning and boring, 1 minute, 45 seconds;

Tools Nos. 3 and 4: finish-facing, turning and boring, 1 minute;

Tool No. 5: finish-reaming, 37 seconds;

Total time for first operation, 3 minutes, 42 seconds.

Time for second series of operations: chucking, 10 seconds;

Tool No. 6: facing, 45 seconds;

Tool No. 7: rough-turning thread end and rough-boring, 1 minute, 3 seconds;

Tool No. 8: finish-turning thread end and finish-boring, 37 seconds;

Tools Nos. 9 and 10: finish-reaming and forming, 45 seconds;

Tool No. 11; threading, 25 seconds;

Total time for second series of operations, 3 minutes, 45 seconds.

TOY CONSTRUCTIONS FOR ENGINEERS

Two or three concerns have lately placed on sale construction materials for boys, amateurs and others interested in the making of models, etc. These devices were first offered as toys pure and simple, but later developments apparently have shown their value for engineers, inventors and others desiring to make working models of bridges, towers, frames, cranes, etc. Models can be quickly and cheaply made to illustrate constructions much more graphically than drawings.

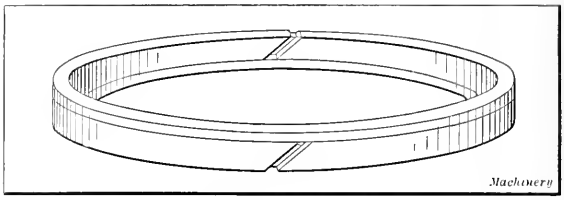
The illustration shows models built of "Bill Deezy" materials, made by the Bill Deezy Co., Boston, Mass. The basic principle of this construction is very simple, consisting of so-called flexible joints and coppered steel constructive rods. The flexible joints are in the form of a tinned sheet metal cross. The arms of the cross are curled, forming four sockets for the construction rods. These joints can be used in a variety of ways. When only three wires are to be joined, the fourth arm is removed with pliers. If only two arms at an angle are required, the other two are removed, etc. The material is sufficiently flexible to allow the arms to be bent to other angles than 90 degrees. Bracing wire, pulleys, car wheels, cable, are also supplied for working models of crane mechanism, etc.

Contractors should often find these construction materials useful when figuring on estimates of work out of the ordinary. Models on a small scale can be made and a better idea of the constructive difficulties can be obtained in many cases, no doubt, than where everything is laid out on paper.

* * *

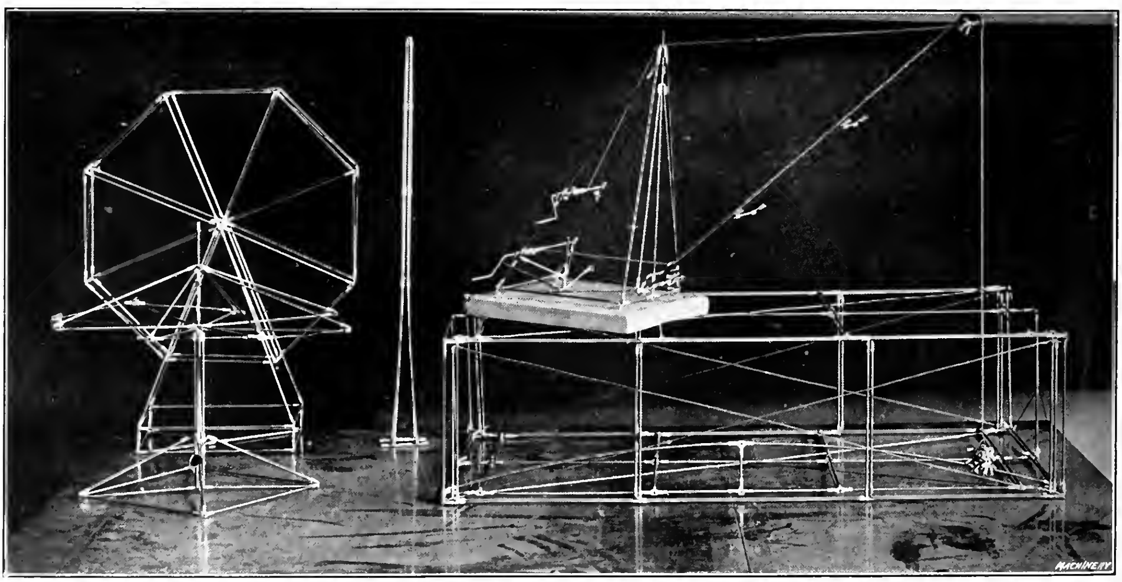
"LEAK-PROOF" PISTON RING

It is a curious fact that the common piston rings of steam and gas engine pistons are makeshift contrivances for which no greatly superior substitutes have been invented. Probably none of the piston rings in use are leak-proof except when the cylinder, piston and rings are newly fitted. As soon as



A "Leak-proof" Piston Ring

wear takes place the steam and gases can escape through the opening in the rings past the piston. Different forms of piston rings have been devised to overcome the fault, but none have been completely successful. They have succeeded in fooling users perhaps, but not the fluids that they were intended to restrain. The illustration shows a double piston ring designed for gas engines that is advertised as "leak-proof." It is a double ring consisting of two concentric angle rings split in the usual manner and fitted together so that the openings in the rings are opposite. No doubt this is an efficient design, but obviously it cannot be leak-proof when the cylinder and piston grooves are worn. When the gases can freely enter the groove beneath the rings from the pressure chamber, they escape readily through the opening in the ring next to the exhaust chamber.



Ferris Wheel and Derrick Models made of "Bill Deezy" Joints and Rods

RECESSING TOOLS*

TOOLS, ARRANGEMENTS AND FIXTURES USED FOR RECESSING IN LATHES AND BORING MILLS

BY ALBERT A. DOWD†

MANY varieties of cylindrical work call for the machining of an annular recess or groove in a place which may be inaccessible to the cutting tools. The form of recess varies greatly and the accuracy required is likewise variable. The form may be either narrow or wide, deep or shallow, while the accuracy called for may be either within narrow or liberal limits, as, for instance, when the recess is for clearance only. In fact, in the majority of cases the purpose of the relief or recess is merely to obtain clearance for some moving part or for tools when machining an adjacent surface. Very frequently a groove is cut to serve as an oil-pocket or to provide a space which can be filled with packing to act as a gland. It is evident that great accuracy is not essential when the work is of this nature. There are occasionally conditions which require more accurate work, as, for instance, when another piece is to be sprung into place, such as a spring ring or something of a similar nature, but even in a case of this kind a certain amount of inaccuracy is permissible. The machines to which recessing tools are most frequently fitted are the engine lathe, the horizontal turret lathe, the vertical turret lathe, the vertical drilling machine and the horizontal boring mill. Other machines are occasionally equipped with tools for the same purpose, but those mentioned are most frequently used.

In many cases the position of the relief or groove is such that it cannot be readily seen by the operator, nor can it be easily calipered. The workman, therefore, must tell how the tool is cutting by the "feeling" of it and by the character of the chips. He is really "working in the dark," and for that very reason every precaution must be taken, in regard to position of tools, diameter and shoulder stops, etc., so that the machining can be done without withdrawing the tool to note the progress of the work. In this connection it is well to bear in mind that the action of any kind of grooving tool is much the same as a cutting-off tool. It must be kept very sharp and set so that the cutting edge is slightly above center, when it is used for internal work. It will be seen that if the tool is slightly above center the springing down of the cutting edge (due to the pressure of the cut) will have a tendency to keep it from "digging in," and will therefore assist in the prevention of chatter. Some of the important points in the design of recessing tools are given herewith.

* For previous articles on this and kindred subjects, see MACHINERY, March, 1914, "Design and Construction of Boring Tools"; February, 1914, "Adjustable and Multi-cutting Turning Tools."
† Address: 84 Washington Terrace, Bridgeport, Conn.

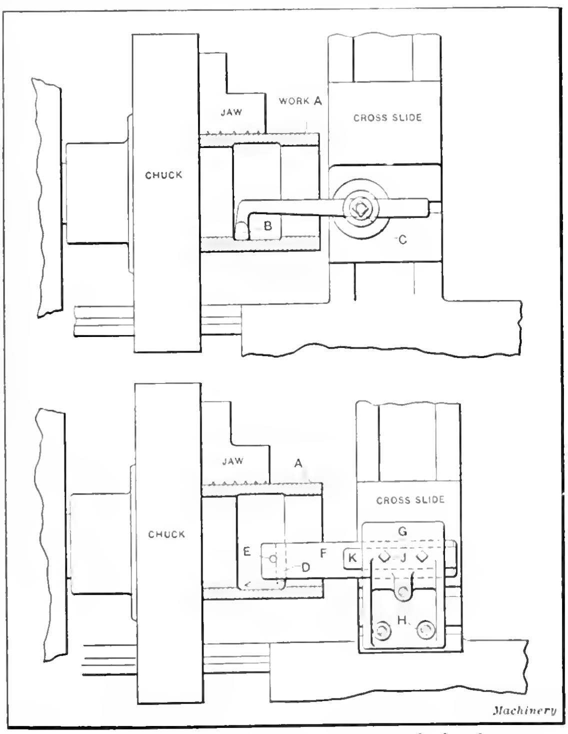


Fig. 1. Two Simple Types of Recessing Tools for the Engine Lathe

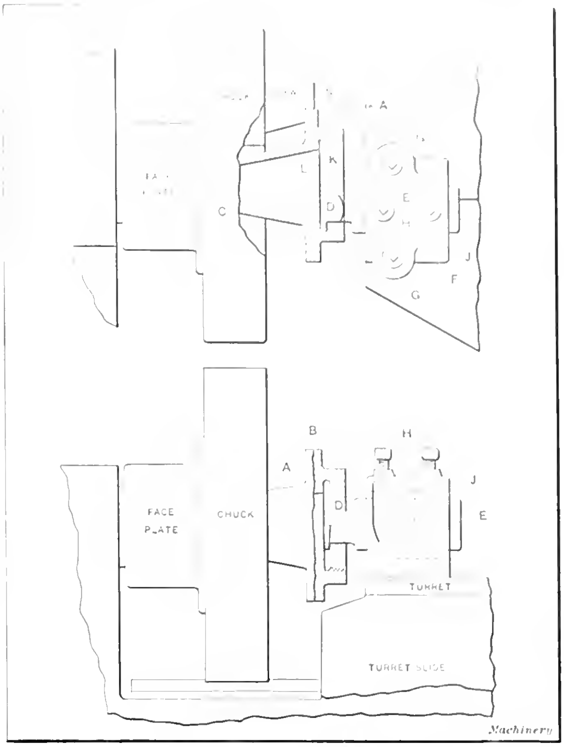

Fig. 2. Recessing Tool used in a Turret Lathe

Points in Design of Recessing Tools

1. Rigidity is of the greatest importance and every precaution should be taken to insure as substantial a holder as possible. The tool itself should be of as great a section as the conditions and the space will permit. Some method of supporting the overhanging end should be provided, either by means of a pilot or in some other way which may suggest itself. Moving parts should have a means of adjustment for wear, and gibs should be set up as snugly as possible and still allow free movement.

2. The feed motion should be carefully considered. Screw feed is best, and may be contained in the tool itself or may be operated by the cut-off slide. Lever feed is uncertain and produces uneven cutting unless the work upon which it is used runs at high speed. When this is the case and if the cut is not too heavy, it can be used with satisfactory results. The work to be done is a factor in determining the method most satisfactory for the feed motion.

3. Means are needed for determining the depth of the cut. There are several ways in which the depth of the cut can be positively determined: a positive stop can be provided; the dial on the cut-off slide can be used when the feed motion of the slide is the operating force; an indicator or a graduated dial on the tool-holder itself may be provided.

4. Rapidity of operation is essential.

5. Adjustment for the cutting tool should be provided.

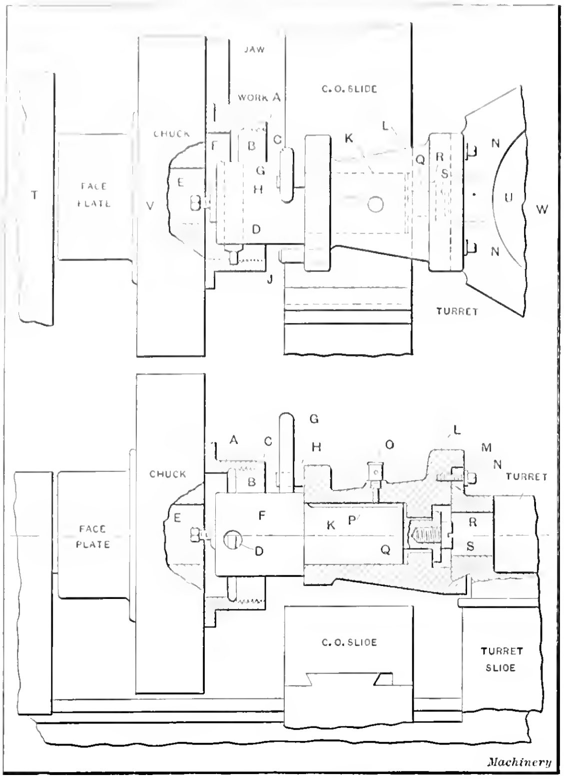

Fig. 3. An Eccentric Recessing Tool for the Turret Lathe

This adjustment may be made either by manipulating the tool by hand or by means of a backing-up screw. The latter method is the better one and should be used whenever practicable. The upkeep of the tool is important, and for that reason inserted tools are preferable to those which form a part of the mechanism itself. In confined situations it is occasionally necessary to make the tool of special shape. This should be done only as a last resort, when necessitated by the conditions governing the work. In cases of this kind several tools should be made to provide for emergencies.

Recessing Tools for the Engine Lathe

The upper illustration in Fig. 1 shows a bushing *A* which is held by the outside in regular chuck jaws. This work is to be done on the engine lathe, and the recess is to be cut at the same setting. A forged tool *B* is held in the regular toolpost *C* on the cross-slide of the lathe, and is forced into the required depth by hand. After this the longitudinal feed is started and the remainder of the recess cut. This type of tool is much used for lathe work when only one or two pieces are to be machined. Its advantages are that it can be easily made and quickly adjusted. Its disadvantage is that it has a tendency to chatter, and is, therefore, suitable only for very light cutting.

The device shown in the lower portion of the same illustration is much more rigid, but is not nearly so adaptable to various conditions. In this arrangement, the tool *D* is of round section and is held in place by taper pin *E*. The bar *F* is of steel and is secured in the holder *G* by the two screws *J* which bear against a flat *K* on the bar. Three screws *H* enter shoes in the cross-slide T-slots and secure the holder firmly to the slide.

Recessing Tool for a Horizontal Turret Lathe

The work *A* shown in Fig. 2 is a steel forging of an automobile hub which is held in a three-jawed chuck by the flange *B*, the tapered portion entering the hole *C* in the chuck body. The inside of the hub is to be threaded at *K* with a collapsing tap. A recess is therefore needed at *L* in order to obtain a clean thread. The machine selected for the work is a Pratt & Whitney turret lathe having a cross-sliding turret of the flat type. The recessing tool is of high-speed steel, with the shank turned and ground cylindrical at *E*. The front end is also turned to form the flange *D*, and is afterward cut away and finished to the shape required, as clearly shown in the lower part of the illustration. The tool-holder *F* is of cast iron and contains a steel split bushing *J* which is compressed by two screws *H* in the top of the holder. The action of this tool was satisfactory, but the upkeep is obviously rather expensive.

Eccentric Recessing Tool for a Horizontal Turret Lathe

The work *A* shown in Fig. 3 is a steel flange which is to be recessed at *B* in order to provide the necessary clearance for the threaded portion *C*. In this instance the cut-off slide was used during the progress of the work, so that a considerable overhang from the turret was required. Strictly speaking, this is not an eccentric tool, for the various parts of the body are concentric, but by a reference to the upper part of the illustration it will be seen that the center-line *VW* of the recessing tool does not coincide with the center-line *TU* of the spindle. Now as the tool-holder *F* revolves on the center-line *VW*, it is evident that the path of the tool *D*, as it swings, will be eccentric to the center-line of the spindle. The body *L* is of cast iron and is mounted on the dovetailed turret face, being securely held in position by the gib *M* and the screws *N*. The tool-holder *F* is of tool steel and is turned down at *K* to a running fit in the body. The end *Q*, with the screw and washer *S* and *R*, acts as a retainer to keep the tool-holder in position. The tool *D* is of round section with the cutting end so shaped that it will cut the recess properly. A set-screw *E* holds it in position. An oiler *O* is located in the body and distributes the oil to the bearing through the oil groove *P*. An operating handle *G* is driven into the holder, and is located between the pins *H* and *J* which act as stops. As the lever *G* is operated, the tool *D*, starting with slight clearance at the bottom of the hole, moves gradually upward and outward until the full depth of cut has been reached. At the completion of the cut the tool stands in the position shown in the illustration. The action of this tool was perfectly satisfactory, and as it is comparatively simple in construction, the cost of building was not excessive.

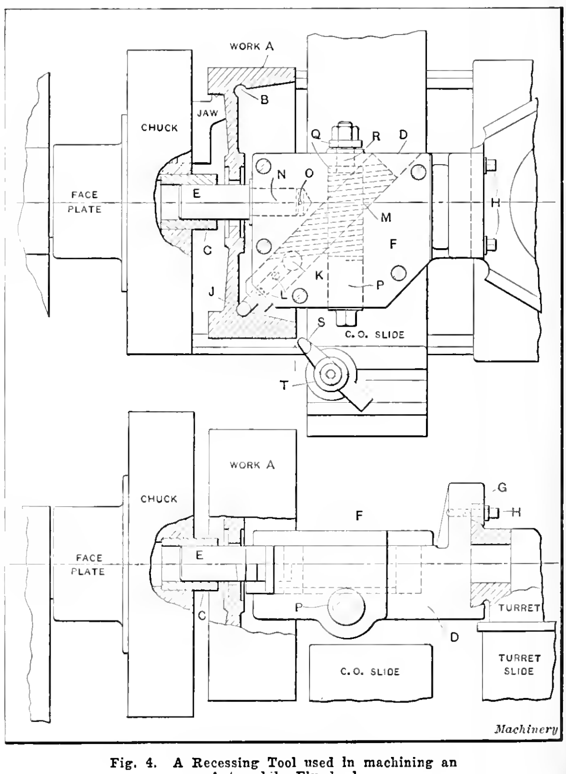

Fig. 4. A Recessing Tool used in machining an Automobile Flywheel

Piloted Recessing Tool for an Automobile Flywheel

A rather peculiar condition is shown in Fig. 4, the work *A* being an automobile flywheel having a semicircular recess at *B*. Attention is called to the fact that this recess is put in at an angle of 45 degrees with the center-line. It is evidently only a clearance groove for the male clutch member, and it is not known to the writer why some other style of groove would not have answered the purpose just as well.

The work *A* is held by the inside of the rim in special jaws. The body of tool *D* is made of cast steel and is fitted to the dovetailed face of the turret, the gib *G* securing it firmly by means of the collar-head screws *H*. A tool-steel pilot *E* enters the bushing *C* in the chuck and assists in supporting the body against the pressure of the cut. This pilot *E* is shouldered and forced into the body at *N*. A small hole *O* is drilled to avoid air compression when forcing in the pilot. If this is not done the fitter may be deceived into thinking that he has secured a good fit at this point when in reality it is the air compression which causes the stem to fit tightly. A cover plate *F* tends to strengthen the body and overcome the weakening effect caused by the cutting of the angular slot, and also assists in preventing the entrance of dirt and chips. Tool *J* is of square section and is held in the sliding block *M* by two screws *L*. Hole *K* is for machining purposes only. The operating screw *P* is squared up on one end to receive a wrench, while the other end is shouldered at *R* and threaded to receive a hexagon nut. There are two thrust washers shown at *Q*. The screw has four Acme threads per inch, right-hand, and meshes with the angular rack cut on the under side of the tool-carrying slide *M*. It is evident that the rotary motion of screw *P* will cause movement of the block, in its longitudinal direction, thus feeding the tool into the work at the desired angle. The forged tool *S*, held in the tool-holder *T* on the cut-off slide, is slowly fed across the rim while the recessing operation is taking place.

Double Recessing Bar for a Rear Axle Housing

The work *A* shown in Fig. 5 is a bronze rear axle housing for an automobile, and the recessing bar is only one of a group of tools used at the same setting of the work. Previous to this setting the finished annular rings at the two ends *D* and *E* of the casting were machined so that they might be used

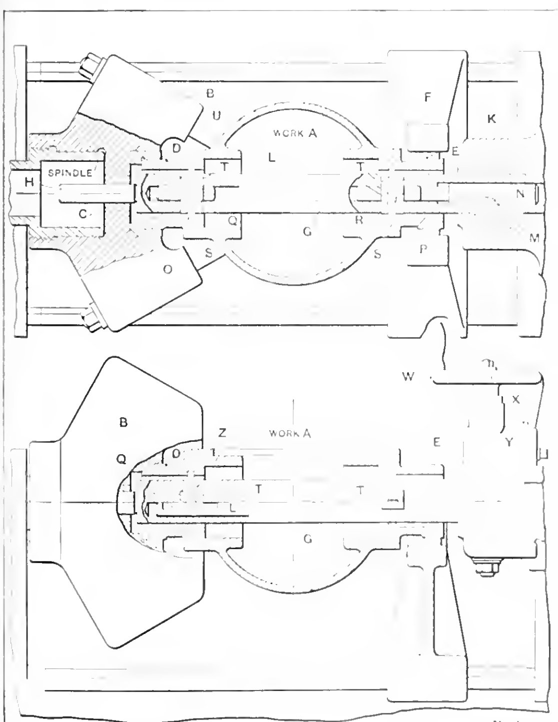

Fig. 5. A Double Recessing Tool Arrangement for a Rear Axle Housing

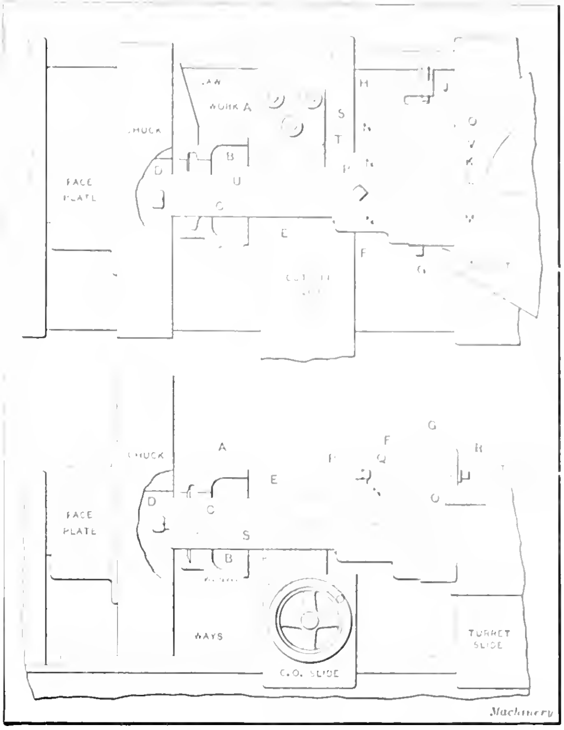

Fig. 6. A Recessing Tool for an Automobile Bearing Retainer

as locating points in this setting. The ring *D* slips into the split bushing in the holding device *B*. The other end *E* revolves in a roller back-rest *F* which is placed on the ways of the turret lathe. This back-rest is not shown in detail, as its construction is not essential in connection with the recessing tool. The two grooves in the work at *S* were to be spaced an exact distance apart and it was partly to insure accurate spacing that this bar was designed, although rapidity of operation was also a factor. A cast-iron bracket *K* is fastened to the dovetailed face of the turret by means of gib *Y*, shown in the lower view. The handwheel *W* is connected to a shaft which drives the pinion *M*. A steel pointer *X* is fastened to the bracket and acts as an indicator on the graduated rim of the wheel. It will be seen that this arrangement makes it very easy to determine the depth of the cut.

The pinion *M* meshes with a rack cut upon the enlarged end *N* of the operating rod *L*. This rod is considerably below the center of the bar and is flatted at *O* and *P*. The tongues *Q* and *R* are angularly cut on these surfaces, and they engage with grooves on the under side of the tool-carrying blocks *T*, so that any longitudinal movement of the rod *L* is transformed into a radial movement of the blocks. The grooving tools *S* are of round section and are held in position by the headless screws *Z*. The backing-up screws *U* permit accurate adjustments to be made with ease. The pilot *H* enters the steel bushing *C* in the body of the holding device and assists in preventing chatter. An added refinement to this tool was an oil-groove from which oil was led directly to the cutting tools. This was supplied with oil through a special piping system and a distributing collar on the turret. In order to avoid confusion in the drawing, this has not been shown. This device gave very satisfactory results.

Recessing Tool for an Automobile Bearing Retainer

The work shown at *A* in Fig. 6 is a malleable iron bearing retainer for an automobile. The casting is held by the outside in a three-jawed chuck; the machine on which the operations are performed is a horizontal turret lathe. The piece is completely finished in one setting. As the cut-off slide front tool carrier was used during the progress of the work, it was found necessary to design the recessing tool so that it extended out over the slide. It is evident that an overhang as great as this would cause trouble unless some means of intermediate

support were provided. The bracket S was therefore used on the rear of the cut-off slide, the portion T being cut out to the radius of the bar so as to act as a support and at the same time provide the feed motion necessary (through the reverse feed of the slide) to force the tool into the work. The cutting tool C is of round section properly shaped at the end to form the required groove B. It is secured in place in the bar E by the set-screw D; radial adjustment is secured through screw U. The rear end of the bar is shouldered and fitted to the sliding bracket F; the set-screw P holds it in place. The slide F is dovetailed and is gibbed to the fixed bracket G by the gib Q which is adjusted for wear by the screws N. The lug H at the end of the slide is provided with a stop-screw J which permits close adjustments to be made for the depth of cut. This lug is not shown in the lower view, but it is set slightly to one side of the cored groove O so that the screw will bear against the solid portion. The bracket G is mounted on the dovetail of the turret and is held in place by the gib R. The special screw M is shouldered to receive the coil spring L which thrusts against it and against lug K on the slide. The strength of the spring may be easily adjusted by the screw to the desired compression. The screw V is simply used to limit the reverse movement of the slide, so that it will not move back too far before or after the work has been done. This device was used for three different pieces by simply changing the tool and regulating the stop-screw. Its performance was thoroughly satisfactory.

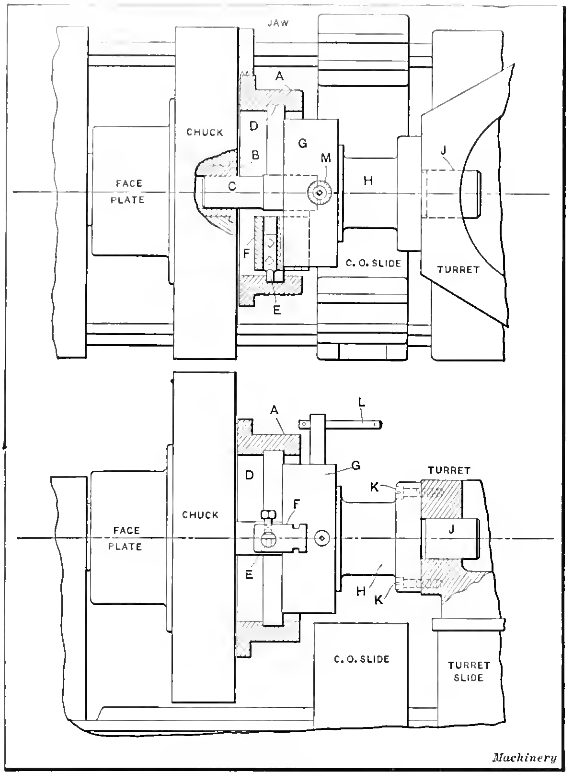

Fig. 7. A Recessing Tool for a Large Collar, used in a Turret Lathe

Recessing Tool for a Large Collar

The large collar A in Fig. 7 was held by the outside of the flange in a three-jawed chuck on a horizontal turret lathe. The internal groove D was to be cut during this setting of the work, and as a small geared scroll chuck was conveniently available, it was arranged as a recessing device for this casting. The cast-iron bracket H was fitted to the faceplate recess at the rear of the chuck body. The stem J was turned down to fit the hole in the turret face, and the four screws K secured it thereto. One of the standard chuck jaws F was annealed and shaped up as shown. It was then drilled to receive the tool E, and tapped out so that two set-screws could be used to hold the tool. The jaw was then rehardened and a small amount of fitting done so that it worked smoothly. A graduated collar was applied at M, and a special wrench L, having a slip handle, served to operate the scroll and thereby caused the tool to move radially as required. A tool-steel pilot C was forced into the center hole in the chuck body G, and a bushing B in the spindle chuck body served as a guide and support for it, thereby greatly increasing the efficiency of the tool and doing away with the chance for chatter.

Recessing Bar for a Triple Groove

In all of the examples which have so far been given, the work has been done in a horizontal plane, but we shall describe a few cases which are handled in a vertical plane on the vertical turret lathe. As this machine has a turret slide which can be traversed horizontally, it is evident that no special attachments are required for plain recessing or grooving, but there are conditions which may be decidedly out of the ordinary, under which a special arrangement for recessing may be used to advantage, for example, any sort of groove which is deep down in a hole, multiple grooving at a considerable depth, or any other condition of a similar nature. When the groove is very deep there is naturally a considerable overhang of any tool which may be used for the work. If the overhang is excessive, it follows that there is apt to be more or less vibration, and vibration means chatter. If, however, a tool or bar having an excessive overhang from the turret is supported at its lower end, the tendency to chatter is at once overcome; but, if support is provided at this point, the horizontal movement of the turret slide cannot be used. Therefore, some method which will give a radial movement to the grooving tool must be used when the bar is to be supported at its lower end.

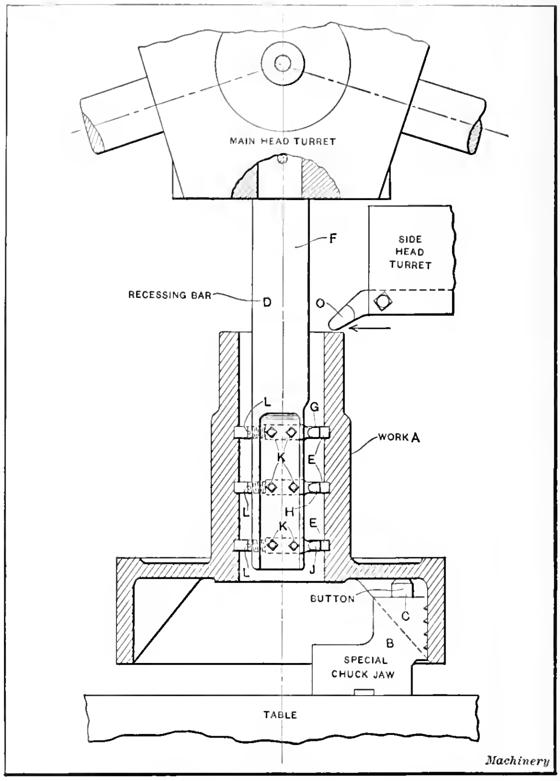

Fig. 8. A Multiple Recessing Tool used in a Vertical Turret Lathe

Fig. 8 shows a piece of work at A which is set up so that it can be machined complete in one setting. The casting is held by the inside of the rim in special chuck jaws B, and is supported at three points on the steel buttons C which rest in pockets in the jaws. The inner ribs of the casting act as drivers against the sides of the jaws. The three grooves E

are to be machined and the tools G, H, and J are correctly spaced to perform the work. These are secured in the bar D by means of the set-screws K, and accurate adjustment is provided by screws L. The bar D is shouldered at the turret face and is driven by a pin in the turret in the usual manner. The tool O in the side head turret is used for facing while the inside work is being done, as this brings the cutting action of the outside and inside tools in opposition and therefore tends to overcome vibration. If a very fine feed is used on the turret traverse, good results may be obtained with this method, although there is a tendency to chatter due to the excessive overhang. Slight variations in the depth of the grooves may also be found on account of the spring of the bar.

Piloted Recessing Bar for a Triple Internal Groove

The cast-iron valve cap shown in Fig. 9 is another example of a piece of work having three grooves equally spaced, and in which the lower groove is at a considerable distance from the turret. This piece is finished complete in one setting and is held by the outside of the flange in the standard chuck jaws C, being supported at three points by the buttons D. This tool is somewhat similar in its operation to that shown in Fig. 5, except that it is arranged in a vertical instead of in a horizontal plane. A heavy cast-iron bracket is bolted against the turret face K by screws L, and a locating plug J centers the device in the turret. The bar H is of steel and has a pilot G at its lower end. This pilot is hardened and ground to fit the bushing E which is inserted in the center of the table. The top of the bushing is milled out to leave three projecting pads F. These pads form a positive stop to insure the correct height; it will be noted that the tendency, when in action, would be to keep these pads clean and free from chips or dirt. The upper end of the bar is shouldered and is fastened to the bracket. As in the former instance the operating rod Z is flatted at certain places and angular tongues P are provided.

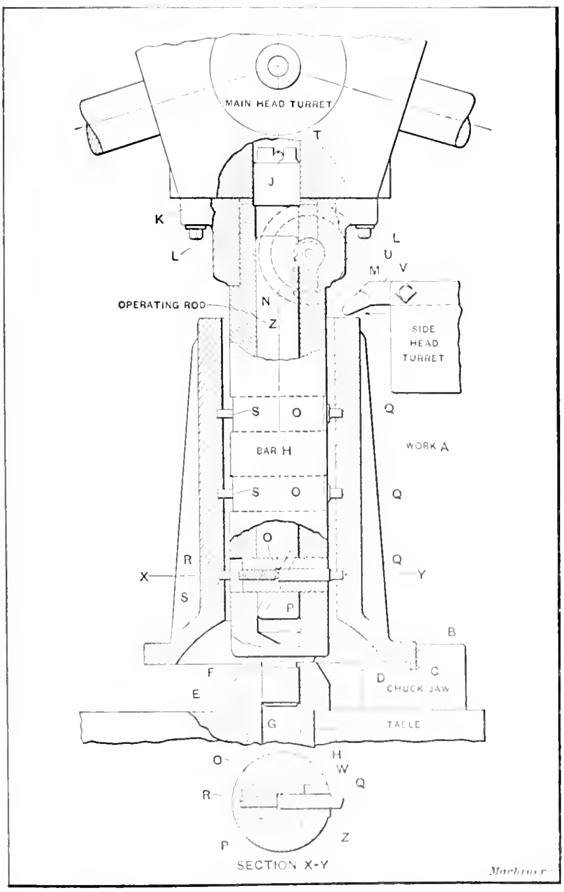

Fig. 9. Another Multiple Recessing Tool used in a Vertical Trrret Lathe

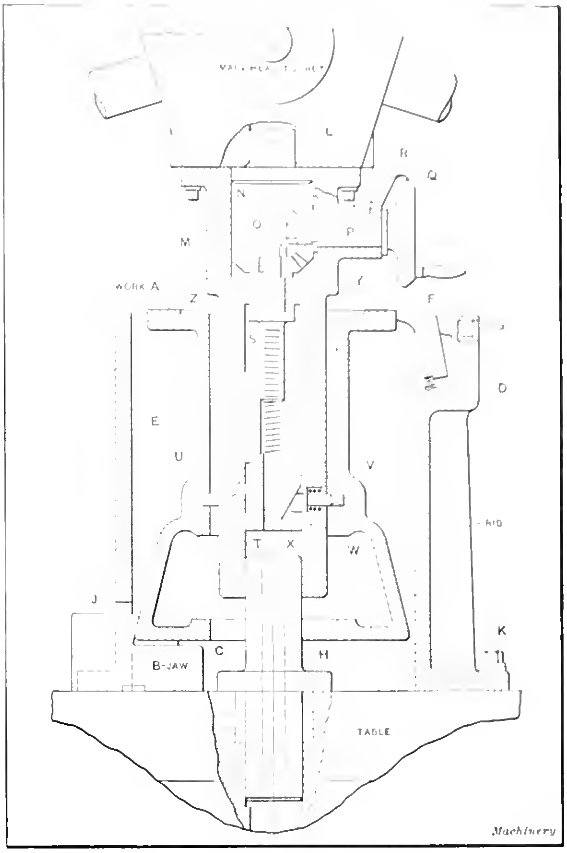

Fig. 10. A Tool for recessing in a Difficult Position, in Use in a Vertical Turret Lathe

These tongues mesh with corresponding grooves in the tool carrying blocks O. The section X-Y gives a good idea of the construction.

The tools Q are held in place by the short set-screws W in the square steel blocks O. The backing-up screws R permit of rapid and easy adjustment. At the upper end of the operating rod the rack N is cut and the pinion M meshes with it and operates the rod. The handwheel through which the pinion is operated is indicated at U by the dotted lines. This portion of the mechanism is identical with that described in Fig. 5. The tool V in the side head turret is used for facing the end of the casting during the progress of the recessing operation.

Recessing Tool Operated by Bevel Gears

A somewhat unusual condition is shown in Fig. 10, this arrangement having been suggested for the work A in order to rapidly perform the grooving operation deep down in the interior of the casting at V. It was desired to machine this casting complete at one setting. The chuck jaws B were of special form, having a slight angle on the inside of the jaw which drew the casting down onto the three points C. A cast-iron pot E was fastened to the table by screws K, and cored openings J were left at the points where the jaws gripped the work. Midway between the jaws, the pot casting took the form shown at D and the dogs F were sunk into the edges of the flange by means of the hollow set-screws G. The bar M is a steel casting which bolts against the turret face at its upper end; it is located by the plug L. The operating sleeve T is of tool steel, hardened and ground, and having an angular slot X at its lower end, which bears against the tool Y. It is well to make up several of these tools, so that replacements can be quickly made in case of breakage. A steel plate W is let into the casting at this point to form a cover plate for the tool and spring pocket. A teat screw I fits a slot in the operating sleeve and prevents it from turning.

The left hand threaded shaft S is journaled at its upper end

Z and the miter gear O is keyed in place. The shaft P carries another gear which meshes with the former, and the entire mechanism is operated by the handwheel Q. (This handwheel, in reality, is located 45 degrees toward the front of the machine from the position shown). A pointer R assists in making accurate readings from the graduated bevel on the handwheel. Steel thrust collars Y are provided for wear. The tool-steel pintle H is fitted to the center of the table and is held down by the screws shown. This pintle acts as a guide upon which the mechanism is located and greatly assists in making it rigid.

Arrangement for External Grooving

A thin piece of work for electrical machinery, shown at A in Fig. 11, has been completely machined with the exception of the groove B. At the time when the operation of grooving takes place, a revolving steel pilot G fits the previously reamed hole C and is held in its position on H by the nut and washer J and K. The upper portion of the bar F is shouldered at E and fits the turret hole, being kept from turning by pin D. A round bar N is flatted on two sides at O and is held in the side-head turret by the three screws R. The lower portion of the bar carries the grooving tool P which is held in place by the two screws Q. A tool-steel pin M is forced into the bar N and forms a sliding tie between the pilot bar F and the side-head bar N. The bushing L is inserted in the pilot bar to receive the pin. It will be readily seen that this method overcomes the vibration which would naturally be caused by the grooving tool acting on the thin and unsupported hub.

Recessing Tool for a Dovetail

The casting shown at A in Fig. 12 is a portion of the clutch mechanism for a farm engine, and it was desired to machine

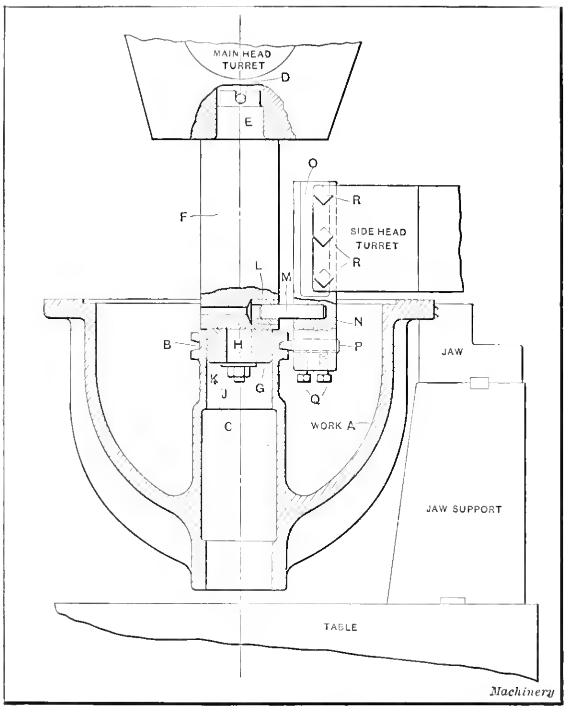

Fig. 11. An Arrangement for cutting a Groove on the Outside of a Sleeve

the piece complete in one setting. The work was, therefore, held by the inside by special jaws B and supported at three points by the steel buttons C. A good driving action was provided by the side of the jaws bearing against the ribs shown. In order to properly make the dovetail cut D, it was necessary to move the tool radially to secure the proper depth and then move it upward and downward in order to machine the corners of the dovetail. The shoulder in the casting made it impossible to see the work which was being done. The steel bushing U was centered in the table and acted as a guide for the pilot-end of bar L. The entire bar is a steel forging and contains a plug V at its lower end against which the coil spring W thrusts. The operating rod N bears against this spring which is sufficiently strong to keep it up to the limit of its upper movement. The lower portion of the rod is slabbed off at X to a 20-degree angle, this angular portion acting as a wedge to force the tool-block S outward. A flat spring T keeps the tool-block back against the angle on the operating rod and assists in releasing the tool after the groove has been cut. The dovetail tool R is held in position in the block by means of the two screws shown. The operating lever O is pivoted at Y and passes through a slot in the operating rod N. A pin Q bears against the elongated slot P and thereby

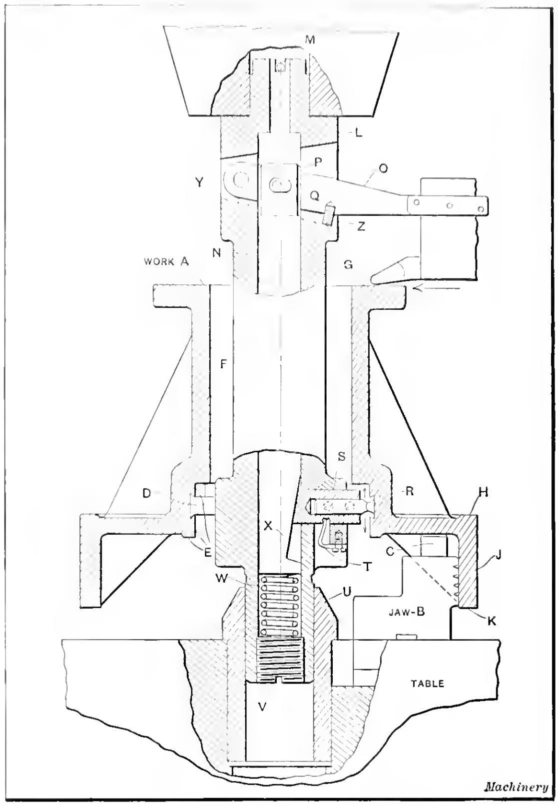

Fig. 12. A Recessing Tool cutting a Dovetail-Shaped Recess

moves the rod in a vertical direction. The adjustable stop-screws Z limit the movement. The lever O is shown in a position 45 degrees toward the rear of the machine from that in which it is really located. It will be noted that the side-head tool may be facing the work at G during the progress of the recessing operation. In machining this piece the surfaces D, E, F, G, H, J, and K were all finished at this setting.

* * *

In an interesting article in the *Manchester Guardian* (England) the author asks what will be the next step in our civilization that will follow the iron age, or as some people prefer to call it, the steel age. Some day it is conceivable that the mineral and coal supplies of the world will give out, and then the world will have to fall back upon the vegetarian substances for all materials of construction, these being the only ones that can be reproduced with such rapidity that there would be a constant supply. When this time arrives, the author says, the great bulk of the world's requirements will be met by the products of the field and the hillside. Fuel will either be grown directly, as timber, or more likely be distilled from suitable plants in the form of alcohol and oils. Structural materials would then, again, be mainly stone and wood, and only tools, ornaments, and products to meet special requirements would be made of metal. When such a time comes, the world will literally go "back to the land" and evolve a new civilization, multiplying the productivity of the land to a degree at present beyond imagination. In the history of the world, the present mineral age is but one brief day.

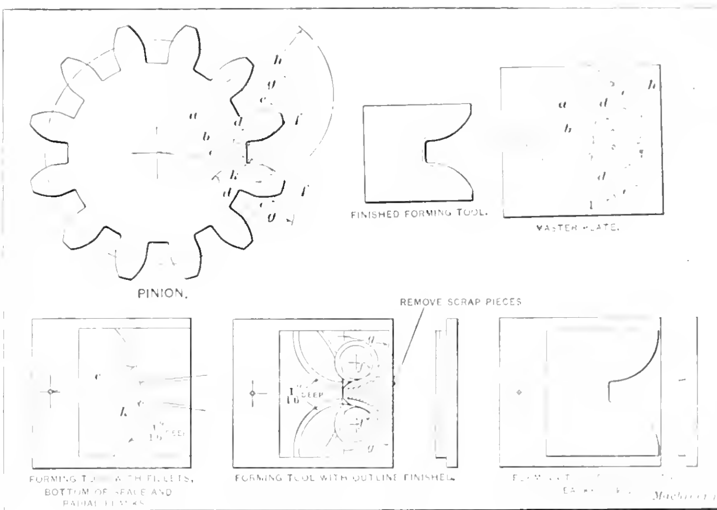
MAKING A FORMING TOOL FOR A GEAR-CUTTER

BY EARLE BUCKINGHAM*

If the shape of the teeth in a rack or gear is known, the shape of the teeth for another gear to mesh with it may be determined by laying out a tooth of the known gear to an enlarged scale and revolving it about the pitch circle of the other gear, thus generating the shape of the required tooth. Arcs may then be found to match this generated shape. Grant's "Treatise On Gear Wheels," pages 29 and 42, gives tables for the shapes of both involute and cycloidal teeth that are close enough for the majority of gears. These tables may also be found in MACHINERY's Handbook on page 583.

There are several ways of making templets and forming tools for the gear-cutter; I wish to describe one method that is simple and accurate, and may be carried out with the tools found in every tool-room. With this method a templet is not necessary, as the forming tool is made directly; but if desired, the templet may be made in a similar manner. After the proper shape of the tooth is determined, the distances between the centers of all of the radii are computed and a master plate is made with holes accurately drilled at all the centers so determined. These holes should all be reamed to the same size—0.250 inch diameter, for example. A plug to fit these holes is turned up in the lathe, and should not be removed before the work is completed. The stock for the forming tool is soldered firmly to this master plate, this stock being left about 1/16 inch thicker than is required for the finished forming tool.

The work is clamped to the face-plate of the lathe so that the hole in the master plate locating the center of one of the fillets at the bottom of the tooth space fits over the plug in the lathe. The holes in the illustration of the master plate are numbered to show the order in which they should be placed over the plug. The hole for the fillet is drilled to the exact size called for. The hole forming the other fillet is then made in a similar manner. After the two fillet holes are finished, the work is set up in a shaper to machine the radial grooves, as shown in the illustration, that form the flanks of the teeth. Using the hole in the master plate representing the center of the gear, and with the two fillet holes to work from, the work is very readily and accurately set up.



Method employed in making Master Plate and Forming Tool

When both grooves are finished, the work is replaced in the lathe with the hole in the master plate locating the center of the gear over the plug. A groove is turned about 1/16 inch deep with its inside edge exactly tangent to the edge of the fillet holes, as shown in the illustration. When the correct diameter is found, the lathe is turned back and forth by hand, stopping at the points of tangency, until the forming tool is cut through. Stops should be attached to the spindle of the lathe to prevent over-travel. The hole locating the center of the radius forming the outer part of the face of the tooth is next placed over the plug. Another circular groove about 1/16 inch deep is turned when the proper diameter is found. The stock for the forming tool should be left large enough so that a full half circle may be turned and measured. After this diameter is found, the lathe is turned by hand, as before, until the forming tool is cut through as shown. The arc forming the other face is then made in the same manner.

The work is next moved again so that the center of the circle forming the tooth at the pitch line is over the plug, and this diameter is found in the same way. After the form is finished, the scrap pieces shown in cross-section are removed from the master plate; the forming tool is next faced off smooth and is then ready to be backed off. To back off the tool, the work is set up in the same manner as for first forming it, while the upper slide of the lathe or the tool slide of the shaper is set at the proper angle. A slight flat or land is left at the cutting edge of the tool. This tool will not allow of much grinding, but after the master plate is made, new forming tools may be quickly made when needed. When the forming cutter is finished, the gear-cutter is made in the usual manner.

A similar method is found to be very accurate when making blanking and piercing punches and dies, the same master plate being used for both punch and die. Drill jigs may also be bored by this method, when extreme accuracy is desired. If, in any case, the centers of the different radii should be so close together that the holes for the plug could not be bored in the same master plate, another plate is doweled to it containing the other holes. I have known of cases where three or four plates were used.

STANDARD SIZES OF CATALOGUES

A committee of the American Society of Mechanical Engineers has made extensive investigation of the various sizes of catalogues in common use, and in a report presented to the society the committee recommends that the standard size of catalogues be made 6 by 9 inches, but that an additional size for bulletins and large catalogues may also be considered as standard, this size being 8½ by 11 inches. For folders, two sizes are also recommended, *viz.*, small folders to be 3⅝ by 6 inches, and large folders, 3¾ by 8½ inches.

For paper covered catalogues intended to be permanently filed, the edges, including the cover, should be trimmed to exact size. No fancy deckled edge should be used. Overlapping edges of the cover should be used only when the catalogue is bound in covers stiff enough to support its weight when resting on the cover edges. Whenever possible, the title should be printed on the exposed back of the catalogue and should read from the top downward. Every catalogue should have the date of its publication on its title page and it is recommended that a standard size index card, 3 by 5 inches, be enclosed in every catalogue, with the title of the book and a brief statement of the character of its contents printed on it.

* * *

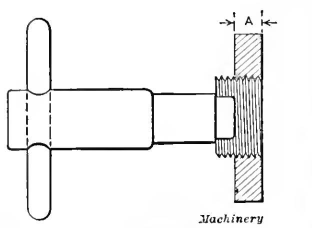
If a good color is to be obtained on brass castings, it is necessary that new metals be used, as a large percentage of scrap in the castings is indicated by a dull color. To produce a good luster on castings which are not machined to any great extent after casting, use at least two-thirds of new metal. An alloy extensively used in the brass trade consists of 88 pounds of copper, 3½ pounds of tin, 6 pounds of zinc, and 2½ pounds of lead.

STANDARDIZATION OF PIPE THREAD GAGES

The following information relating to standards for Briggs pipe thread gages has been abstracted from the report of a Committee on the Standardization of Pipe Threads appointed by the American Society of Mechanical Engineers. The purpose of the Committee on Standardization of Pipe Threads has been to fix manufacturing limits for the use of the Briggs standard pipe thread gages when tapping fittings or flanges, so that pipe cut to the Briggs standard might always enter a definite number of turns. Although the Briggs standard is used almost universally for pipe threads in the United States, the method of its use for female threads has not been established, in that no determinations have ever been made of the standard depths to which hand plug gages should enter. This has resulted in much confusion in the past, inasmuch as pipe threaded to the Briggs standard is liable to vary in the number of threads it would screw into fittings tapped at different shops. This tendency is so marked that pipe fitting is handled in practically all cases by sending the flanges to the shop where the pipe is cut, to be sure of satisfactory results.

This matter is conceded to be a simple one in that all it requires is an agreement among the manufacturers of fittings

STANDARD THICKNESS OF PIPE RING GAGES



Pipe Size	Thickness A, Inches	Pipe Size	Thickness A, Inches
1/8	0.1801	1	0.400
1/4	0.200	1 1/4	0.420
3/8	0.240	1 1/2	0.420
1/2	0 320	2	0.436
3/4	0.339	2 1/2	0.682

Pipe Size	Thickness A, Inches
3	0.766
3 1/2	0.821
4	0.844
4 1/2	0.875
5	0.937
6	0.958
7	1.000
8	1.063

as to the point at which a ring should be attached to the gage, to establish, when the gage is inserted by hand, the proper depth of the thread. To this end the committee has met in conference with representatives of the manufacturers and also of the committee of the Society on International Standards for Pipe Threads. Mr. C. A. Olson, chairman of the Manufacturers' Sub-committee on Pipe Thread Gages, stated at this meeting that his committee had made a study of present practice among the various manufacturers and had adopted tentative definitions of the gages to be used, of the proposed thickness of ring gages acceptable to the manufacturers, and of the tolerances to be allowed. These he submitted as follows:

The gages shall consist of one plug and one ring gage of each size.

The plug gage shall be the Briggs standard pipe thread as adopted by the manufacturers of pipe fittings and valves, and recommended by the American Society of Mechanical Engineers in 1886. The plug is to have a flat or notch indicating the distance that it shall enter the ring by hand.

The ring gage is to be known as the American Briggs standard adopted by the Manufacturers' Standardization Committee in 1913, and recommended by the American Society of Mechanical Engineers, the committee on International Standard for Pipe Threads, and the Pratt & Whitney Co., manufacturer of gages. The thickness of the ring is given in the accompanying table. It shall be flush with the small end of the plug. This will locate the end of the flat on the plug flush with the large side of the ring.

When using the plug gage, as shown in the illustration accompanying the table, the flat indicates the exact size, and the allowable limits should be one thread large or small. When using the ring gage, the male threads are to gage when the plug gage is flush with the small end of the ring. The allowable limits are one thread large or small. A set of these gages to be known as the "American Briggs Standard for Pipe Threads" is to be deposited with the Bureau of Standards at Washington, D. C.

HEAT AND LIGHT OF THE SUN NOT REAL

Edwin F. Naulty, in an article published in the *New York Herald* March 15, states that the sun is not hot, despite all that has been taught to the contrary for thousands of years and the apparent evidence of our senses. He sets up the theory that the sun does not radiate light and heat and that the actual body of the sun is probably cool. The tremendous energy poured forth by the sun is not light and heat initially. Solar energy is invisible and is without temperature. Not until the rays of solar energy enter the atmosphere of the earth do they become light and heat. He likens the atmosphere of the earth to a huge spherical transformer which, by resistance, changes cold and invisible solar energy into light and heat, precisely as the filament in an electric lamp transforms the cold and invisible electric fluid that feeds it into light and heat. Only the solar rays entering the atmosphere of the earth or that of any other planet are so transformed. All other rays pass outward from it into space as cold and invisible as when they leave the sun. Outside the atmosphere of any planet is utter darkness as complete and absolute as if there were no sun.

Mr. Naulty affirms that the fact that the gases composing the outer shell of the sun are in a state of violent motion does not necessarily mean that they are on fire. An observer on the moon looking at the earth while a tornado was raging would see the atmosphere of the earth apparently on fire. Violent motion does not mean flames. In the upper levels of the earth's atmosphere the winds sometimes blow at the high rate of five hundred miles an hour and yet they remain cold.

If the sun were made of the best steam coal and were burning up it would be wholly consumed in five thousand years. If the sun were constantly pouring out heat, the solar system, in all these myriads of millenniums it has been in existence, would, by the cumulative effect, have become so superheated that the earth, the moon, Venus and Mercury would long ago have been expanded to gases. A burning sun is poor mechanics and a burning sun is a wasteful way of running the solar system. Because it is a wasteful way and because it is not mechanically perfect we may be sure that it is not the way heat and light are produced.

Mr. Naulty advances the theory that the energy of the sun which we perceive as light and heat is due to an electrical flux in the equatorial plane. The greatest strength of this electrical flux is exerted within a zone of about twenty degrees in width. The sun is considered to be a great combined generator and dynamo, deriving its initial energy from the entire solar system and, in turn, changing this into a radiant energy that spins the planets in their orbits and furnishes the invisible force which the atmospheres of the planets, in their turn, transform into light and heat. He claims that the theory of contraction of the sun as a means of generating light and heat is absurd and that of meteorites producing it by falling into the sun is equally absurd. In fact he denies the possibility of meteorites falling into the sun because it is the center of the solar system. As proof that the atmosphere of the earth is the transformer which changes the radiating energy to light and heat, he calls attention to the fact that at the equator the perpendicular rays of the sun at noon may be so energetic that the thermometer will stand at 120 degrees F. while at a distance of a mile above the temperature will be only 70 degrees and at a height of three miles on the mountains in Equador, we find the mercury below the freezing point, and still at each of the three points the thermometer is under the perpendicular rays of the sun.

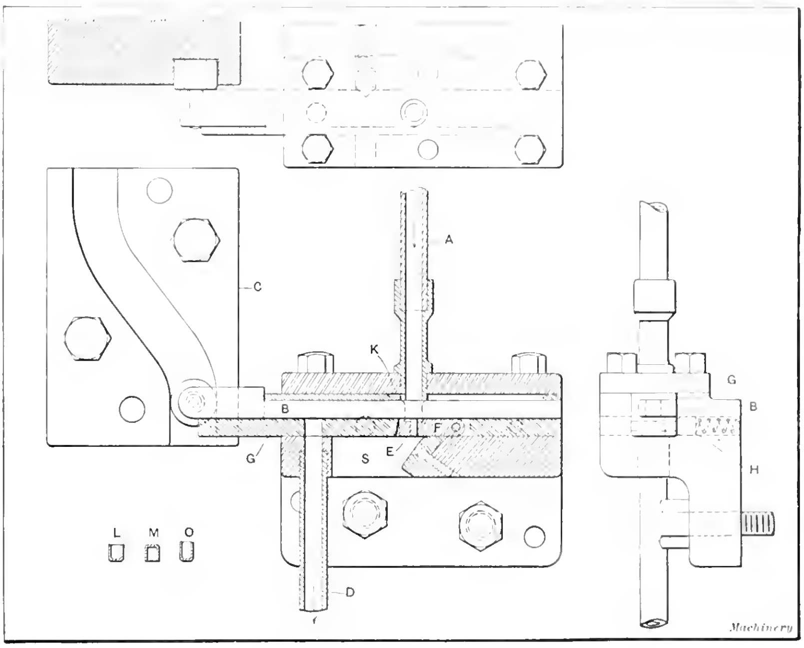
AUTOMATIC FEED MECHANISM FOR SMALL BRASS CUPS

The accompanying illustration shows an attachment for a press for heading the small brass cups shown in the lower left-hand corner. These are called "battery cups" and are used in shot-gun shell cartridges. The attachment was designed with the object of preventing broken tools and rejecting all cups that had not previously been trimmed to length. The cups feed down through the supply pipe *A* from the usual feed hopper, in the position shown at *L*. Slide *B* is reciprocated by the plate cam *C* carried on the cross-head. The cup is picked up by the cavity in slide *B* and is carried over and dropped into the supply pipe *D*, from which it passes to the feed dial. It sometimes happens that the cup will find its way into the feed pipe *A* in an inverted position, as indicated at *M*. When it enters slide *B* in this position it falls into the cavity around pin *E* and slide *G* is carried over along with slide *B*. The function of pin *E* is not primarily to catch the cups that fall with the mouth downward, but to hold up the cups that fall with the head downward, so that the bottom of the cups is level with the bottom of the slide *B* under normal conditions. When, however, the cup falls with the mouth downward over pin *E*, which is riveted in hinge *F*, the latter drops down over a hardened block, as slide *G* is carried forward, and the inverted cup drops out through cavity *S*. Slide *B* then returns slide *G* to its former position during the return stroke. Normally, the slide is held in position by plunger *H*.



Automatic Feed Mechanism for Small Brass Cups

A cup that is too long or that has not been previously trimmed, as at *O*, is caught by the edge *K* of slide *G*; the slide is then carried forward and the cup dropped out through cavity *S*, as before.

LAWRENCE FAY

SHOP EMPLOYES' SAVINGS AND LOAN DEPARTMENT

The particular advantages and benefits of encouraging a savings and loan department among shop employes are effectively shown by the results obtained at the plant of the Celluloid Co., of Newark, N. J. The Savings & Loan Department of the Celluloid Club, composed of about four hundred male and female operatives of the company, has recently issued a statement of its work for the past six months, showing total deposits of $11,500, or an average individual saving of approximately $29. This sum represents the savings of the rank and file of the shop workers, exclusively. The department is operated by employes for employes, without any assistance from officials of the company, or deposits from salaried or higher paid associates; and it is entirely separate from any other branch of welfare work carried on by the company.

This department of the club has now been in operation slightly over seven years, during which period its deposits have aggregated about $130,000. The organization of such a branch was the idea of President Lefferts of the company, offering a practical plan for the encouragement of the saving habit among its members; and it has proved a popular success from the start. The savings end of the department is operated in periods of six months duration. These are known as "series," and the regular withdrawal dates are in December, just before the mid-winter holidays, and about the middle of June, prior to the summer vacation season. The loan branch of the department renders temporary financial assistance to the depositors, and in this particular has shown that the lending of money to employes who are known to be steady and conscientious workers is a logical and safe departure. Beyond this, it eliminates the necessity for such employes to seek outside aid when in need of funds, and the attendant disheartening features of customary loan brokerage methods.

Members are privileged to borrow sums ranging from $1 to $200, at a charge varying from two per cent a month to six per cent per annum. The particular amount which the borrower has on deposit does not affect the extent of the loan allowed; an employe may deposit twenty-five cents at any time, and immediately obtain the maximum of $200. In the case of minors, however, the department requires the approval in writing of the parent or guardian for all loans desired in excess of $10.

Under regular conditions, no indorsement is needed for loans under $25, but above this sum an additional responsibility is requested in the form of a second guarantor, this usually being the written indorsement of a trusted employe. Notes given for loans are limited to a period of three months, and are renewable upon maturity. Borrowers must make weekly deposits to the fund, the object being to assist them out of their financial difficulty, as the borrowing of money is not encouraged for financial benefit of the department.

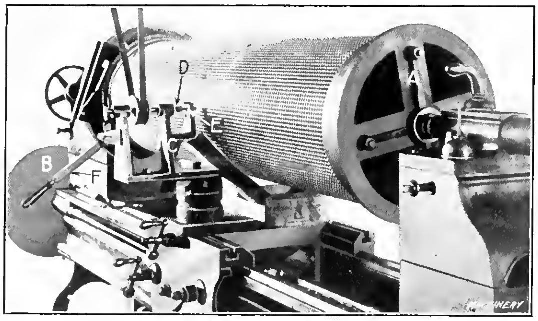
Should a borrower fail to keep an agreement to enter regular deposits, or fail to pay a note when due, the further advantage of accommodation for future loans is lost, as the department will not permit loans to such a member. Following the payment of a loan, the transaction becomes known by number, and the borrower's name is taken from the regular record of business. By loaning money on character in this

manner, the department encourages honesty and thrift among employes, and indirectly impresses them with the value of good habits and integrity in business. A. R.

DRILLING A BRONZE DRUM

A problem of drilling was placed before us a few days ago that had to be handled with the equipment ordinarily found in machine manufacturing plants. As it was out of the ordinary line of work, a few special fixtures were necessary. The piece in question was a bronze drum with an outside diameter of 23⅜ inches, bored inside so as to leave a wall practically ½ inch thick. It was necessary to drill this piece so that the spacing of the holes was exactly ½ inch from center to center, the size of the drilled holes being 3/16 inch. After the drilling operation was completed, the top or outside diameter of the drum had to have these holes countersunk with a countersink of 45 degrees angle and to a sufficient depth so that it would allow a little flat surface of the actual diameter between the countersunk portion and the surface of the drum practically 1/32 inch wide.

The drilling had to be done accurately, and in order to handle this work the following means were resorted to. Having a lathe large enough to swing the diameter of the drum and also take it in between centers, it was decided to do the work on this lathe. Two cast-iron plates *A* were made and shoulders turned on them so as to set in each end of the bronze shell, serving as heads. Hardened plug centers were inserted in the center of these heads, and four ⅝-inch bolts were placed in the four arms so as to bolt the two heads together and make them fast with the shell. The head nearest to the faceplate of the lathe was used as an index and 128 V-notches were cut in it. An index finger was provided on the faceplate of the machine. The spindle was locked and the front bearing of the lathe bound to hold it from any lost motion. As the feed-screw on the machine was 4-pitch, it was used for indexing the holes longitudinally, and by two turns of the feed-screw the spacing of ½ inch was obtained.



Simple Method of drilling a Bronze Drum

As a means of locking the feed-screw and bringing it to an exact point at every indexing, a hole was drilled in the large pulley *B* and a pin placed in this hole was received in the end of the bed of the lathe. A small cast-iron drilling head *C* was made up as shown in the illustration. This was bolted to the rest of the lathe and fitted with babbitt bearings. The drill chuck is shown at *D* and at the point indicated by *E*, a hardened bushing was inserted for guiding the drill. A lever *F* was provided to apply pressure on the spindle for feeding the drill. Between the end of the spindle and the lever a hardened steel plug was placed, the point of this plug that comes in contact with the lever being made ball shaped. Between the pulley and front bearing of the drilling head there was a small spiral spring which returned the drill automatically ready for drilling another hole.

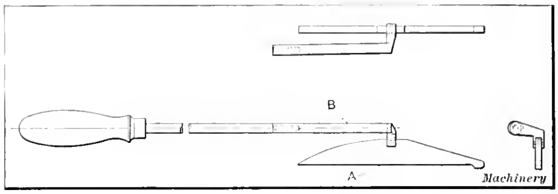
The drilling of this drum required two operators, one for indexing and the other for feeding the drill. The number of holes drilled in the shell was 16,512. It is usually thought that work of this class requires a special machine and the illustration of a method of handling this type of work in a simple way will, no doubt, be of interest to readers of MACHINERY. The drilling and indexing of the 3/16-inch holes was at the rate of about six holes per minute. It will be seen from this that it required but a few seconds per hole to index the work. This work was performed at the plant of the J. N. Lapointe Co., New London, Conn.

New London, Conn. FRANK J. LAPOINTE

MAGNET FOR DETERMINING HARDENING TEMPERATURE OF STEEL

A piece of tool steel loses its power to attract a magnet when its temperature has been raised up to or beyond the point of decalescence at which it should be quenched for hardening. This fact has been taken advantage of in determining hardening temperatures, for which purpose various forms of magnets have been designed to test the temperature of the steel while in the furnace. The accompanying illustration shows a convenient form of magnet, and by following the instructions outlined for using it, very satisfactory results can be obtained.

This tool consists of a piece of magnetized steel *A* which is pivoted to the arm *B* so that it is free to swing. The arm



Useful Form of Magnet for determining Hardening Temperature of Steel

B is made of brass or some other non-magnetic metal, and the magnet is pivoted so that in the event of differences in temperature between parts of the work, either end of the magnet can swing down to indicate such an inequality in the intensity of the heat at different sections of the furnace. It will be seen that a hook is formed at the end of the magnet opposite the handle, for the purpose of drawing light pieces of work out of the furnace when the desired temperature has been reached.

In testing the temperature of steel in this way, the magnet is brought into contact with the work at frequent intervals as it is heated in the furnace, and the steel will continue to attract the magnet until the desired hardening temperature has been reached. When the magnet ceases to be attracted by any part of the steel, it shows that the proper hardening temperature has been attained; and the work should then be withdrawn from the furnace and quenched. Frequent tests should be conducted during the heating of the steel, and care should be taken not to allow the magnet to become too hot. This makes it necessary to withdraw the magnet from the furnace immediately after making each test.

Hartford, Conn. HENRY E. GERRISH

TO OXIDIZE BRASS BLACK

A method of oxidizing brass which I have used and found satisfactory is as follows: Prepare a solution of copper nitrate by dissolving pure copper in commercially pure nitric acid until all action ceases. This should be done in a large jar out of doors, as the chemical action throws off a dense brown vapor which will rust steel or iron, and the volume of the acid increases as it heats. After all action ceases and the mixture becomes cold, the clear liquid is decanted into another jar. Sand-blast the work or clean it thoroughly by some other method, so that it is free from grease of any kind. Work washed in a solution of hot lye and soda, dried in sawdust, and then kept from contact with the fingers or grease until the blackening solution is applied will give the best finish.

Heat the work to a temperature of about 212 degrees F., or the boiling point of water, immerse it in the copper nitrate solution, then remove and heat again until it is just hot enough to dry off the solution and to burn off the green color which appears. This process may be repeated, if it is thought necessary. The work is then cooled and all free

oxide removed by brushing, after which it is dipped in ammonia and rubbed dry with a soft cloth or in sawdust. This will leave the work with a brownish color. To get the dead black color, heat the piece to a temperature that is not high enough to burn the hands but very warm, and rub it with a piece of soft leather having a few drops of pure olive oil on it, after which it should be heated enough to dry the oil.

Highly polished work, if well cleaned and dipped in commercial ammonia before applying the copper nitrate, will take a permanent black. Work that is sand-blasted takes a black that cannot be removed by ordinary wear. Plates used to label steam valves are usually located in semi-dark localities. Good plates may be made for this purpose by stamping the letters into a piece of brass, sand-blasting and oxidizing them and then filling the letters with a mixture of chalk and ammonia. Different colors of chalk may be used and the letters show very plainly in a place where the light is dim. The chalk put in in this way will stand considerable handling before it is dislodged. This is the most permanent black finish that I have ever found and may be applied very economically in quantities.

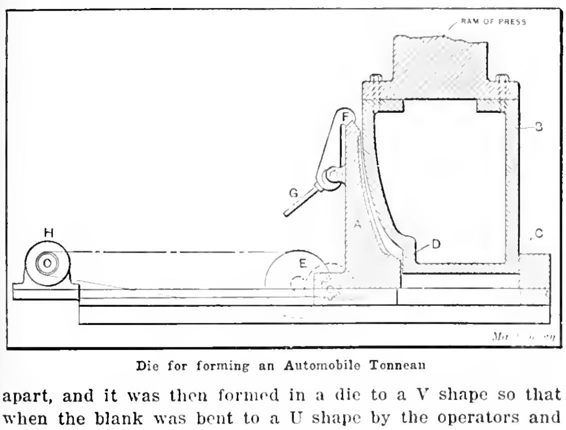
Southbridge, Mass. WARREN E. THOMPSON

DRAWING AN AUTOMOBILE TONNEAU

Some time ago we had an order for steel automobile bodies, and among other shapes we had the tonneau or back of the rear seat to form. The total height of this piece was 23½ inches, while the stroke of the only power press available for the work was 11½ inches. The method of doing the work that was finally adopted was as follows:

The punch *B* was cast and machined to size. The die *A* was fitted to *B* all around at *C* and *D*; the two were then put together and the recess in the die was poured full of type metal. Along the back, on the two sides and the front edges, clamps *F* were fitted; these were operated by eccentric cams. The whole die was fitted to a slide and suitable gearing was provided at *E* to move the die in or out. This gearing was driven by a motor *H* wired to run in either direction.

In operation, the blank was first cut to shape; then the top edge was slit in about 2½ inches at spaces a few inches



Die for forming an Automobile Tonneau

apart, and it was then formed in a die to a V shape so that when the blank was bent to a U shape by the operators and dropped into the die, the top edge fitted on the top of the die, ready for the clamps *F* to engage. The piece was put in place and the side and back clamps locked with the die out at the end of its track. Then the die was run in to a position under the punch and the front edges clamped.

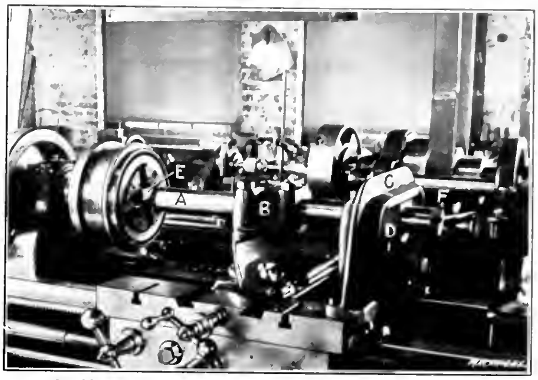
When the punch came down it engaged the backing at *C* and the metal at *D*. As the blank was firmly held at the top, the only place it could draw was from the bottom, and most of the shape was stretched from the metal itself. The die worked fairly satisfactorily and several thousand pieces were formed with it. The blank used was considerably wider than the finished piece, allowing it to project down into the straight part of the die and provide metal to draw from.

This is not offered as the best possible way of doing a job of this kind, but it was the only way possible with the equipment at hand. It is probable that most of the tonneaus in use today could not be made by this method, because the difference in size at the top and bottom would be so great that the metal could not be stretched sufficiently to form them without breaking.

Philadelphia, Pa. W. A. VALLENTINE

RIGID BORING AND THREADING TOOL

An unusually stiff bar for boring and threading high-speed steel dies was needed, and to meet the requirements of this work, the bar shown in the accompanying illustration was designed. It is shown in use on a 16-inch Le Blond engine lathe and it was unnecessary to change the construction of the lathe in any way except to drill and tap three 3/8-inch holes for the cap-screws which hold the yoke *C* to the carriage.



Combination Boring and Threading Bar with Rigid Support

The design of this equipment differs from that of most rigs in that the strain resulting from the overhang of the bar *A* is carried by the yoke *C*. This yoke is provided with a finished pad on its under side, on which the shoe *D* slides to provide for transverse adjustment. Longitudinal adjustment is also provided to allow different lengths of the bar to project. The holder *B* has a tongue on its under side which enters the toolpost slot, and the holder is set at an angle of 29½ degrees, which has been found most desirable. A Novo steel thread chaser *E* is shown working at the end of the bar, and at the opposite end of the bar there is a Novo steel bit *F*. The same bar is available for both boring and threading operations, it being merely necessary to change it end for end. This bar was made of two-inch extra-heavy pipe plugged at each end. The depth of cut and the coarseness of the feed which can be handled are dependent upon the rigidity and pulling power of the lathe.

Pottstown, Pa. CLAYTON DANE

LAYING OUT GEAR-CUTTER FORMS

In the January number of MACHINERY, How and Why section, A. J. T. asks for information relating to gear-cutters. The writer does not pretend to know the method used by gear-cutter makers—they seem to try to keep this matter very secret—but offers the following which has been used in actual practice several times and given satisfactory results.

Some time ago, the writer was employed in a factory where a machine was built in which the teeth in a gear transmission were required to be as nearly correct as possible. The shape of the teeth had to be correct for the exact number of teeth in the gear and pinion, in as far as theoretical accuracy was commercially possible. This requirement eliminated the circular cutter method of milling with standard cutters, as these are correct only for a certain number of teeth, and only approximately correct for the great majority of numbers of teeth in the range covered by one cutter. The gears could have been cut on a Fellows gear shaper and the desired results obtained, but there were other conditions which prevented this, so it was necessary to use a circular cutter. A special cutter, however, had to be made. The writer was given the job and

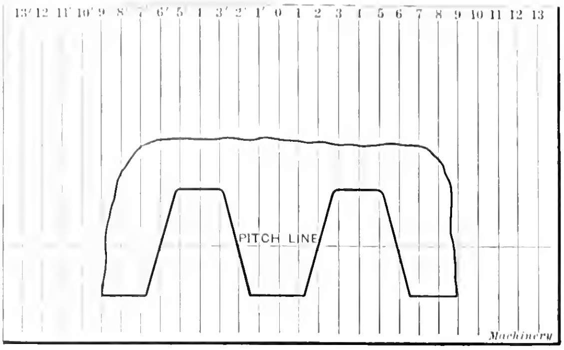


Fig. 1. Short Section of Rack laid out on Enlarged Scale

looked for information on the subject everywhere, but without success.

Starting, however, from the fact that if two gears work perfectly with a rack they will also mesh perfectly with each other, the following method was devised: On a piece of paper lay out a short section of a rack as carefully as possible to correct proportions, and on an enlarged scale, say ten times full size. Make arbitrary divisions and draw lines parallel to the center line, numbering them as shown in Fig. 1. Now on a piece of tracing paper or cloth, draw a center line and scribe the pitch circle, top circle and clearance circle of the gear required, to the same enlarged scale as the rack tooth. Lay off divisions on the pitch circle, draw lines toward the center, and number them as shown in Fig. 3. The divisions on the pitch circle, Fig. 3, are, of course, equal in length to the divisions in Fig. 1. The zero line on the rack is in the center of a tooth and the zero line on the gear will be the center line of a space. The tracing should be tacked firmly to the drawing board. Now slip the rack drawing under the tracing so that the pitch and zero lines coincide, and trace the rack tooth on the tracing cloth. Move the rack drawing so that lines No. 1 coincide and then trace the tooth as before. Do this with every position on both sides of the zero line, and the result is a drawing showing the positions which the rack tooth would occupy if a rack and gear were rolled together. Through the points and lines thus determined draw curves, and we have the exact shape of a formed cutter which will cut an accurate gear. The shape, of course, is on an enlarged scale. Determine the outline by filling in on the tracing with solid black ink. Then draw around the shape thus determined a rectangle *ABCD* of such dimensions that the sides are conveniently divisible by 10, if ten times the natural size has been chosen as the scale.

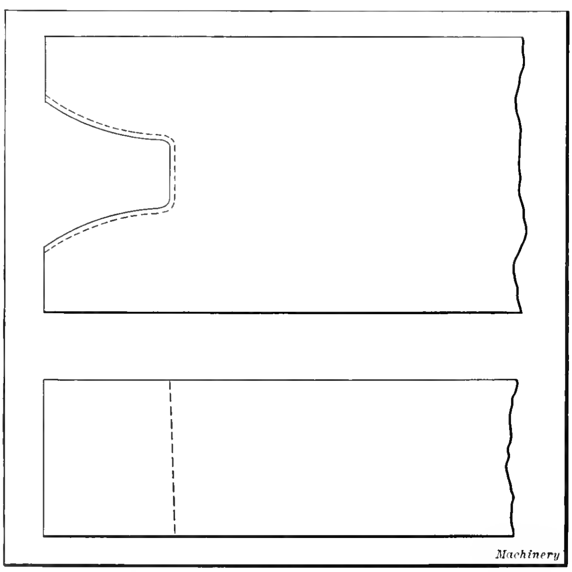

Fig. 2. Formed Tool made from Layout in Fig. 3

The next step is to reduce the tooth outline by photographic means to the natural size. On the ground glass of the camera draw a rectangle one-tenth of the rectangle *ABCD* in Fig. 3. Pin the drawing squarely in front of the camera and focus so that the rectangles match up correctly. Expose the plate, and develop and print by the usual methods. We have now prints showing the exact shape and size of the cutter tooth as nearly correct as it is possible to get them. The next step is for the toolmaker to make a flat cutter from these, as shown in Fig. 2. This is the most difficult part of the work, but it is not as difficult as one might think, when carefully carried out.

The circular cutter is now made, and, after having been rough-turned as nearly to shape as possible, the formed tool, Fig. 2, is used to finish off with a light cut. After the cutter has been gashed to form the teeth, the formed tool is used to

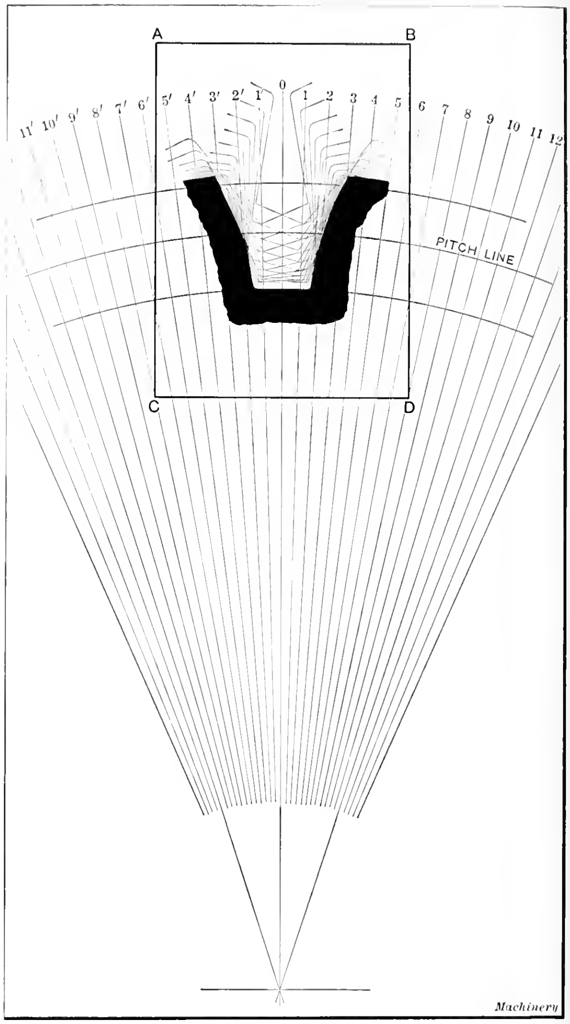

Fig. 3. Tracing of Rack Tooth in Various Positions, giving Form of Gear-cutter

back off or relieve the teeth, preferably in a backing-off machine or in a lathe with a backing-off attachment. If neither of these means is available, the next best way is to pull the belt of the lathe by hand, with the back-gears in, and feed by the cross-slide for each tooth. All that now remains is to harden the cutter carefully and grind the faces of the teeth.

Pawtucket, R. I. RICHARD W. DICKINSON

MEAN CIRCUMFERENCE OF A RING

The usual formula for obtaining the mean circumference of a ring of the form shown at the right-hand side of the accompanying illustration is:

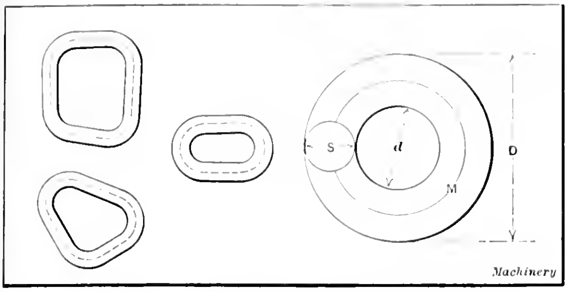

Diagram used in deriving Formula and Examples of Odd shaped Rings

$$\text{Mean circumference} = \pi \times \frac{D + d}{2}$$

where D and d are the inside and outside diameters.

The length L of the wire in a spiral is given by the following:

$$L = N\pi \times \frac{D + d}{2}$$

where N is the number of coils in the spiral.

In working on a certain device where there were a number of rings of different shapes, and in such positions that it was only possible to measure the periphery and the diameter S of the wire, the following formulas were found more convenient to use:

Mean circumference $= \pi\ (D - S) = \pi\ (d + S)$.

Similarly, for spirals, the length L of the wire is given by the following formula:

$$L = N\pi\ (D - S) = N\pi\ (d + S).$$

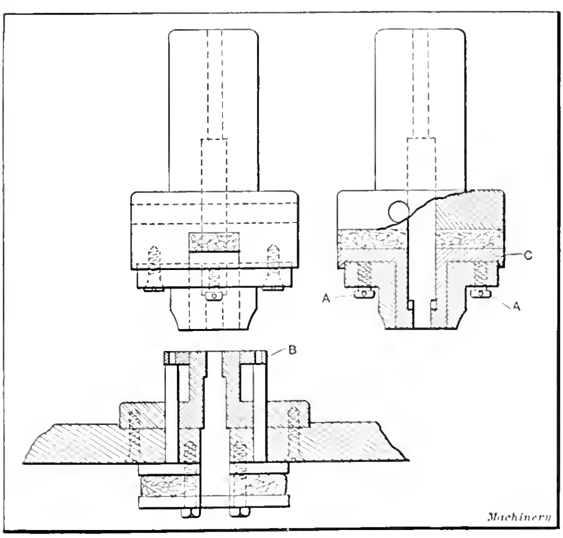
The three small rings shown at the left-hand side of the illustration are examples on which these formulas can be used to advantage.

Syracuse, N. Y. E. J. Engman

DIE FOR MICA WASHERS

The die shown in the accompanying illustration was designed for cutting small mica washers. The familiar form of punch and die made with a leader to push the blank down through the die does not work well on mica, as the material has a tendency to flake off and stick to the bottom of the punch. Mica is also found to wear a die of this form very rapidly. In handling mica in a punch and die, the material should be put in a bath of turpentine and kept in the liquor until it is to be worked up under the press.

The die illustrated in this connection gives good results in making mica washers and affords the operator plenty of room



Compound Die for cutting Mica Washers

to handle the strips of mica. He is able to see through the material to locate it in position over the die so that unnecessary waste will be avoided. The screws A are used in setting the die. By turning them up, the ejector C is forced into the rubber pad. The stripper B is next raised and lifted out It is made free enough to be drawn up by hand. Then the punch and die may be put together ready for setting up on the press; after setting, the stripper B is put back into place Guide pins could be used but they would be in the way in operating the die on scrap stock.

Stamford, Ontario, Can. R. Wilcox

JIG AND FIXTURE DESIGN

In the December number of Machinery, I noticed an interesting article by "Server" describing a variety of clamping devices applicable for use in jig and fixture design. I would like to suggest a few methods that practice has proved to be superior to some shown in the article referred to.

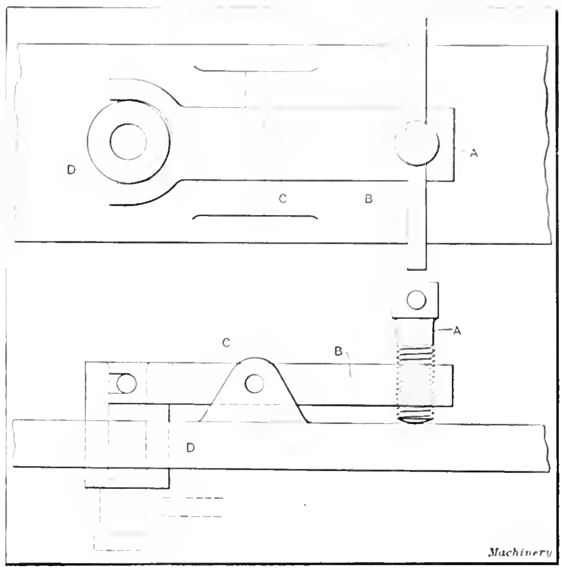


Fig. 1. Good Substitute for Bellmouthed Bushing

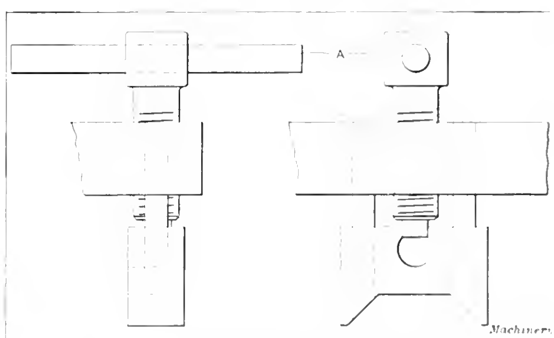

Fig. 2. Superior Method of turning Screw Clamps which avoids Sore Hands

Fig. 5 of "Server's" article showed a bell-mouthed screw bushing which locates and clamps the work for drilling and reaming. This style of bushing requires an extra long drill, and if made with two sizes of holes, as shown, particular care will have to be taken in using small drills to prevent breaking a number of them. Another objectionable feature of this clamping device is that chips work into the threads and prevent turning the bushing easily; this also shortens the life of the thread

Fig. 1 of the present article shows a clamping device which, although a little more expensive, the writer believes to be far superior to "Server's" method. This device would prob-

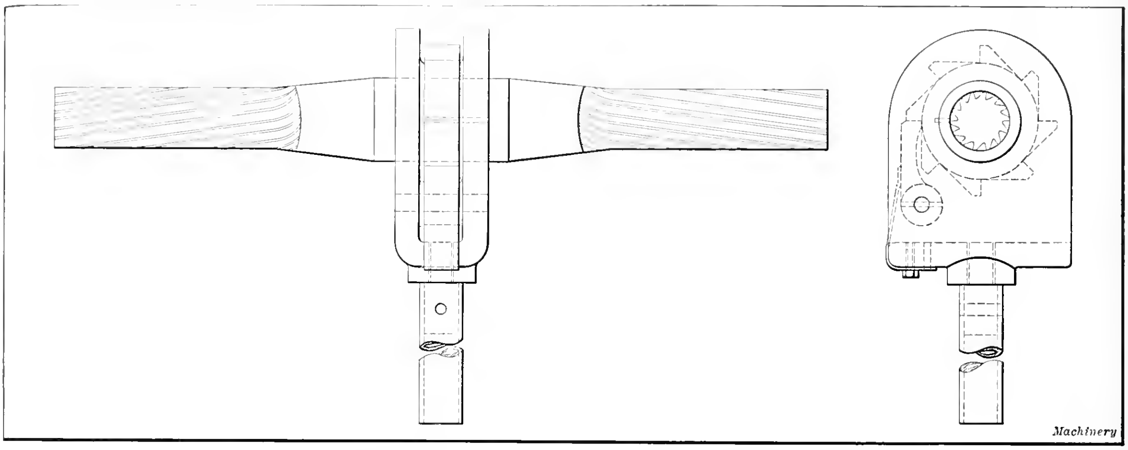
ably pay for itself in saving the breaking of drills, as the bushing on this jig can be made shorter and with one sized hole. Little explanation is necessary to make the operation of this device clear to any mechanic. The screw *A* swings the lever *B* about pin *C* and pushes down the bushing *D* which is a slip fit in the body of the jig.

Figs. 9, 10, 11 and 15 in the article previously referred to showed jigs in which a cast-iron knob was employed for turning the clamping screws. I have seen operators with sores on their hands which were caused by manipulating these cast-iron screw knobs. If it is necessary to use a hand-screw for clamping work in a jig, the design shown in Fig. 2 of the present article will be found far superior. A screw of this kind is cheaper to make and does not injure the workman's hands, as the pin *A*, which is pressed into the head of the screw, may be 3 or 4 inches in length, thus affording ample leverage for tightening the screw. The only reason that I can see for using a cast-iron screw knob is that it looks well in the drawing.

Detroit, Mich. CHARLES STAPLES

REAMING FIXTURE FOR CAM-SHAFT BEARINGS

A great deal of time and labor is required to properly scrape a bearing by hand, and any tool or fixture that will do better work or assist the operator to do the work in a short space of time is a money saver. The reaming fixture shown in the accompanying illustration was designed to overcome the difficulty we had experienced in scraping the bearings for oil engine cam-shafts by hand. These bearings were always babbitted in place in the crank-case by means of a special babbitting mandrel which was designed to bring the cam-shaft bearings in proper alignment with each other, and in the proper relation to the crankshaft bearings. The hand scraping was slow and unsatisfactory and ordinary reaming was of little assistance because of the impossibility of obtaining the required degree of accuracy.



Duplex Reaming Fixture with Ratchet Drive for finishing Cam-shaft Bearings

The spiral reaming fixture which forms the subject of this article is equipped with a ratchet handle for turning it. It will be seen that one right-hand and one left-hand spiral reamer are used, the two reamers being a single unit to prevent any tendency for them to draw away from or push against each other. By placing the reamers in the cam-shaft bearings and tightening the nuts down on the bearing caps, while turning the reamers by means of the ratchet handle, a smooth accurate bearing surface is produced. The bearings are brought to the proper size and in accurate alignment with each other in a very short space of time. M. W. W.

THE "FOLLOW-UP" ENGINEER

To sell a machine and then promptly forget about it until it is thought the same purchaser might be in the market for additional equipment, is fast becoming a selling plan that represents a relic of bygone days. It has long been conceded that a "satisfied customer is the best advertisement," but although this business axiom has been universally revered it has seldom been acted upon so as to really accomplish results. There is, however, a decided tendency toward the increased use of expert demonstrators; in fact, the expert demonstrator might be more properly called a "follow-up" engineer. The activity of the so-called expert demonstrator is no longer confined, by progressive manufacturers, to the aid his services may bring in effecting an immediate sale, but rather as a substantial means of building up a future business. It is in this respect that the activity of the expert demonstrator as a "follow-up" engineer can be made an influence for far-reaching good.

Let us assume that a number of competitive machines are at work in a certain machine shop. Each machine is capable of performing work up to a certain capacity, and if that capacity is not reached, the loss will be felt eventually by the builder of the machine and possibly to a greater extent than by the user. So long as a machine is permitted to be used under conditions that impair its efficiency, it remains a chronic injury to the reputation and business of the builder. Ordinarily, the services of an expert demonstrator circulating among the shops of the users of a certain machine are looked upon as entirely gratis on the part of the builder, but progressive firms have learned that such a practice is mutually beneficial. Aside from the enormous advertising value accruing from the fact that manufacturers' products are working up to a capacity that stamp them as efficient tools, there is an additional benefit to the manufacturers that is often entirely overlooked.

Let us assume, for example, that a grinding machine manufacturer employs as a regular part of the selling organization, the services of an expert demonstrator whose duty it is to visit periodically the shops of users of the product of his company with a view to assisting in bringing the machines up to an increased standard of production. Undoubtedly such an expert is in a position to lend material assistance to the manufacturer which, in itself, should be sufficient recompense. It will be just as readily appreciated, however, that such a circulating expert can also become of great value to the designing organization of the manufacturer whom he represents, in that he is constantly coming in contact with mechanics whose ingenuity is often a potent factor in increasing the utility of the machines they are using. In this way the manufacturer's representative has an opportunity of observing improvised improvements designed for special purposes, that can well be made a part of the design of improved machines as they are brought out from time to time. It is safe to say that many an improvement in the design of machine tools originated in the shops of users. In the same way that a shop that permits no visitors, probably

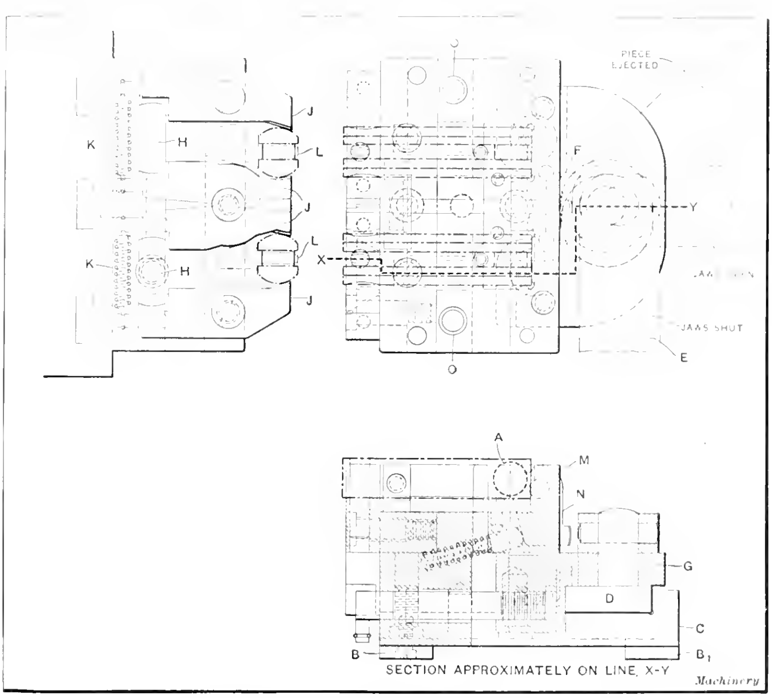
loses as much as it keeps away from competitors, the expert demonstrator learns as much as he dispenses.

A. V. Francis

FIXTURE WITH CLAMPING AND EJECTING DEVICES

The fixture shown in the end, plan, and sectional views of the accompanying illustration was designed for holding the two parts shown by the dot-and-dash lines, while the ends were being ground in an ordinary disk grinder. Each piece consists of two hardened steel strips, shaped as shown by the end view. These two strips are joined by a circular spacer *A*, to which they are electrically welded. The fixture is mounted on the sliding table of the grinder. When grinding, the ends are brought up against the abrasive disk, after which the work is moved back and forth across the face of the disk in the usual manner. The length of the parts is regulated by a stop on the grinder table.

This fixture was made of steel throughout and some of the details were hardened. The fixture is located on the grinder table by the tongue pieces *B* and B_1 attached to part *C*, which, in turn, is fastened in a slot formed in the main body. This member *C* takes the thrust of cam *D* which is operated by lever *E* and serves to clamp the work in position by means of the wedge and lever clamping arrangement seen in the end view. This cam, instead of having a fixed center, floats between parts *C* and *F* and is held sideways by yoke *G*. This yoke has enough swiveling motion to compensate for any inequality in the clamping, due to variations in the size of the work. The clamping bolts *H* are threaded into yoke *G* and have wedge shaped ends which engage the clamping levers *J*. The threaded connection allows for adjustment when the cam or other members become worn. The jaws *J* swivel about the screws shown and are normally held open by springs *K*.



Grinding Fixture so designed that Work is clamped and ejected from Locating Pins by a Single Handle

The work is located by pins *L* and the end-stop *M*. Owing to variations in the size of the work, some of the pieces stuck to the front pins *L* and could not readily be removed. To overcome this difficulty, the ejector *N* was provided to "strip" the parts from the pins. This ejector is operated by the same handle *E* which controls the movement of the clamping jaws. After the jaws are open sufficiently to release the clamps, a further motion of the handle brings it into contact with the end of ejector *N*, thus raising the front end and forcing the work off the pins. The holes marked *O* are used for clamping the fixture to the grinder table by means of screws and T-nuts.

One of the points that facilitated the operation of this fixture was that the handle moved to the left to tighten the jaws and this motion was continued after the work was clamped, thus pushing the grinder table, which moved freely, over toward the abrasive disk and in position for grinding. On the other hand, when the work was to be removed, the pressure on the handle necessary to release the clamps moved the table back away from the wheel.

ADVERTISING IN THE PROFESSIONS

There are many kinds of advertising but the object of all advertising is to increase business. The merchant who has goods that he wishes to sell at a profit buys newspaper space and uses it to tell buyers that his goods are the best obtainable for the money; but that is only one of the ways in which he advertises. His window display is an advertisement, he donates goods to fairs, gives prizes for contests, and, in fact, misses no opportunity to get his name and his goods before the buying public. He is not accused of lack of modesty when he praises his goods and claims that he has made the best selection possible when he bought his stock.

The professional man also has goods to sell. His stock in trade is his services, and the value of his services depends on his ability to get results. It is not good form for a professional man to buy newspaper space and use it to exploit the desirable qualities of his own services, but there are other ways of advertising his ability that are legitimate and are constantly used by professional men. You can hardly pick up a newspaper without seeing an item stating that Dr. So-and-So, the local expert on tuberculosis, delivered a lecture on the benefits of the Red Cross stamp fund, to the Woman's Club, or that Mr. Somebody, the noted lawyer, addressed the Chamber of Commerce on the working of the new income tax law, or that the Honorable Somebody-or-Other—congressman from the first district—addressed a mass meeting on the duty of congress to the people, and, once in awhile, we read of John Jones, the well known engineer, delivering a lecture on efficiency in every-day life.

In this day and age it is not only perfectly legitimate to advertise what you have to sell, but necessary for any large success, and if engineers advertised more extensively than they do their professional standing would be better recognized. It is true that the engineer is not interested in advertising his ability to the general crowd, in the same degree as is the doctor and lawyer; nevertheless, if Joe Brown, the factory superintendent, delivered a lecture to the business men on how to handle men, the "Boss" would be impressed with the fact that Joe did have less trouble with the men than his former superintendent. Furthermore, other bosses that heard the lecture or read of it would note that Joe had some good ideas and was the kind of man they would like to have in their organizations. The opportunities for delivering lectures to general audiences are limited, but one has a good audience at any meeting of the engineering societies to which he belongs. There is another medium, however,

that reaches a large and select audience and that is the technical magazines.

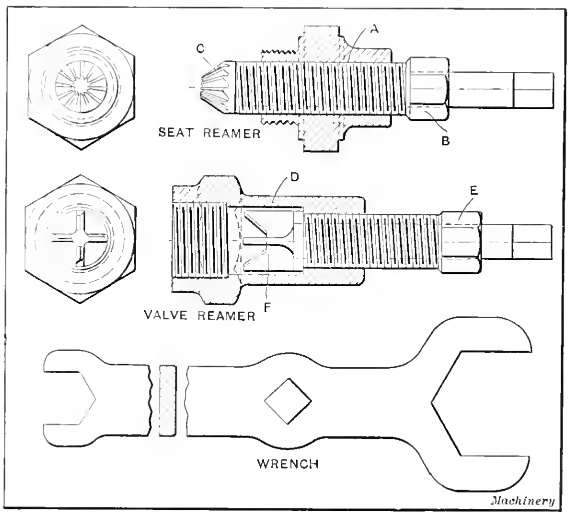
Advertising of this sort, whether it consists of lectures delivered personally or articles published, has a two-fold value: First, it secures a desirable publicity and, second, it provides an incentive for improvement. The man who delivers a good lecture or has a valuable article published begins to think he really does amount to something and he gets the ambition to do something better. He becomes so interested in his subject that it is a pleasure to burn the "midnight oil," digging up everything he can find on that subject, and he goes to the office or shop with a new interest, his field is broadened because his ideas are presented to people all over the world, and if his ideas are faulty, people from all over the world will tell him so, too. This puts him on his mettle to perfect his ideas and defend them, until he is soon looked upon both by others and himself as an authority in his line. When he has secured this result he has reached the same stage as the manufacturer who puts out a staple line of goods with a countrywide reputation. He can sell his services anywhere and the position he reaches is limited only by his ability and energy. This does not mean that advertising need be the only reason for presenting papers personally or through the press, but the advertising and the incentive to better and broader work, are enough to well repay any man for his trouble, and many a man made his start out of the rut in this manner.

NAVILLUS

TOOLS FOR TRUING VALVES AND VALVE SEATS

Keeping gage cocks in good condition is often a serious problem in districts where the water is bad. In such cases the sediment in the water has a tendency to cut the valve and seat. The usual method of grinding takes a considerable amount of time and on account of the difficulty that is experienced in holding the valve exactly in line with the seat during the grinding operation, it is not always possible to get a good tight joint.

The accompanying illustration shows tools which make it possible to grind valves and valve seats with a high degree



Tools used for truing the Valves and Seats of Boiler Gage Cocks

of accuracy. The parts of this outfit consist of a seat reamer, a valve reamer and a wrench for adjusting the parts. The body of the seat reaming tool *A* is screwed into the body of the gage cock, and the adjusting screw *B* is turned until the reamer *C* rests lightly on the seat. Then using the square hole in the handle of the wrench, it is only necessary to give the reamer a few turns in order to true up the seat. Similarly, the valve reamer body *D* is screwed onto the gage cock bonnet with the valve in position, after which the adjusting screw *E* is turned to bring the reamer *F* into contact with the valve. The valve is then trued up in the same way that the seat of the valve was refinished.

The importance of having the cutting face of both reamers of exactly the same angle is evident, for if they do not correspond it is obvious that the valve will not fit properly in its seat. These tools cut rapidly and the operator who uses them should be instructed to apply a very light pressure and to be careful not to ream away more material than is necessary to insure a good fit. Although these tools were designed for use on gage cocks, the design could be easily modified to produce a tool suitable for use on any common type of valve having the same style of seat.

Lincoln, Neb. H. E. GILLETTE

GAGE FOR SCREW MACHINE WORK

A type arm pivot made on the automatic screw machine is illustrated in Fig. 1, and an interesting form of gage for testing the accuracy of these parts is shown in Fig. 2. The thin ends of this part constitute the main bearings of the pivot and it will be seen that the limit of tolerance allowed is very small. Referring to the illustration of the gage shown in Fig. 2, it will be seen that the block *A* is secured to the base by means of two screws and two pins and that it is drilled to receive the gage *B*. This gage is a press fit in the block *A*. A similar block *C* is secured to the base and drilled to receive the gage *D*. This block is of greater length in order to accommodate the spring which returns the gage to its original position after it has been moved back by the handle *E* to allow the work to be put in place.

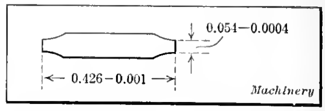


Fig. 1. Screw Machine Work to be gaged

To check the dimensions of a piece of work with this gage, the inspector pulls back the lever which moves the gage *D*

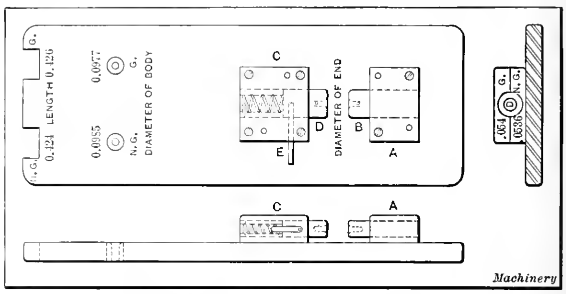

Fig. 2. Gage for Piece shown in Fig. 1

with it. This enables one end of the type arm pivot to be slipped into the gage *B*, which has a hole in it of exactly the same shape as the end of the work to be gaged. The handle *E* is then released and the spring returns the gage *D* over the opposite end of the work. It will be seen from the illustrations that the limit of tolerance on these pins is between 0.0536 and 0.0540 inch, and the gage indicates whether the dimensions are within these limits by the position of the movable gage *D*. All screw machine operators do not have a micrometer graduated to 0.0001 inch and this gage takes the place of such a micrometer with perfect satisfaction. It will also be seen that holes and slots are provided at the left-hand end of the gage for checking the dimensions of the large diameter and the length of the work.

LEO MORTON

* * *

Automobile engineering as a career will be made the subject of a series of talks before the engineering societies of various colleges, according to a plan that has been formulated by the metropolitan section of the Society of Automobile Engineers. The need of trained men is constantly felt in the automobile industry, and it is believed that it properly devolves upon this society to assist in attracting the attention of undergraduates to this field. Incidentally, the advantages of junior membership will be advocated as a means of getting into touch with current practice before engaging in practical work.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

TO REMOVE OIL VAPOR FROM COMPRESSED AIR

O. B. M. Co.—We are interested in a device for extracting oil vapor from compressed air. We use compressed air to blow bottles with our bottle machine, and the oil vapor, we believe, causes the inside surface of the bottle to become smoky. We will be glad to receive details of any successful device for removing the oil vapor resulting from the lubrication of the air compressor cylinder.

A.—The apparatus used by the large watch companies for purifying the air supplied to rooms in which certain operations are conducted would, perhaps, answer your requirements. The Waltham Watch Co. has been fairly successful in removing lubricating oil from compressed air by passing the air through an after-cooler and settling chamber before it enters the discharge pipes. The after-cooler breaks the air up into small columns and the air is cooled to a temperature that causes a large percentage of the oil to be deposited in the bottom of the settling chamber. Further refinement is accomplished by the use of oil separators in the air mains provided with suitable drip connections. It is necessary to cool the air, and to reduce its travel to a low velocity in the settling chamber in order to remove the oil efficiently.

STRESSES IN SHEAR FRAME

W. W. McK.—I wish to build a small hydraulic shear and would like to have some information regarding the forces acting on and in the frame. Referring to Fig. 8, there is a driving force of 40,000 pounds acting at A. When the plate or bar to be sheared is held perpendicular to the line of action of the driving force A, what will be the force tending to separate the shear blades; *i. e.*, what will be the amount in pounds or in terms of the driving force A of the forces at B and C? I would also like to know what the angle θ in degrees should be between the top and bottom shear blades in order to offer the least possible resistance to shearing.

Answered by William L. Cathcart

The angle between the blades, that is, the inclination of the upper blade to the horizontal, varies between 5 and 15 degrees — 5 degrees for thin, and 15 degrees for thick material.

General Methods of Determining Stresses

In finding the principal stresses in this shear, the methods of graphic statics will be used, since, in this case, they will be simpler and more compact than analytical treatment. The leading principles on which these methods are based are as follows: To every action there is an equal and opposite reaction. Thus, if an anvil be struck by a hammer, it will strike back with a reacting force equal to the force of the hammer blow. When two bodies strike each other or are pressed together, the reaction of the body struck or pressed upon is, disregarding friction, always normal to the surfaces in contact. A body in motion may be considered as in momentary equilibrium at any instant under the action of the forces and reactions acting upon it at that instant. In order that a body shall be in equilibrium, the lines of action of its forces and reactions must meet in some common point; if they do not thus meet, there is a resultant couple tending to make the body rotate. The particulars required to be known as to each force or reaction of any given system are its magnitude and direction. When all but two of these particulars are known for the system, a "force triangle" or—for more than three forces or reactions—a "force polygon" can be drawn, with each of its sides parallel to the line of action of a corresponding force or reaction. From such a triangle or polygon the unknown magnitudes or directions can be determined. In order that a body shall be in equilibrium, there are two conditions: the force triangle or polygon must close, that is, its sides must meet; and, second, the forces and reactions must all have the same direction in passing around the periphery of the triangle or polygon. When, on the other hand, the direction of any one force in such a triangle or polygon is opposed to that of all of the others, the corresponding side represents, in magnitude and direction, the resultant of a system acting on a body which is not in equilibrium.

Negligible Factors

There are some factors in this problem which, for all practical purposes, may be disregarded, since they have no very material effect on the results, and their omission will greatly simplify the analysis. For example, friction will not be considered although, acting near the upper left-hand corner of the tilted moving blade, it has a relatively slight effect in opposing and reducing the driving force. Again, the cutting edges of the blades are usually ground to an angle of about

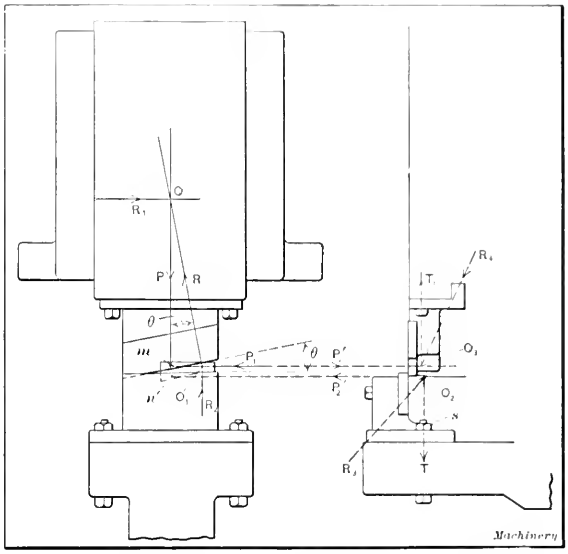

Fig. 1. Diagram showing Forces and Reactions to be considered

87 degrees, that is, 3 degrees with the horizontal, which diverts the effective shearing force and blade reactions into a plane 3 degrees from the vertical. This inclination is too small for consideration in this machine and the shearing faces of the blades will, therefore, be taken as horizontal. Again, the upper blade, after shearing the plate, bends it as the blade moves downward, which reduces the gross driving force by the amount required for bending—a factor which may be neglected. Finally, in finding the reactions of the guide and the lower blade, these reactions and the driving force will be temporarily taken in Fig. 1 as in the same vertical plane, an assumption which will not modify the results appreciably.

Effective Shearing Force and Thrust on Guide

The effective shearing force is the component of the driving force which is normal to the cutting face of the upper blade. The thrust on the guide is the horizontal component of the driving force. Referring to Fig. 1, the driving force is uniformly distributed over the cutting face of the upper blade and the resultant of these distributed forces is a single, concentrated force P, having a vertical line of action at the middle of the blade. The upper reactions of the plate or bar which is being sheared have a resultant R which is normal to the cutting face of the blade. Similarly, the reactions of the guide against the thrust of the blade have a resultant R_1 which, disregarding friction, is normal to the surfaces in contact and is therefore horizontal. At any point in its stroke the upper blade may be taken as in momentary equilibrium under the action of P, R, and R_1. While the position of the line of action of P is fixed, the positions—although not the inclinations—of the lines of action of R and R_1 vary with the position of the blade and that of the bar under shear. As the blade is in equilibrium, the

three lines of action must meet in a common point. Assume that point to be O for this position of the blade and bar.

The driving force is given as 40,000 pounds. In Fig. 2 lay off ab parallel to the line of action of P and equal, to any convenient scale, to 40,000 pounds. From b, draw bc and from a lay off ac, parallel, respectively, to the lines of action of R and R_1. Then, measured on the same scale, $bc = R$ and $ca = R_1$. The directions of P, R, and R_1, as transferred from Fig. 1, are the same in passing around the triangle abc, and hence the blade is in equilibrium. The effective shearing force is equal to R but opposite in direction. Similarly, the thrust on the guide is equal and opposed to R_1. If friction had been considered, R_1 would have been inclined upward from the horizontal by the amount of the angle of friction and the thrust on the guide would have a downward component. In Fig. 1, let θ be the angle between the blades. Then, in Fig. 2, the angle abc is also, by geometry, equal to θ. Hence, analytically, we have:

$$\text{Cos } \theta = \frac{ab}{cb} = \frac{P}{cb}.$$

$$\text{Effective shearing force} = cb = \frac{P}{\cos \theta}.$$

This force is greater than P, as it is distributed over the inclined shearing face of the blade. Similarly:

$$\text{Reaction of lower blade} = R_2 = \frac{P \cos \theta}{\cos \theta} = P.$$

Tilting Couple acting to Force Blades Apart

Fig. 4 shows a vertical section of the blades and bar being sheared, the section being taken just to the right of the middle of the blades in Fig. 1. Shearing is not a cutting or sawing action, but a detrusion—a bodily thrusting down by the upper blade of the metal along the plane of shear. The effective shearing force, $\frac{P}{\cos \theta}$, is normal to the cutting edge of the inclined upper blade; it has a vertical component equal to the driving force P, which component is opposed by the reaction from the lower blade, and, as has been shown, this reaction is also equal to P. As the cutting edges are ground to an angle of but 3 degrees with the horizontal, there is no tendency to tip the bar when the upper blade first strikes it, since the pressure of the latter and the reaction of the lower blade have practically the same line of action; but, as soon as the cutting faces of the blades engage the bar fully, the lines of action of the force and reaction move to the centers of their respective blades, and, as shown in Fig. 4, are then distant by an amount x which depends on the thickness of the blades. The two equal and opposite forces P, whose lines of action are separated by the distance x, constitute a couple

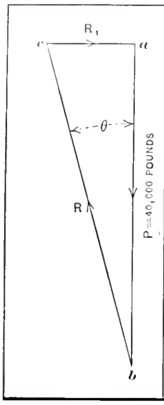

Fig. 2. Force Triangle for Reaction of Upper Blade

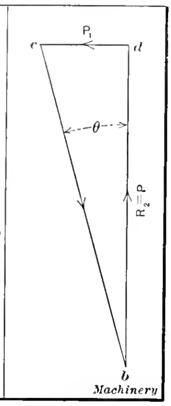

Fig. 3. Force Triangle for Reaction of Lower Blade

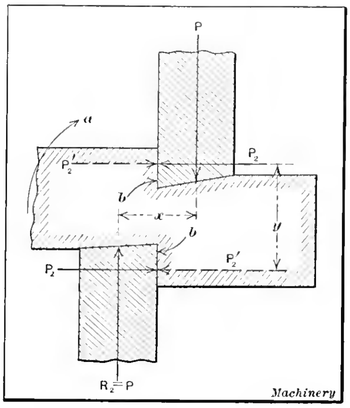

Fig. 4. Diagram showing Tilting Couple and Couple resisting Tilting

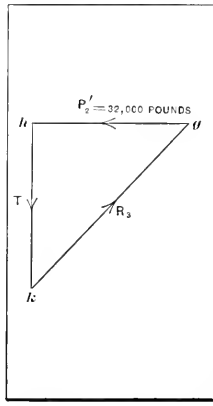

Fig. 5. Force Triangle for Forces and Reaction of Lower Bracket

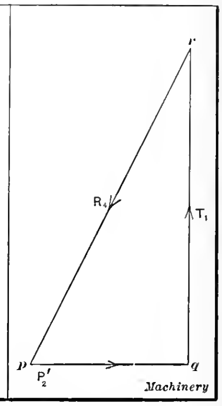

Fig. 6. Force Triangle for Forces and Reaction of Upper Bracket

$$\text{Sin } \theta = \frac{ac}{cb} = \frac{ac \cos \theta}{P}.$$

$$\text{Thrust on guide} = ac = \frac{P \sin \theta}{\cos \theta} = P \tan \theta.$$

Reaction of Lower Blade

Referring again to Fig. 1 and assuming, as previously stated, that the lines of action of the forces and reactions of the blades all lie in the same vertical plane, the bar which is being sheared is in equilibrium under the action of the effective shearing force, which is the reaction R reversed; the reaction R_2 from the lower blade, which is normal to the surfaces in contact and therefore vertical; and a force P_1 which is equivalent to the effect of friction and acts horizontally toward the left. If there were no friction and if this force were absent, the bar would slide out of the shear toward the right as soon as the upper blade put pressure on it. Since the bar is in equilibrium, these three lines of action meet at the common point O_1.

In Fig. 3, lay off to any convenient scale, cb equal to the effective shearing force and parallel to its line of action. From b, draw bd and from c lay off cd, parallel, respectively, to the lines of action of R_2 and P_1. Then, measured on the same scale, $bd = R_2$ and $dc = P_1$. The angle $cbd = \theta$ and as:

$$cb = \frac{P}{\cos \theta}$$

$$\text{Cos } cbd = \cos \theta = \frac{bd}{cb} = \frac{R_2 \cos \theta}{P}.$$

whose moment or power is equal to the product of one of the forces and the arm of the couple, that is:

Moment of tilting couple $= Px$ inch-pounds.

The tendency of a couple is always to produce rotation of the body on which it acts. As shown by the arrowhead a, this couple, if unopposed, would revolve the bar in a clockwise direction and press it against the blades, tending to force them apart as indicated by the arrows b.

It should be observed that this tilting moment Px is a theoretical maximum which will not be fully attained in practice. It disregards the friction of the upper blade in its guide and assumes that the bar being sheared is thick enough and wide enough to require the full driving force to shear it and to bend the sheared part under the upper blade, as shown in Fig. 1. Further, while the common theory of flexure assumes the shearing stress to be uniformly distributed over the cross-section of a bar under shear, the actual power required to shear such a bar varies at different points in the depth. Thus, Prof. Goodman, in "Mechanics Applied to Engineering," page 315, states that, from autographic shearing diagrams it is found that the maximum force required occurs when the shearing "tackle" is about one-fifth of the way through the bar. At this point then the tilting couple would be a maximum. As, at all other points in the depth of the bar, it would be less, and as the inclination of the upper blade makes every point of its cutting edge shear simultaneously at a different depth, it is wholly probable that the average tilting moment at any point in its stroke is considerably less than the theoretical maximum calculated above—how much less is, however, indeterminate theoretically.

The Couple Resisting Tilting

As has been stated, the couple Px tends to rotate the bar. Since the bar does not thus rotate, this couple must be opposed and balanced. A couple can only be balanced by an opposite couple of equal moment. This resisting couple must be constituted by the reactions of the blades to the pressure upon them by the bar, owing to its attempted rotation by the tilting couple. In other words, the blades make fulcrums of their supports to withstand the strain produced by their own action in different vertical planes, as is essential in shearing. The resisting couple is represented in Fig. 4 by the forces P_2 with the arm y, which arm decreases as the blade moves downward. In accepting the theoretical maximum of the tilting couple as above, we shall err on the side of safety. To balance each other, the moments of the two couples must be equal. Therefore:

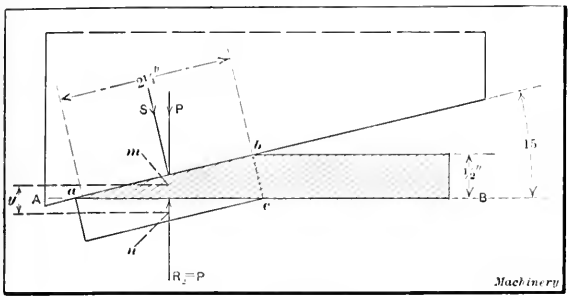

Fig. 7. Section through Plate under Shear showing Average Value of Arm y of Resisting Couple

Moment of resisting couple $= P_2y = Px$ inch-pounds.

It is evident that, so far as tilting is concerned, the couple Px may be replaced by the equivalent couple P'_2y, having the same line of action as the resisting couple P_2y. Then:

Moment of equivalent tilting couple $= P'_2y = Px$ inch-pounds, in which $P'_2 = P_2$.

From this equation, the normal pressure acting near the extremity of each blade to force the blades apart is:

$$\text{Normal tilting force} = P'_2 = \frac{Px}{y} \text{ pounds.}$$

Numerical Results

Substituting in the several equations deduced above, we have the numerical results given in the table. These results apply strictly only when the bar to be sheared is so thick and wide that the total driving force of 40,000 pounds is required to split it. The data for a blade angle of 5 degrees can be found similarly from these equations, if the driving force P be given a suitable value for this metal. In any case, average values of the tilting couple and normal pressure should be estimated from the maximum values tabulated.

TABLE OF SUMMARY OF RESULTS

Blade Angle $\theta = 15°$: Driving Force $P = 40{,}000$ pounds.

Natural functions of 15°: sin $= 0.259$; cos $= 0.966$; tan $= 0.268$.

$$\text{Effective shearing force} = \frac{40{,}000}{0.966} = 41{,}408 \text{ pounds.}$$

Horizontal thrust on guide $= 40{,}000 \times 0.268 = 10{,}720$ pounds.

Reaction of lower blade $= 40{,}000$ pounds.

Maximum moment of tilting couple $= 40{,}000 \times x$ inch-pounds.

Maximum normal tilting pressure on each blade $= 40{,}000 \times \frac{x}{y}$ pounds.

Stresses in Holding Bolts of Jaw

The stresses in the bolts holding the jaw, due to the tilting forces on the blades, can be ascertained with accuracy by the methods of graphical statics, when a drawing made to a fairly large scale is available. The results given below — found from a cut no larger than Fig. 1 — are necessarily somewhat approximate. The methods of obtaining them, however, can be made entirely clear, and will serve for later application to a suitable drawing. Each of the two brackets of the jaw should be considered separately and regarded as in equilibrium under the action of the forces and reactions acting upon it. The lower bracket is of the same height throughout; the upper bracket, however, slants downward and is deepest at the left, giving the normal pressure a greater leverage there. The force P'_2 represents the total tilting force on each blade, and, while it is distributed along the part of the edge which is cutting it may be considered as concentrated at any selected point where the resultant of its distributed forces may be assumed to act. This force should be given a definite value, in order to find the stresses in the bolts. Assume that a narrow bar of 1/2-inch steel is to be sheared, and that it will be inserted at about the center line of the blades, as shown in Fig. 1. Take $x = 3/8$ inch and $y = 3/8$ inch as an average value when the maximum resistance to shearing occurs; and estimate four-fifths of the maximum tilting pressure as the average normal pressure along the cut at this time. Then, from the table:

Normal tilting pressure $P'_2 = 4/5 \times 40{,}000 \times 3/8 \times 8/3 = 32{,}000$ pounds.

Now, assume the forces P'_2 as acting at the points m and n near the center lines of the blades. Consider the lower bracket of the jaw; as the force P'_2 is regarded as concentrated at the point n, we may take the total tensile stresses in the two bolts as temporarily concentrated in a single bolt s, which alone secures the flange and is in the vertical plane passing through the points m and n. The bracket is, therefore, in equilibrium under the action of the force P'_2, acting toward the left; the tensile stress T in the bolt, acting downward; and a reaction R_3 from the frame. From n project the line of action P'_2 on the side elevation of the bracket and draw through the center of the bolt the vertical line representing the line of action of T. These two lines of action meet at the point O_2. Under the thrust of the force P'_2, the bracket will tend to tip, pivoting on the lower, left-hand corner. This corner gives one point in the line of action of R_3; the other point is determined by the fact that, for equilibrium, the lines of action of all forces and reactions must meet at a common point, which is the point O_2. The line of action of R_3 therefore passes through O_2 and the lower, left-hand corner of the bracket and is so drawn in Fig. 1.

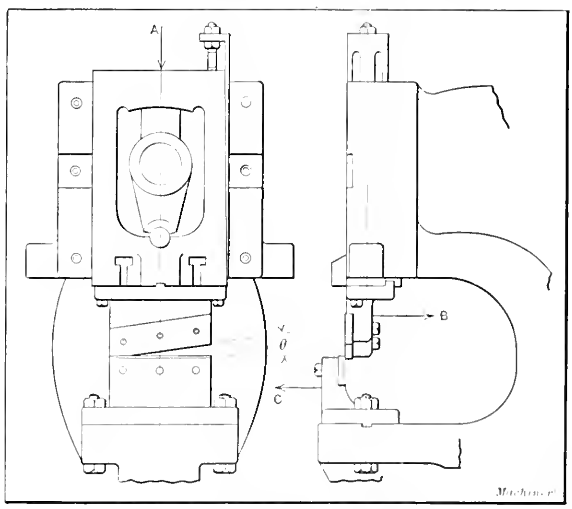

Fig. 8. Type of Shear to be Designed

In Fig. 5 — which should be drawn to as large a scale as possible — lay off gh parallel to the line of action of P'_2 in Fig. 1 and equal to 32,000 pounds. From g and h, draw gk and hk parallel, respectively, to the lines of action of R_3 and T, as given in Fig. 1. Then, measured on the same scale, the total tensile stress T will be found to be 34,130 pounds. As there are two bolts, the stress in each will be 17,065 pounds, since the points m and n are on the center lines of the blades. If the bolts are made small enough to stretch to an appreciable extent when under strain, tensile bending stress will also occur in them. With moderately large, body-bound bolts, the effect of bending may be disregarded.

Fig. 6 shows the force triangle for the upper bracket. It is drawn similarly. The line of action of P'_2 in Fig. 1, projected from the point m, meets the line of action of the upward tensile stress T_1 in the bolt at the point O_3. The bracket pivots on its upper right-hand corner. The line of action of the reaction R_4 passes through this corner and the point O_3. The bracket is in equilibrium under the action of P'_2, T_1, and R_4. In Fig. 6, the line pq is drawn parallel to the line of action of P'_2 and equal, as before, to 32,000 pounds. From q and p, the lines qr and pr are laid off parallel, respectively, to the lines of action of T_1 and R_4, as given in Fig. 1. Then, measuring on the same scale, we have $qr = T_1 = 64{,}000$ pounds or 32,000 pounds in each of the two bolts. As in Fig. 5, the direction of the reaction R_4 is determined by the condition that, in passing around the triangle, all forces and reactions must have the same direction.

The greater tensile stress in the upper bolts, as compared with that in the lower, is due to two conditions: first, the distance from the point m to the flange above it is slightly greater than the corresponding distance from the point n to the lower flange, giving the pressure on the upper blade a greater leverage; and, second, according to the cut, the base of the upper bracket is narrower than that of the lower, which makes the inclination of the line of action of its reaction more nearly vertical than that of the lower bracket. It should be remembered, as to these results, that they are neither exact nor closely approximate, owing, first, to the necessary assumptions as to the average magnitude and location of the resultants of the normal tilting forces on the blades, and, second, to the small scale of the drawing from which the directions of the reactions were found. The method of obtaining them has, however, been made sufficiently clear to enable more accurate results to be obtained under suitable conditions.

In any event, the values of the resisting couple and the normal pressures on the blades will vary with any differences in the thickness and shearing strength of the plate to be sheared. The maximum possible values should, of course, be used in designing. Thus, if the driving force P be taken as 40,000 pounds and the ultimate shearing strength of steel as 70,000 pounds per square inch, then $\frac{40{,}000}{70{,}000} = 0.57$ square inches, the greatest possible area of the triangular section abc under shear in Fig. 7. This gives a thickness of plate of ½ inch, a length ab of 2¼ inches, and an average value of y of about 0.35 inch, or slightly less than ⅜ inch. It will be seen that the points m and n and the locations of the forces P and R_2 move to the right as the blade descends. Hence, if plates of nearly the full width of the blades are to be sheared, the total normal pressure on either blade cannot be considered as equally divided between the two holding bolts, but must be taken as applied at some points as near relatively to each bolt as is shown for the left-hand bolt in Fig. 7, which is drawn approximately to scale. In this figure, AB represents the top of the lower blade and S the effective shearing force which has been made equal to P to allow roughly for friction and bending. The force P'_2 should be taken as near as practicable to either bolt and then divided between the two bolts, inversely as their distances from it. Thus, if P'_2 acts three times as far from one bolt as from the other, the latter will have a maximum strain of ¾ P'_2.

* * *

GENERAL TREND OF AMERICAN MOTOR DESIGN

In a paper presented by W. M. Power before the Metropolitan Section of the Society of Automobile Engineers in New York City March 26, 1914, a comparison was made between the general developments of American and British motors. American motors, with few exceptions, are characterized by large cylinders, the ratio of bore to stroke, compression, piston speed, maximum output per pound, and economy being low. The British automobile makers have gone to the other extreme and are building motors having almost exactly opposite characteristics, from which they are getting power outputs which, a few years ago, would have been considered impossible. The fuel economy of these engines is far beyond anything obtained by American makers. These results are due to very large valves and ports, the latter being designed to give smooth flow lines. High compression and very high piston speeds, well above 3000 feet per minute, are characteristic of these motors; but these engines must be driven carefully if they are to give maximum service. The motor must never be allowed to run on wide open throttle at low speeds. This means, of course, that gear changing is frequently necessary. These engines require great care in driving and adjustment, and the overhauling must be carefully done.

The British and American types of motors have advantages peculiar to themselves both from the manufacturing and operating standpoint. Given proper equipment in the shop, the workmanship required in the two types is about the same, except that the light connecting-rods and pistons required for the small motor are somewhat more costly and more difficult to manufacture.

The probability is that the most suitable motor for service in America is a compromise between the extreme British type and the present American type, being designed to give a well sustained torque up to about 2000 feet piston speeds per minute. The capacity of an engine for a five-passenger car should probably be about 4000 to 4500 cubic centimeters for a four-cylinder motor and about 5500 to 6000 cubic centimeters for a six-cylinder car.

* * *

WORLD'S OUTPUT OF IRON AND STEEL

The probable world's output of iron ore in 1912 was about 152,000,000 tons, or more than 5 per cent above that of 1910. The principal producers were the United States, Germany, France, the United Kingdom and Spain, in the order given, these five countries producing about six-sevenths of the total output of the world. The following table gives the output of iron ore in 1911 and 1912:

	1911, Tons	1912, Tons
United States	43,877,000	55,150,000
Germany (including Luxemburg)	29,399,000	32,190,000
France	16,372,000	18,744,000
United Kingdom	15,519,000	13,790,000
Spain	8,633,000	———
Russia (excluding Finland)	6,882,000	8,054,000
Sweden	6,055,000	6,593,000
Austria-Hungary	4,640,000	2,880,000
Canada	188,000	156,000
Belgium	148,000	165,000

The ore resources of the world are given in an estimate made at the International Geographical Congress at Stockholm in 1910. It was then estimated that the total actual resources of iron ore existing in deposits that can at present be worked at an economic profit amount to 22,408,000,000 tons, representing 10,192,000,000 tons of iron. This total would supply the requirements of the world for considerably less than two centuries, even were the present rate of output not exceeded. The actual resources of the principal ore-producing countries are estimated to be, in the United States 4,258,000,000 tons, the equivalent in metallic iron being 2,305,000,000 tons; in Germany and Luxemburg, 3,878,000,000 tons, estimated to yield 1,360,000,000 tons of metallic iron; in the United Kingdom 1,300,000,000 tons, equal to 455,000,000 tons of metal; in France 3,300,000,000 tons, equal to 1,140,000,000 tons of metal; and in Spain 711,000,000 tons, equal to 349,000,000 tons of metal. In addition, the potential resources of the world not yet developed are estimated, so far as they can be calculated in figures, to amount to 123,377,000,000 tons of ore, representing 53,136,000,000 tons of iron. Further, very large supplies of iron ore are understood to exist in China, Canada, and other countries.

The world's production of pig iron in 1912 was about 72,000,000 tons, the United States, Germany, and the United Kingdom accounting for about seven-ninths of the total. The United States' output was 29,727,000 tons; Germany's, 17,582,000 tons; and the United Kingdom's, 8,751,000 tons. For the first half year of 1913 the figures for the three principal countries were: United States, 16,489,000 tons; Germany, 9,414,000 tons; United Kingdom, 5,411,000 tons.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

UNION FORMED CUTTER GRINDER

The grinding machine which forms the subject of this article has been developed by the Union Twist Drill Co., Athol, Mass., for use in sharpening gear-cutters and similar types of formed cutters. Its use enables the cutting face of the teeth to be ground radial, with the periphery of each tooth at the same distance from the center of the cutter. The grinding wheel is mounted on the lower end of the vertical spindle, the spindle being carried by a slide which has a vertical movement to provide for advancing the wheel to the cut. The spindle may also be moved in a plane at right angles to its axis to suit the diameter of the cutter to be ground. The cutter is mounted on a horizontal arbor supported by the table. The capacity of the machine is for cutters up to 8 inches in diameter by 3 inches face width, and the size of the grinding wheel used is 6 inches in diameter, with an adjustment of 4 inches to or from the work in a horizontal plane.

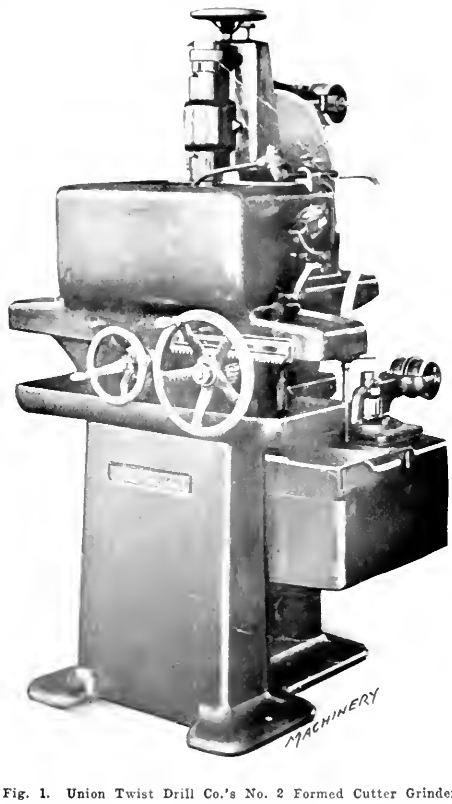

Fig. 1. Union Twist Drill Co.'s No. 2 Formed Cutter Grinder

A pump and tank provide an ample flow of water to the grinding wheel and the spray thrown off by the wheel is caught by the walls of the tank in which the cutter and wheel are located. In the operation of sharpening the cutter, the table carrying the cutter is moved back and forth past the grinding wheel. An extra movement of the table toward the right carries a diamond across the face of the grinding wheel. This diamond serves two purposes. First, it may be used to remove glaze and true the face of the wheel; second, it acts as a stop for the vertical adjustment of the wheel when sharpening each tooth of the cutter. The diamond is located in the horizontal plane passing through the center of the cutter arbor by means of a gage provided for the purpose. When the wheel slide has been adjusted downward until the wheel makes contact with the diamond, the cutting face of the wheel must be in the same plane as the center of the cutter, and the face of the teeth of the cutter ground with the wheel in this position must be truly radial.

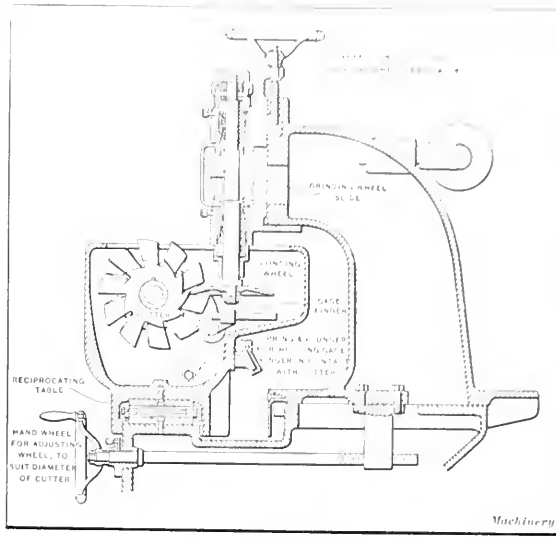

Fig. 2. Cross-section through Grinder showing the Gage Finger for measuring the Peripheral Eccentricity

For indexing the teeth of the cutter when grinding, a patented principle is employed. In explanation it may be remarked that if an evenly spaced index plate is used for locating each tooth of a cutter relative to the grinding wheel, the cutter may not run true, *i. e.*, the periphery of each tooth need not be at the same exact distance from the center of the cutter. This is due to the change of form which frequently takes place when the cutter is hardened. When hardened, the cutter will have a tendency to assume an elliptical shape, in which event it will not run true when the teeth have been evenly spaced. The eccentricity of the different teeth of the cutter suggests a way of correcting this error resulting from the hardening operation. By gaging each tooth, it is possible to determine which teeth are farthest from the center, and by grinding these teeth on their radial face, the distance of the periphery of each tooth from the center can be made the same. The design of the Union Twist Drill Co.'s No. 2 cutter grinder is such that the amount ground off the radial face of each tooth is proportional to the distance of the periphery of that tooth from the center of the cutter.

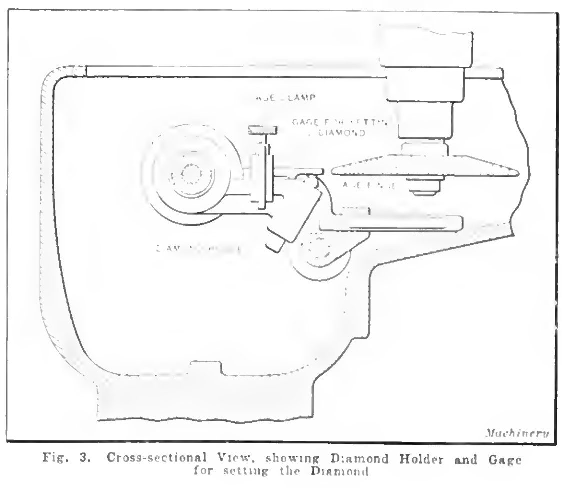

Fig. 3. Cross-sectional View, showing Diamond Holder and Gage for setting the Diamond

After the cutter is correctly ground, it may be that the teeth will not be accurately spaced but the cutter will run very true. This result is obtained by means of a gage finger shown in Fig. 2, which is adjusted to engage with the relieved periphery of a tooth of the cutter at a point near the radial face of the tooth. The gage is held in contact with the cutter by a spring and the exact location of the point of the gage relative to the center of the cutter is indicated on a dial. A movable pointer on this dial is actuated through a system of multiplying levers so that a variation in position of the gage finger of 0.001 inch may be easily read. This gage is virtually a radius caliper. By applying the finger of the gage to each successive tooth of the cutter, and rotating the cutter on its axis until the reading of the pointer on the dial is the same for each tooth, the particular point in the periphery which is at the same distance from the center may be de-

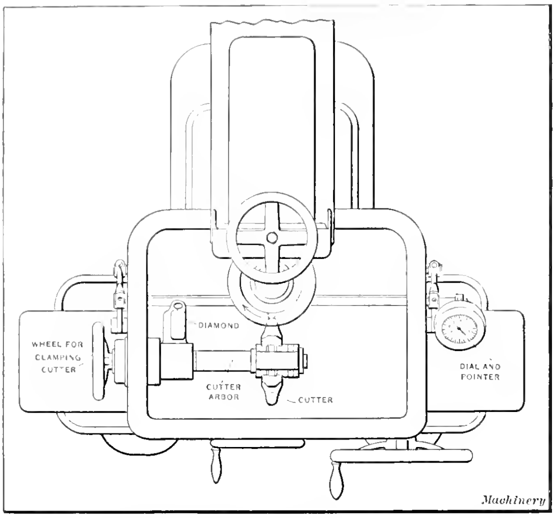

Fig. 4. Arrangement of the Cutter Arbor and Dial of the Gage for testing the Work

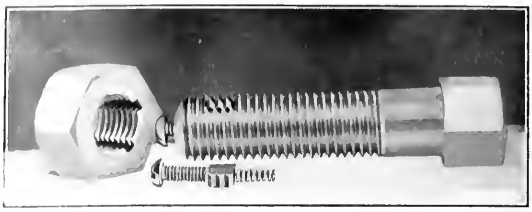
termined. It now only remains to grind the radial face of each tooth with exact reference to the gage finger to insure the truth of the cutter.

SCHUM LOCK-NUT

A lock-nut of somewhat unusual design, which is illustrated herewith, is a recent product of Schum Bros., Metropolitan Tower, New York City. Referring to the illustration it will be seen that a bolt and nut arranged for this system of locking are shown, and also a binding screw and locking key which have been removed from the bolt in order to illustrate the principle of operation. The nut to be locked has four slots broached in it, two of these slots being clearly shown. A hole is drilled into the end of the bolt and a small compression spring fits into the bottom of this hole, while the upper part of the hole is tapped to receive the binding screw. It will also be seen that a transverse slot is cut through the bolt and the ends of a key which fits loosely in this slot are threaded to correspond with the threads on the bolt. When the screw is turned down, this key is pushed to the right so that the threads are brought into alignment with the threads on the bolt. Under these conditions the nut can be screwed onto the bolt in the usual way.

When the nut has been screwed down into place and it is desired to lock it in position, it is merely necessary to loosen the small screw in the end of the bolt. When this is done the compression spring pushes the key



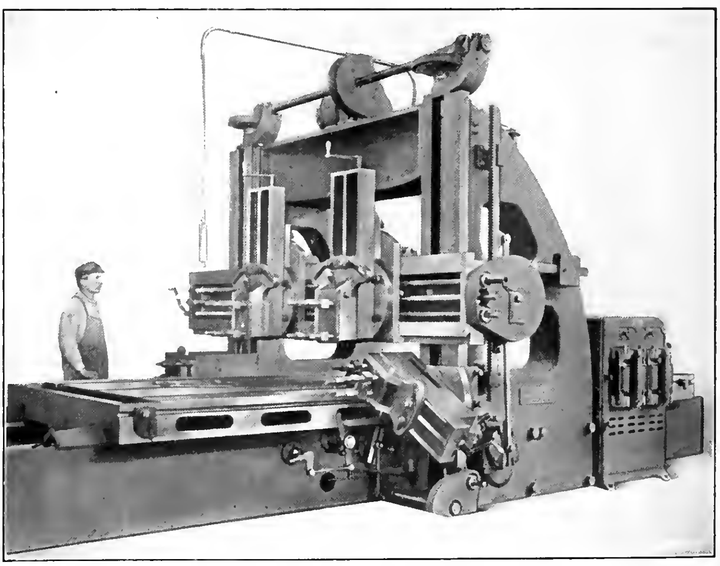
Schum Lock-nut

toward the left (as the bolt appears in the illustration). Should the nut start to loosen, it can only turn far enough to bring the key into the first slot in the nut. When this point is reached, the spring will push the key up so that the threads are out of alignment with the threads on the bolt. In this way the key is held in one of the slots in the nut and cannot enter the threads on the opposite side of the slot to enable the nut to turn any farther. As there are four slots in the nut it is obvious that the maximum distance through which the nut can turn before being positively locked is one-fourth revolution. When it is desired to remove the nut it is merely necessary to tighten the adjusting screw, thus forcing the key down into alignment with the threads on the bolt to enable the nut to be turned off in the usual way.

NILES-BEMENT-POND PLANERS

Heavy-duty planers with capacities of 120 by 72 inches, 96 by 72 inches and 86 by 48 inches have recently been built by the Niles-Bement-Pond Co., 111 Broadway, New York City, for use in the plant of the Commonwealth Steel Co., of St. Louis, Mo. All of these machines have capacities for planing work up to 18 feet long and they are all equipped with two heads on the cross-rail and a side head on each of the housings. These planers were constructed for very severe work on steel castings, and to meet the requirements of this service it was necessary for the construction to be worked out along exceptionally heavy lines. All of the gears are made of steel castings or steel forgings, and all of the bearings are bronze bushed and supplied with provision for ample lubrication. All of the shafts are unusually heavy and all wearing surfaces are proportioned for long and accurate service.

The accompanying illustration shows one of the 86 by 48 inch by 18 foot machines. This planer is 88 inches wide between the uprights and takes 50 inches between the table and cross-rail; the table is 80 inches wide by 20 feet long. The drive is from a 50-horsepower reversing motor of the Niles-Bement-Pond Co.'s system, which is direct connected to the



Niles-Bement-Pond 86-inch by 48-inch by 18-foot Planer built for the Commonwealth Steel Co.

gearing. The speed of the table may be instantly adjusted by handwheels which are conveniently located on the controller, without requiring the planer to be stopped. The speed range is from 25 to 50 feet per minute for the cutting stroke and from 50 to 90 feet per minute for the return stroke. The driving motor is direct-connected to the first driving shaft at the back of the planer, and the controller, resistance, pilot switch and circuit breaker are mounted in a ventilated cabinet which also contains all of the wiring except the wires from the controller to the motor, which are carried across the planer bed in a metal conduit.

Operating levers on the front and back of the bed are connected to the reversing switch and may be operated by hand or automatically by means of adjustable dogs on the table. At the instant of reversal, the motor—through proper connections in the controller—is disconnected from the line and becomes a powerful dynamic brake, stopping the table at once without taking current from the line. A patented pendant switch, carried by a swiveling bracket mounted on the arch, may be moved by the operator to any convenient position and gives him control of the driving motor for starting, stopping or reversing the table. This switch is particularly convenient in handling work which requires the operator to be in such a position that he cannot reach either of the levers on the front or back of the bed. In order to prevent the table running off the gearing, or damage to the tools or machine caused by failure of the line current or overload, a circuit breaker is provided which will stop the motor at once by dynamic braking. The cross-rail is raised and lowered by an independent reversible motor.

SHUSTER STRAIGHTENING AND CUTTING-OFF MACHINE

The machine for straightening and cutting off round, square or hexagonal bar stock, which is illustrated in Figs. 1 and 2, is a recent product of the F. B. Shuster Co., New Haven, Conn. The design follows the general lines of the No. 6 machine of this company's manufacture which was illustrated and described in the April, 1912, number of MACHINERY. The special feature of the No. 17 machine, which is the subject of the present article, is the provision of independent adjustment for each of the vertical and horizontal straightening rolls. This is obtained by means of universal joints which connect all of the straightening roll shafts and roll gears, giving a wide adjustment of the rolls without changing the gears. This makes it possible to handle round, square or hexagonal stock from 3/8 to 3/4 inch in size with one set of rolls, thus saving the expense of extra rolls and the time consumed in changing. It will, of course, be understood that one set of rolls is only applicable for handling one shape of stock. The rolls are grooved to correspond with the shape of the material which they are intended to handle and the range of the machine is for work from 3/8 to 3/4 inch in size.

The machine consists of a substantial bed, on which a housing is mounted which supports five vertical and five horizontal straightening rolls that are adjusted by means of square-head screws. There is a set of feed rolls at the rear and another set at the front of the machine. A balance wheel, which connects with a train of gears that operates all of the rolls, drives the machine. The method of operation is as follows: the coil of material to be straightened and cut up is placed on a reel at the rear of the machine and the end is carried through guides and passed between the feed rolls. These rolls grip the stock and carry it along through the horizontal and vertical straightening rolls, from which it passes to the front feed rolls and then through the stationary die. After

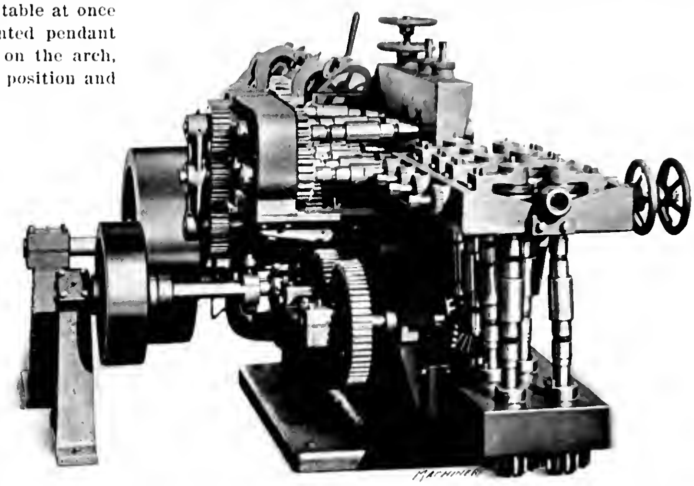


Fig. 2. Rear View of Shuster Straightening and Cutting-off Machine

leaving the die, the stock enters the covered guide bar and moves forward until it strikes a gage which is set for the desired length of pieces that are to be cut off.

When the stock strikes the gage it operates a clutch mechanism which instantly stops the feeding of the stock and operates the cut-off. The cutter severs the piece, after which the cover of the guide bar is raised and the straightened bar drops into the forked holders placed to receive it. The return of the cutter to its starting point sets the feed rolls in motion and another piece is fed through the machine and cut off, the cycle of operations being repeated over and over until all the material on the reel is cut up. The stopping of the feed rolls during the cutting operation prevents any crowding of material against the cutters. The machine shown in the illustrations is arranged to cut off lengths up to 20 feet but

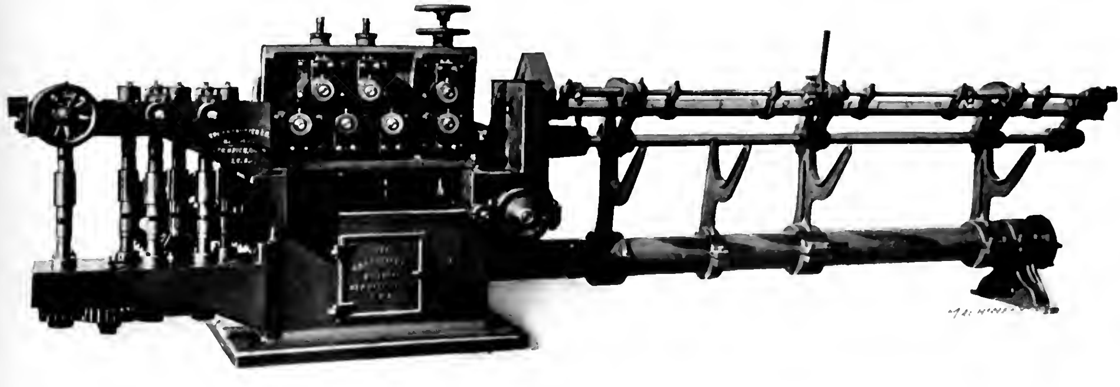

Fig. 1. Shuster No. 17 Straightening and Cutting-off Machine for Square, Hexagonal or Round Stock

only a portion of the extension of the machine is shown. Machines of the same type could be made to cut off longer bars if desired.

SLEEPER & HARTLEY SPRING COILING MACHINE

Sleeper & Hartley, Worcester, Mass., have recently brought out a special spring coiling machine which is made in five sizes. The No. 1 machine which is shown in the accompanying illustration has a capacity for coiling springs of wire ranging from 0.023 to 0.080 inch in diameter. These machines are particularly intended for the rapid production of straight springs in long or short lengths, and of either the extension or compression type. A cutting-off attachment, a diameter varying attachment and adjustable pitch tools can be provided. Either open or close coil springs of straight, conical or barrel shape may be wound. The No. 1 machine will coil springs at an average rate of 200 feet of wire per minute on any size within the capacity of the machine. It will not, however, produce open coil springs having the end coils laid close.

A front view of the machine is shown in Fig. 1, and Fig. 2 illustrates the side of the machine where the cam-shafts are

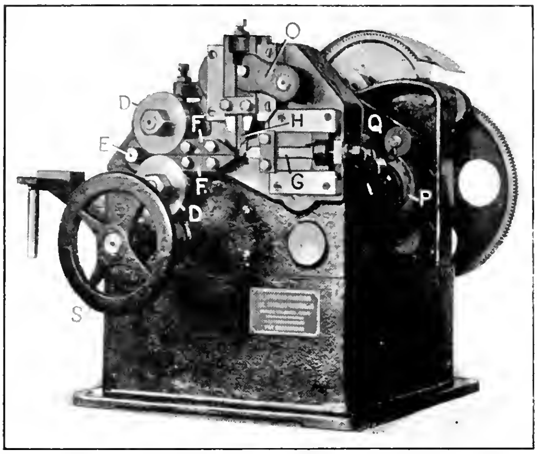

Fig. 1. Front View of Sleeper & Hartley Spring Coiling Machine

located which operate the feed and cut-off mechanisms. Referring to Fig. 2, power is transmitted from the driving pulley *A* to the camshaft, upon which the large gear *B* is mounted. The feed roll shafts are also driven through gearing from pulley *A*; these shafts are almost hidden as they are very nearly in line with two other shafts nearer the front of the machine.

The wire is fed between the feed rolls *D*, Fig. 1. Before being gripped by the feed rolls, it passes through the guide bushing *E* and after passing through the rolls it is fed between the guides *F* and strikes the coiling point or deflector *G*. The point of this deflector may be adjusted so that springs of any required diameter may be coiled. As soon as the required length of coil has been run off, the cutter *H* descends and severs the wire. This cutter is actuated from the shaft *K*, Fig. 2, on which there is a cam *M* that acts on the lever *N*. The lever *N* is located on a short shaft and transmits motion to the lever *O* at the front of the machine. The end of the lever *O* is slotted and fits over a pin in the cut-off slide, the slide being reciprocated through the action of this system of levers and the cam.

While the cutter is operating the wire is at a standstill. This interruption of the wire feed is secured by raising the upper feed roll *D* so that it is out of contact with its mate, thus releasing the wire. This movement of the feed roll is governed by the leaf cam *P* on the shaft *K*. The cam *P* actuates a lever *Q* carried by the shaft *R*. Levers from the shaft *R* extend over the upper feed roll shaft and by means of the cam action, these levers raise or lower the upper feed roll. By means of the three leaf cams, any desired length of feed may be secured. A handwheel *S* provides for trying the machine on any set-up before commencing to operate it under power. This machine is entirely automatic in action, coiling

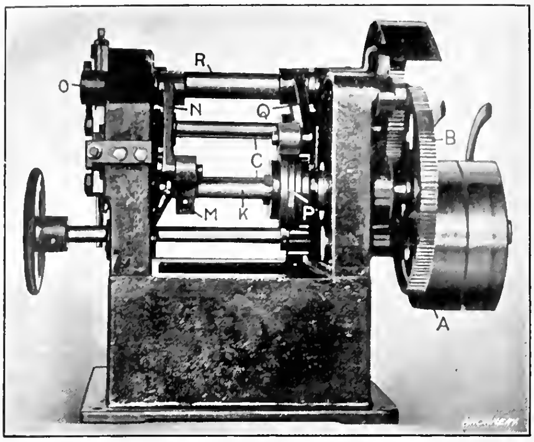

Fig. 2. Side View of Machine showing the Cam-shafts for controlling the Feed and Cut-off

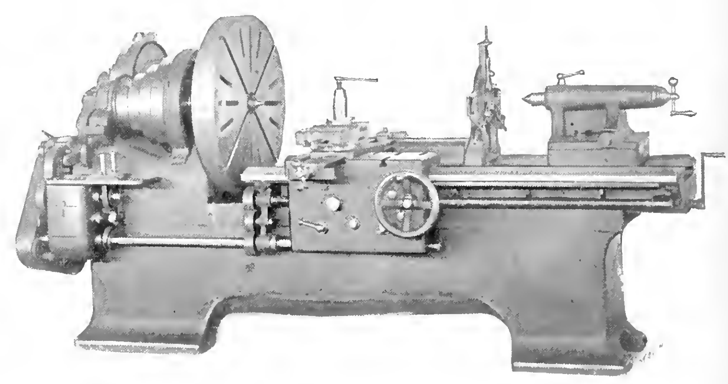
any shape of springs within its range and automatically cutting them off without requiring attention from the operator.

BARNES EXTENSION GAP LATHE

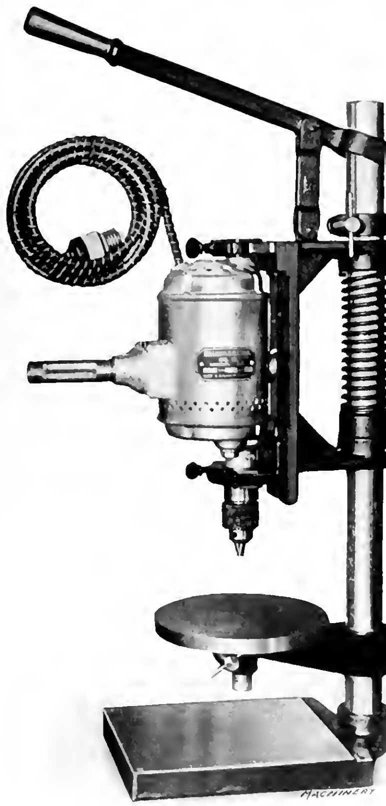
The Barnes Drill Co., 814 Chestnut St., Rockford, Ill., is now building the heavy-duty extension gap lathe which is illustrated herewith. This machine swings 22 inches over the bed, 36 inches through the gap and 14 inches over the carriage. It takes 50 inches between centers when closed and 86 inches between centers when extended; the gap opens 36 inches. The ratio of the back gearing is 8 to 1 and of the double back gearing 44 to 1. There are twelve changes of spindle speed ranging from 2.3 to 400 revolutions per minute and six changes of geared feed as follows: 0.008, 0.15, 0.27, 0.39, 0.71 and 0.123 inch per revolution.

The lathe is intended for heavy duty and is of exceptionally rigid construction. The bed is adequately braced and of ample proportions, with the top of the sliding bed 24 7/8 inches wide in order to afford strong support for the carriage when the machine is operating on large work through the gap. The spindle is 3 15/16 inches in diameter in the front bearing and has a 2 1/8-inch hole through it. The steps of the cone pulley are made of exceptionally large diameter to afford ample power from a 3-inch belt, this plan having been adopted in place of increasing the width of the steps. This enables the headstock to be shorter than would otherwise be the case.



Barnes Double Back Geared Extension Gap Lathe

The diameter of the four steps of the cone pulley are 18, 15, 12 and 9 inches, respectively, by $3\frac{1}{8}$ inches wide. The machine will cut from 2 to 20 threads per inch. The regular



Cincinnati Combination Hand Drill and Sensitive Drilling Stand

length of bed furnished with the lathe is 8 feet $6\frac{1}{2}$ inches, and with a bed of this length the approximate weight is 5300 pounds.

CINCINNATI SENSITIVE DRILLING STAND

The accompanying illustration shows the combination of a portable electric hand drill and a stand upon which this tool can be mounted. With the hand drill set up in position on the stand, the combination constitutes the equivalent of a sensitive bench drill, while the drill may be removed from the stand and used as a portable tool. The hand drill may be mounted in the stand in a few seconds by means of thumb nuts which secure hinged caps that lock the drill in the bracket. The bracket has a feed of 3 inches on the column and is provided with quick return; the feed is operated by means of a hand lever. The bracket also has a vertical adjustment through the clamping screws on the column and can be set at any desired point. A stop regulates the depth to which the holes are to be drilled.

This sensitive drilling stand is made to receive hand drills of $\frac{1}{4}$, $\frac{3}{8}$ and $\frac{1}{2}$ inch capacities. It weighs 60 pounds. The table is 8 inches in diameter and is adjustable for height; it can be swung to one side to enable the machine to handle work for which the table is not required. The distance from the column to the center of the table is 5 inches and the column is 30 inches high by $1\frac{3}{4}$ inch diameter. The base of the machine is 9 by 11 inches in size. This combination hand drill and sensitive drilling stand, which is a recent product of the Cincinnati Electrical Tool Co., Cincinnati, Ohio, will be found particularly handy for use in shops where the work includes bench drilling and drilling operations for which a portable tool is required. The stand can be set up anywhere and occupies very little space.

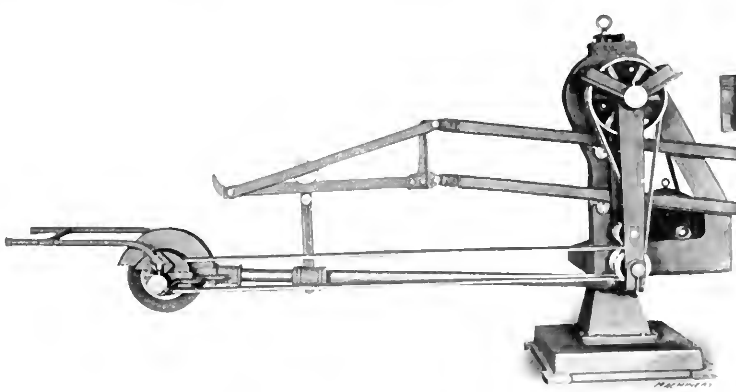
MUMMERT-DIXON RADIAL GRINDER

The Mummert-Dixon Co., Hanover, Pa., has recently added to its line of grinding machines the radial swing grinder which is illustrated herewith. This machine is intended for grinding large and medium size castings and for handling general classes of buffing work. It will be evident from the illustration that the machine is fully self-contained, being driven by a motor mounted on a platform which is part of the main housing of the machine.

The machine is adapted for portable service and requires no preliminary work in setting it up before it is ready for work. This feature enables the grinder to be carried about by a crane, the eye at the top of the pedestal being convenient for receiving the crane hook. This is a complete radial grinder, it being possible to swing the arm carrying the grinding head through a complete revolution. The grinding head and swinging arm are carried back and forth by a roller bearing trolley which runs on a track held in a horizontal position by two parallel arms. The counterweight is placed at the opposite end of these arms. This arrangement of parallel arms or "paradox lever combination," as it is sometimes called, keeps the head perfectly balanced for any position of the trolley on the track and gives a free movement to the swinging arm. The grinding head can be twisted in either direction up to 90 degrees, which is a great convenience in grinding the sides of castings.

The emery wheel is driven by a single belt which is carried around the jointed connection of the swinging arm and hanging swing frame by two self-oiling idler pulleys from which the belt runs to the large pulley at the top of the machine. The upper pulley is driven by a shaft from the driving pulley, which is located on the inside of the housing, the motor being belted to the driving pulley. The machine is mounted on a substantial base which supports a vertical pedestal, and the main frame or housing is mounted on this pedestal, being free to turn on it.

On the side of the housing, there is a bracket which carries the swing frame in which the pulleys are supported. The swinging arm to which the grinding head is attached is joined to the lower end of this frame. The swing frame hangs on two phosphor-bronze bushings which extend through the bracket, these bushings forming the bearing for the main driving pulley. The emery wheel in the grinding head is protected by a hood and the handles attached to the head enable the operator to obtain a good hold and to have full control of the head at all times. The wheel arbor runs



Mummert-Dixon Portable Radial Swing Grinder

in phosphor-bronze bearings with provision for taking up wear. The arbor has safety flanges to protect the wheel and carries a wheel 18 inches in diameter by 3 inches face width.

ROBERTSON NO. 7 POWER SAW

The latest addition to the line of "Economy" power saws built by the W. Robertson Machine & Foundry Co., Buffalo, N. Y., is the No. 7 machine illustrated herewith. This tool has a capacity for work up to 10 by 24 inches in size, and work can be cut at angles up to 45 degrees. In mentioning the capacity of this machine it should be stated that stock as small as ½ inch can be cut very accurately, the range extending from this size up to 10 by 24 inches.

The machine is of heavy construction to adapt it for the large work for which it is intended, and the bearings are of ample proportions and provided with efficient means of lubrication so that the saw operates smoothly and quietly. The cut is taken on the draw stroke and the blade is lifted clear of the work on the return stroke by means of the Robertson dash-pot mechanism. This consists of a plunger which is so timed in relation to the crankshaft of the machine, that it starts to compress oil contained in a cylinder below the bed at the same time that the saw starts on the return or idle stroke. The result is that the blade is lifted clear of the work so that it is not exposed to the wear which would result by dragging it. At the end of the stroke, the pressure in the oil cylinder is released and the saw is let carefully down into contact with the work ready for another cut. This feature has been used for several years on Robertson hacksaws with

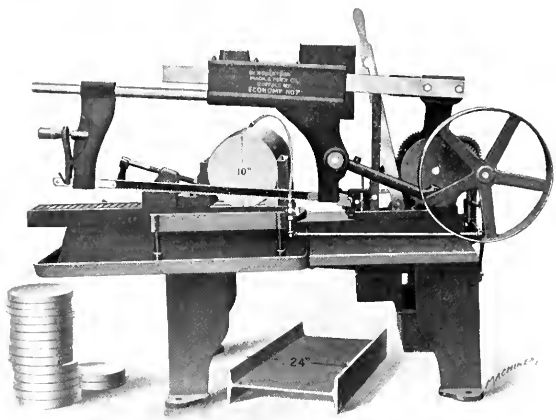


Fig. 1. Robertson No. 7 "Economy" Power Saw

very satisfactory results. Another feature of this machine is the two-speed drive, which was briefly described in the March number of MACHINERY. The arrangement consists of a set of sliding gears by means of which the high speed may be employed for cutting soft steel and the slow speed for cutting tool steel, either speed being obtained by simply pulling out or pushing in a knob.

The vise used on this machine is of the quick-acting type and can be opened or closed through its full range of 24 inches in less than one second. The vise swivels up to 45 degrees and is substantially supported on an extension to the bed which is provided with a T-slot by which the outer end of the vise is guided. This T-slot also provides for clamping the vise rigidly in any required position. When the vise has been swiveled to the full angular adjustment of 45 degrees, work up to 15 inches can be handled. The lubricant for cooling the blade is contained in a tank located under the bed of the machine. In order to protect the teeth of the saw in cutting through thin flanges on structural steel, and also for adapting the machine for operation on the wide range of sizes which can be cut, the counterweight on the frame is made adjustable. For small work or while cutting through flanges on structural steel, the weight is moved back to its extreme position; but when the saw is working on large sections this weight is moved out to apply a pressure of 195 pounds on the cutting stroke. When the weight is moved back the saw frame is evenly balanced. The blades used may be from 12 to 32 inches in length and the stroke

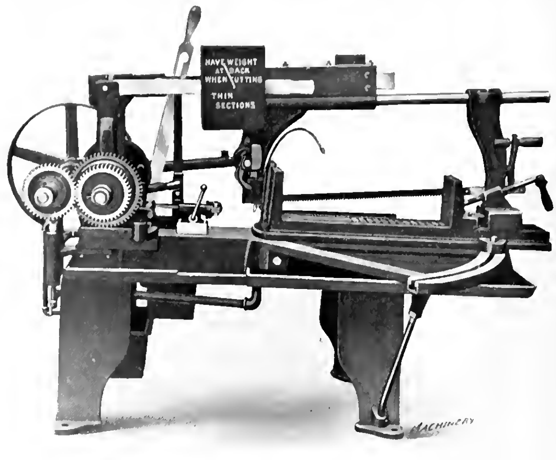

Fig. 2. Opposite Side of Machine showing Vise Support and Two-speed Drive

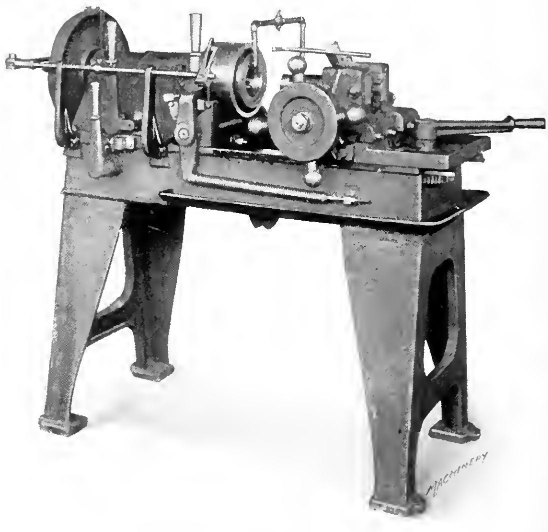
of the saw is 6 inches. The net weight of the machine is 900 pounds.

WILLIAMS PIPE THREADING MACHINE

The accompanying illustration shows a semi-automatic machine for cutting nipples, short lengths of pipe and bolts, which is a recent product of the Williams Tool Co., Erie, Pa. This machine is made in two sizes, one of which has a capacity for work ranging from ¼ to 1 inch in diameter and the other for work from 1 to 2 inches in diameter. The machine is designed along lines which adapt it for a high rate of production. The pipe to be threaded is gripped in a sliding chuck, the jaws of which are operated by a screw and handwheel. The pipe is reamed while the thread is being cut and the dies open automatically.



Williams Semi-automatic Pipe Threading Machine

LEES-BRADNER GEAR HOBBER

The Lees-Bradner Co., Cleveland, Ohio, has recently applied single pulley drive to its No. 5 gear generator in place of the cone pulley drive which was formerly used. The single pulley is situated below the shaft on which the cone was mounted. From this lower shaft gears transmit the power up to the original driving shaft. The gearing provides nine changes of speed for the cutter, with a range of from 44 to 147

revolutions per minute. The machine is double back geared with ratios of 3 1/3 to 1, and 10.8 to 1. The extreme ratio of 10.8 to 1 makes it possible to take advantage of the exceptionally rigid construction of the machine when operating on heavy work, while the ratio of 3 1/3 to 1 provides satisfactory results when using small hobs on light work.

The machine stops automatically when the work is finished, and the lever for starting is located at the front just to the left of the micrometer handwheel. This arrangement is the means of increasing the efficiency when the time required to

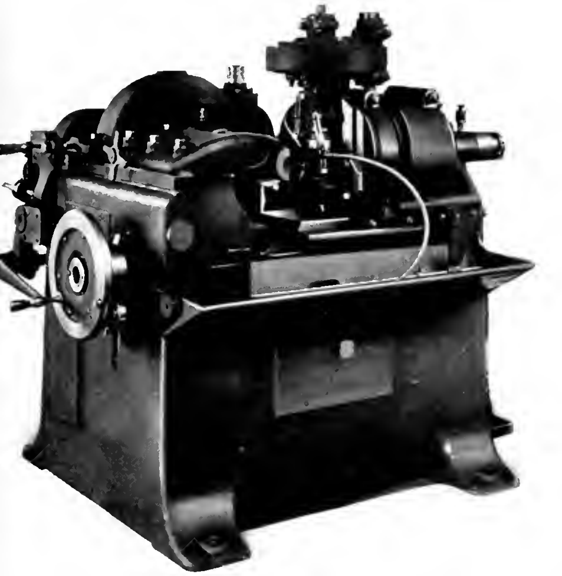


Fig. 1. Front View of Improved Lees-Bradner Gear Hobber

complete one set of blanks is not very long. With the present arrangement, the operator controls all of the movements from the front of the machine. The longitudinal feed of the work-slide is controlled by a hand lever which replaces the friction clutch formerly employed. A shield has been placed over the feed gearing and the shield may be readily swung back to cover the gears from the rotation shaft to the feed-screw, when used on the universal machine.

The new design makes the machine particularly well adapted for the application of individual electric motor drive. A constant-speed motor can be located at the rear of the machine either above or below the main driving pulley. The loose pulley is mounted on a roller bearing, with the

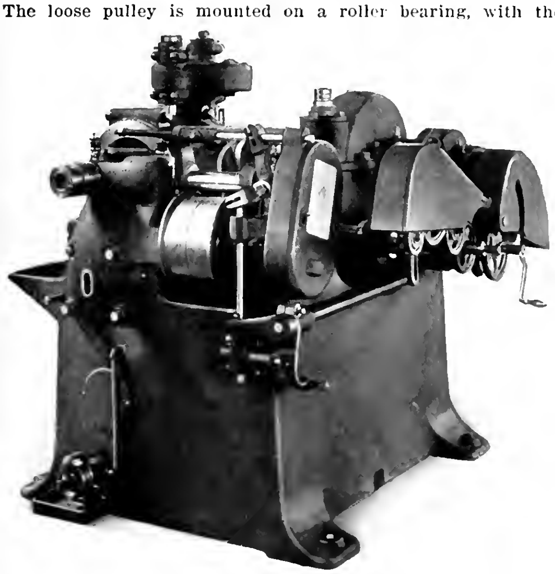

Fig. 2. Opposite Side of Machine showing Single Pulley Drive

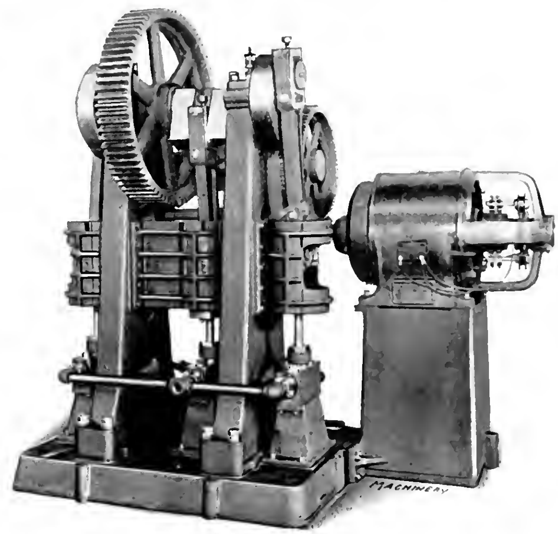
rollers running on a hardened and ground bushing. In this way the trouble often experienced from loose pulleys wearing out their bearings and becoming noisy is done away with. This generator will cut spur gears, helical gears, worm-wheels and worms. The standard size in which the machine is built is for work up to 11 inches in diameter, but a special machine is also made which takes work up to 17½ inches in diameter. Worms 8 inches in diameter by 8 inches long and up to 1 inch pitch can be threaded on the universal machine.

HYDRAULIC TRIPLEX PUMPS

The accompanying illustration shows a vertical type of single acting triplex hydraulic pump which has recently been added to the line of the Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mount Gilead, Ohio. Pumps of this type are made in three series of sizes which are known as the Series J, Series JJ and Series JJJ. The Series J pumps have a stroke of 8 inches and are equipped with plungers ranging in size from ¾ inch to 3¼ inches in diameter. The Series JJ pumps have a stroke of 12 inches and plungers ranging in size from 1 inch to 4½ inches in diameter. The Series JJJ pumps have a stroke of 12 inches and plungers ranging in size from 1¼ to



Hydraulic Style JJ Triplex Pump

5 inches in diameter. The pressure capacity is from 600 pounds to 16,000 pounds per square inch, depending upon the size of the piston. The pumps are either belt driven or equipped with individual electric motor drive. The J pumps require 25 horsepower to operate them; the JJ pumps require 50 horsepower, and the JJJ pumps, 100 horsepower. The effective speed of each of the three pistons is 33 1/3 feet per minute for the J pumps and 45 feet per minute for the JJ and JJJ pumps.

These pumps are fitted with screw glands working against followers when they are equipped for high-pressure work, or with stud glands when they are equipped with large pistons for low-pressure work. The pistons are packed with compression packing. Forged steel is used in the construction of the high-pressure pump cylinders and crankshafts. The cross-heads are guided and fitted with cast-iron adjusting shoes which are bored to provide a perfect guide. The connecting-rods are made of open-hearth cast steel and have bronze bearings with wedge and screw adjustments.

When these pumps are operated by belt, there is a single reduction of gears for the J pumps and double reduction for the JJ and JJJ pumps. The pulleys can be arranged to drive from either end. When motor drive is employed, there is a double reduction of gears for all sizes of pumps. The first reduction has a ratio of 5 to 1 and the second reduction depends upon the speed of the motor that is used. The height of the J pump is 5 feet 9 inches; of the JJ pump, 8 feet 1½ inch, and of the JJJ pump 8 feet 10 inches.

NEWMAN-COFFINGER DRILLING AND TAPPING MACHINE

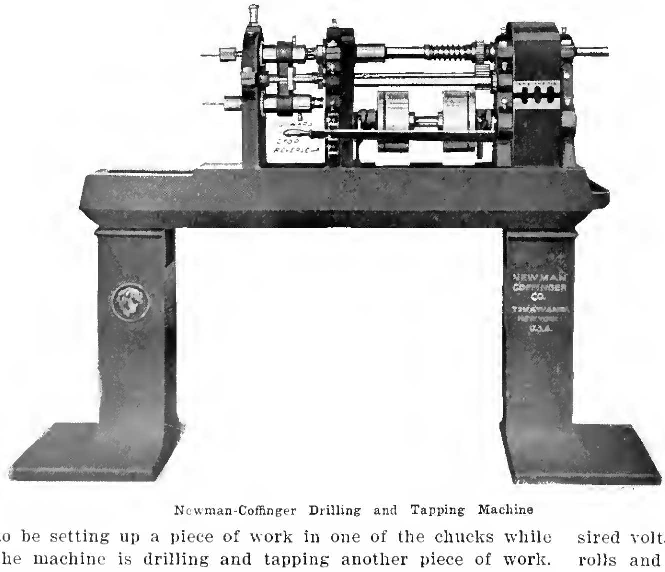
The combination drilling and tapping machine shown in the accompanying illustration is a recent product of the Newman-Coffinger Co., Tonawanda, N. Y. This machine is adapted for drilling, tapping, counterboring, hollow milling and similar operations. As two operations may be performed and the operator may be preparing another piece of work while the machine is so engaged, it will be evident that a high rate of production is attainable.

The method of operating the machine may be briefly described as follows: Assuming that one of the collets has been connected with the feed shaft, the operator shifts the drilling lever to the "forward" position. This connects the friction clutch with the forward driving pulley and starts the machine. The shaft upon which the driving pulleys and friction clutch are mounted transmits power to the spindle through a train of spur gears. Passing through the spindle there is a feed-shaft casing fastened to the spindle by a set-screw which slides in a groove to allow forward and reverse motion. The feed-shaft is fastened to the casing. This shaft is threaded at one end to provide for feeding the tool and there is a coupling at the other end which connects with the collets of the machine. The drilling and tapping spindles are bored No. 2 Morse taper.

The proper rate of feed is obtained by the train of gears previously referred to. The shaft upon which the clutch revolves has a driving gear keyed to it. This gear transmits power through an intermediate gear to the driven gear on the feed-shaft. The driven gear has a nut in it through which the threaded feed-shaft passes. When the hole has been drilled to the required depth the operator shifts the lever to the "reverse" position, which results in driving the machine in the opposite direction to back out the tool.

The turntable is actuated in the following manner: The feed-shaft passes through a neutral gear which becomes active when the direction of rotation of the machine is reversed. In this way the turntable is caused to revolve through one-half revolution, which is completed before the lever is shifted back to the forward position.

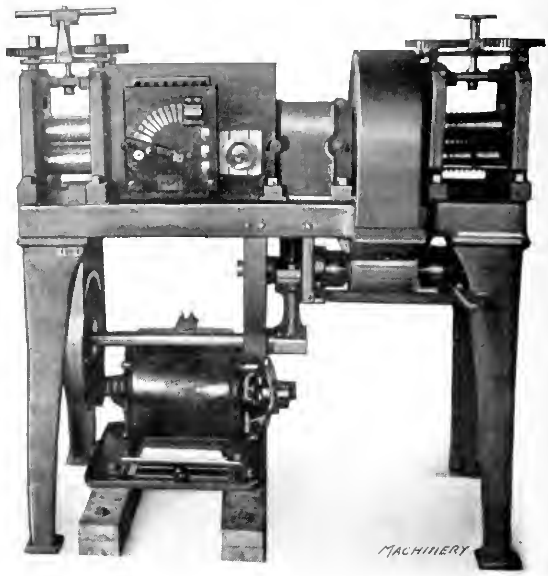
It will readily be seen that with the entire machine under instant control by means of a single lever, the operator would be idle during the time that the machine was working. To make use of this time, the turret tailstock is equipped with two work chucks. This makes it possible for the operator to be setting up a piece of work in one of the chucks while the machine is drilling and tapping another piece of work. When the drilling and tapping operation is completed, and while the machine is automatically reversing, the operator simply turns the turret around to bring the next piece into position to be machined. The machine can be built in various sizes and with either two or four collets. The work holding fixture is made to suit the requirements of the parts to be machined.



Newman-Coffinger Drilling and Tapping Machine

LEIMAN COMBINATION ROLLING MILLS

For use in rolling gold, silver, brass, copper and similar metals, Leiman Bros., 62 John St., New York City, have developed a combination rolling mill in which two sets of rolls are mounted in a single machine. The machine shown in the illustration is equipped with one set of rolls for flat work and one set for rolling wire, but machines may be equipped with two sets of rolls for flat work or two sets of wire rolls.



Leiman Combination Rolling Mill for producing Flat Work and Wire

Although these machines can be arranged for any form of drive, the most satisfactory method is that in which an individual motor is employed. Where this system is used the motor is mounted under the machine and provided with a rawhide pinion which meshes with the first spur gear. The power is transmitted to a second pair of spur gears and then through a pair of spiral gears to the driving shaft. The application of spiral gears in this machine is particularly important because the vibration would tend to take up the lost motion in spur gears and destroy the uniformity of the rotation of the rolls. This, in turn, would show itself on the work in the form of ripples. The frame and housings of the machine are of particularly rigid construction, reducing possibility of vibration to a minimum; and this precaution, in connection with the application of spiral gears, results in work of exceptionally good finish.

The ends of the driving shaft are squared and a sliding coupling fits over each of these squared ends of the shaft. These couplings are controlled by individual levers and may be slid over so that they connect with corresponding squared ends on the shafts which drive the rolls at either end of the machine. This arrangement makes it possible to operate both pairs of rolls at the same time, or to use either pair as required. The motor employed for driving the machine is of standard design and may be supplied in any desired voltage. For a machine equipped with one pair of flat rolls and one pair of rolls for rolling wire, the motor required to drive the machine should develop about 1½ horsepower.

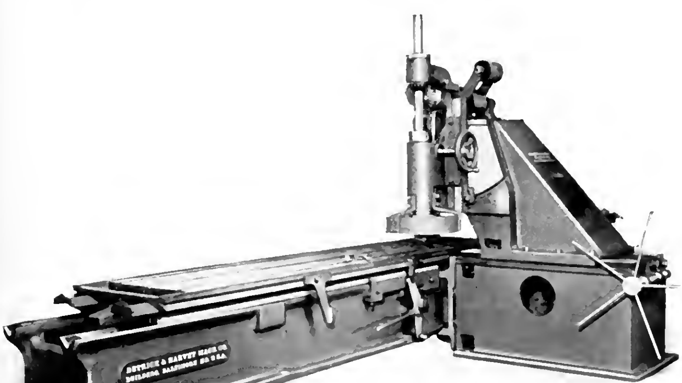
The rolls are made of a special steel which experience has shown to be suitable for this class of work, and the housings are equipped with bronze bushed bearings in which the rolls

run. A handwheel at the top of the housing at each end of the machine provides for adjusting the center distance between the rolls. The adjustment of either pair of rolls is secured by means of two screws which fit in tapped holes in the housings. When these screws are turned by means of the handwheel and gearing, yokes which fit over each end of the movable roll cause this roll to be raised or lowered as required. While both the flat rolls and wire rolls are provided with means of adjustment, it is not necessary to adjust the rolls used for producing wire. The spiral driving gear is located in the casing shown close to the wire rolls and the driving shaft which transmits power to the flat rolls is arranged with universal joints. The object of having the spiral gear close to the wire rolls is that the maximum adjustment for the flat rolls is made possible by this arrangement.

DETRICK & HARVEY GRINDING MACHINE

The grinding machine shown in the accompanying illustration is built by the Detrick & Harvey Machine Co., Baltimore, Md. This machine is particularly intended for edge grinding operations on safe and vault work but could be successfully employed in a variety of other lines. The table is 32 inches wide and gibbed down on one side to prevent it from tilting; the table speed is 24 feet per minute in both directions. The machine is belted to the countershaft and driven through a pair of bevel gears and a spiral worm engaging a rack on the under side of the table. The bed has two V-slides for the table, these slides being 21 inches between centers. It is planed on one side to provide a surface to which a sub-base is tongued and bolted. This sub-base is for the purpose of supporting the driving and belt shifting mechanisms.

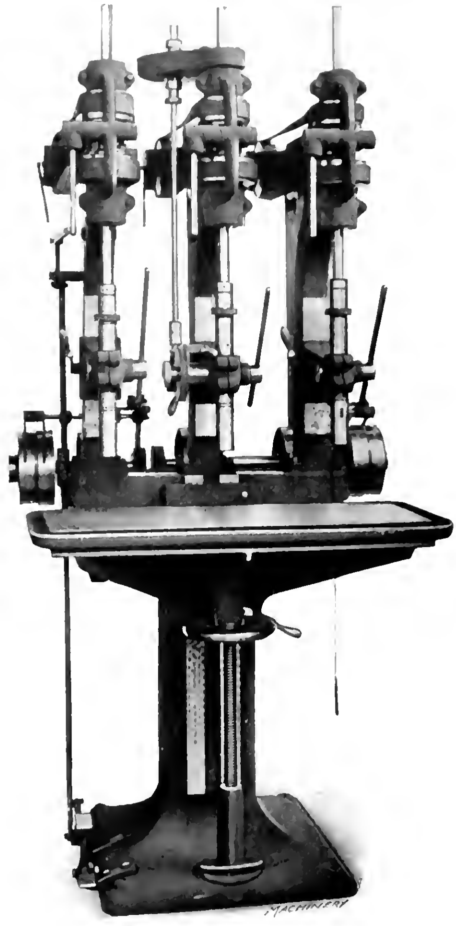
The spindle is 3½ inches in diameter and runs in a bronze bushed bearing, the bushing being tapered on the outside and provided with means of adjustment for wear. The spindle carries a grinding wheel 20 inches in diameter by 4 inches face width and runs at 600 revolutions per minute. Power is transmitted to the spindle through bronze and steel bevel gears, the power for driving the spindle being taken from the countershaft by an 8-inch belt. The spindle bearing has a vertical adjustment of 12 inches to provide for the proper alignment of the grinding wheel when the bearing is swiveled for angular grinding. This spindle bearing is clamped to a swiveling bracket which swings from a trunnion bearing through which the driving shaft revolves. A T-slotted plate is attached to the upright and the swiveling bracket is bolted to this plate. The upright is mounted on the top surface of the sub-base and can be adjusted either toward or away from the table. The adjustment is made by means of a handwheel and screw. The countershaft is of the hanger type and designed to run at 300 revolutions per minute when it is desired to operate the table at a speed of 24 feet per minute.



Detrick & Harvey Edge Grinding Machine for Safe and Vault Work

KERN BALL BEARING DRILL

The Kern Machine Tool Co., Hamilton, Ohio, is now building the three-spindle high-speed ball bearing drill press shown.



Kern High-speed Ball Bearing Drill Press

Several new ideas have been incorporated in the present machine. It will be noted that the left-hand head is equipped with a friction tapping attachment and that it may be operated by either a foot treadle or a hand lever. This arrangement enables the operator to use one hand to control the jig and the other hand to start and withdraw the tap. It will also be seen that the tapping column of the machine is provided with an independent backshaft which may be operated at 450 revolutions per minute. On the slow speed, this gives a tapping speed of about 300 revolutions per minute in addition to three higher speeds. At a tapping speed of 300 R. P. M. it has been found possible to tap cast-iron plates for ¼-inch gas pipe and produce a nice "full thread." The machine was also tested by tapping through a ¾-inch cast-iron plate with a ½-inch standard U. S. tap; and another test to which the machine was subjected consisted of tapping ½-inch flat steel bars with a ⅜-inch machine tap. Satisfactory results were obtained on all of these classes of work.

The middle spindle of the machine is provided with power feed. This feed mechanism is driven from the spindle by gearing which is fully enclosed, two changes of feed being provided—0.006 and 0.008 inch per revolution, respectively. The feed shaft comes down and is connected to the worm-wheel by hardened steel clutches; and a suitable trip lever is provided to either knock off automatically at any point to

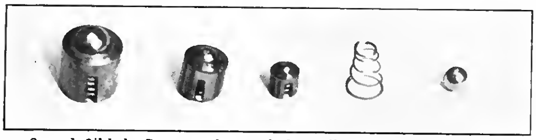
which the depth collar is set, or to be tripped by hand. In addition, the machine is provided with friction feed, the knurled nut at the left being used to engage or disengage the friction.

The right hand head is equipped with the standard hand feed mechanism used by the Kern Machine Tool Co., which is too well known to require detailed description. As each of the drilling heads are individual units, more than one head can be equipped with power feed if so desired. Experience has shown that it is advisable to locate the tapping attachment at the outside of the machine on account of the necessity of reaching it with the foot treadle. With this combination of heads on a single machine, it is possible to drill several small holes by hand while the power feed is employed for drilling a deeper hole. Then if there is any tapping to be done, the tapping operations may be performed before the work is taken from the machine.

OSGOOD OIL-HOLE COVERS

The J. L. Osgood Co., 43 Pearl St., Buffalo, N. Y., is now making a line of oil-hole covers, which comprises seven different sizes ranging from ¼ to ½ inch. Three of these sizes are shown in the accompanying illustration, together with one of the balls used to close the cover and the conical shaped spring which holds the ball in contact with the hole in the top of the shell.

A fairly good idea of these oil-hole covers will be obtained from the illustration. The cover consists of three parts—



Osgood Oil-hole Covers and one of the Balls and Retaining Springs

the brass shell which fits into the oil-hole, the ball which closes the hole at the top of the shell, and a conical spring which retains the ball in position. The hole in the shell is machined to form a close fitting bearing for the ball, and in this way it is insured that the ball will always return to its proper position after having been pushed down by the nose of the oil-can. The brass shell is split at the bottom so that there is a certain amount of latitude to permit the shell to adapt itself to the size of the oil-hole. The bottom of the shell is spun over to retain the spring in place.

WRIGHT PIPE WRENCH

The A. Harvey's Sons Mfg. Co., Ltd., Detroit, Mich., is now making an adjustable pipe wrench which is illustrated herewith. The important feature of this tool is its simplicity, and the fact that it can be instantly adjusted for any size of pipe which comes within its range without requiring the use of both hands. This wrench consists of three essential parts, which are the rocking jaw, the yoke or frame and the handle bar on which the fixed jaw is formed. These parts pivot on each other instead of on a rivet and it is

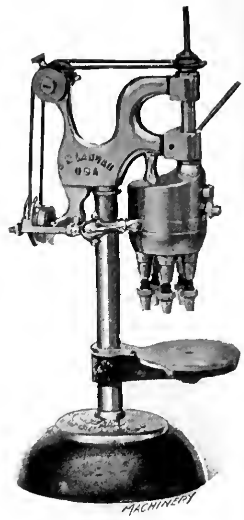
Wright Pipe Wrench made by A. Harvey's Sons Mfg. Co.

claimed that this construction adds very materially to the strength and durability of the tool. If any one part of the wrench is held stationary, the other two parts pivot about it and this action has led to the use of the name "planetary wrench" as applied to this tool.

To operate the wrench, the man takes it in his hand and places his thumb on top of the back strap of the yoke. While pressing his thumb down on the back strap, he pushes the yoke forward or back to adjust the wrench to the required size. In setting for a given size the jaws are opened wider than the point at which they are required to be. The tip of the stationary jaw is then put against the pipe and the rocking jaw is pulled back against the pipe on the opposite side. The thumb pressure is then released and the wrench drops into the proper adjustment. It is used in the same way as any other pipe wrench. At present, the wrench is being made with a 9-inch handle and a pipe opening up to 1 inch; and with 14- and 18-inch handles, with a maximum pipe opening of 2 inches.

LANDAU MULTIPLE CHUCK DRILL

J. N. Landau, 101 W. 117th St., New York City, has recently brought out an automatic multiple chuck drill shown in the accompanying illustration. This little machine has a capacity for handling drills ranging in size from a No. 70 up to ¼ inch in diameter, and reamers, counterbores, etc., of similar sizes. It will be seen from the illustration that there are five chucks in the turret. Tools required for performing successive operations on a piece of work are mounted in these chucks and can be rotated to bring them into the operating position. The multiple head of this machine may be attached to any drill press or the head may be set up in the tailstock of a lathe to serve as a turret attachment.



Five Spindle Landau Multiple Chuck Drill

The multiple head consists essentially of three parts—a stationary bonnet which is secured to the frame of the machine, a rotating turret in which are mounted any number of chucks up to ten, and the operating ring and handle which are used to rotate the turret. After any tool has finished its work the operator grasps the handle shown at the left-hand side of the head and pulls it around. The first movement of 15 degrees of the operating ring causes a cam to disengage the locking pin which holds the turret in any given position. As the ring continues to revolve, it pulls the turret around with it and the locking pin slips along until it registers with the next hole in the turret. The pin is pushed into this hole by a spring and locates the next spindle in the operating position. The operator then releases the handle, and the handle and ring are returned to the starting point by a spring.

Each of the spindles in the turret has a positive pin clutch at its upper end, and this clutch engages with a corresponding clutch member at the bottom of the machine spindle. The chuck in the operating position is the only one that rotates, so there is no waste of power in driving idle chucks. The arrangement of the drive will be evident from the illustration and the feed is obtained by the hand lever seen at the right-hand side of the machine. An eccentric adjustment is provided on the idler pulleys at the back of the machine so that the belt is lined up properly when changing from the fast to the slow speed or *vice versa*. This eccentric also provides a certain amount of adjustment for the belt tension. The mechanism is completely enclosed by the stationary bonnet and combines the features of strength and simplicity.

GARDNER NO. 1 DISK GRINDER

The Gardner Machine Co., Beloit, Wis., has recently added to its line of grinding and polishing machines the No. 1 disk grinder which is shown in the accompanying illustrations. Fig. 1 shows the floor type of machine which is equipped with disk wheels 12 inches in diameter, and with plain work tables. The spindle runs in ball bearings and is driven by a pulley 3 inches in diameter by 3¼ inches face width. The rocker shaft which supports the work tables is

1½ inch in diameter and 30 inches long. The floor space occupied by the machine is approximately 3 by 4 feet. The full equipment includes a countershaft, bench wheel-press, two extra disk wheels, an assortment of abrasive disks and the necessary glue and brushes for use in securing them to the wheels. The complete weight of the machine is 550 pounds.

Fig. 1. Floor Type of Gardner No. 1 Disk Grinder

Fig. 2 shows the same type of machine built for bench work. With the exception of the pedestal, this machine is of the same design as the floor type. The same equipment is furnished with both the floor and bench type machines.

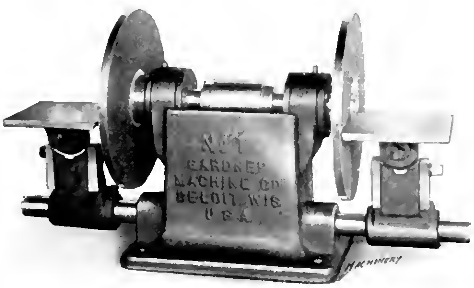


Fig. 2. Bench Type of Gardner No. 1 Disk Grinder

These No. 1 disk grinders are built with ball bearings and are particularly adapted for use in tool-rooms, assembling departments, model works, garages and other places where small work is handled which is required to fit closely.

BRISTOL ELECTRIC TACHOMETER

The field of usefulness of recording tachometers covers the application of these instruments in connection with engines, machinery and shafting, where information is desired in regard to the speed of rotation. Some of the most important applications of instruments of this type are on engines, turbines, generators, blast furnace blowing engines, motors and pumps. As recording tachometers are usually required for continuous service under ordinary shop or mill conditions, they must be made especially durable.

The Bristol Co., Waterbury, Conn., has recently brought out an A. C. electric tachometer which has been particularly designed to adapt it for use in industrial plants. Two of the most important features of this tachometer which make it suitable for the rough usage which such instruments receive in industrial work are, first: the application of the induction magneto; and, second: the voltmeter movement. The application of the induction type of magneto eliminates the use of sliding contacts or brushes and the indicating and recording instruments are voltmeters.

The indicating instrument is equipped with a Weston jeweled pivot bearing voltmeter movement, and the recording instrument is equipped with an improved Bristol voltmeter movement which is so designed that ample power is provided for actuating the recording arm, even though the pen is in continuous contact with the chart. The movement is mounted on frictionless knife edge bearings and equipped with a new supporting device for the moving elements, which eliminates the effect of changes of temperature. This recorder can be furnished for use with 6, 8 or 12 inch charts.

The accompanying illustration shows a combination indicating and recording instrument. The indicating instrument is for the use of the operator and the recording instrument is set up in the office of the superintendent or foreman. Suitable lengths of leads can be furnished for locating either instrument in any desired position. If so desired, connections can be furnished for more than two instruments. A simple form of this tachometer can also be furnished with either the indicating or the recording instrument as desired.

Bristol A. C. Electric Recording and Indicating Tachometer

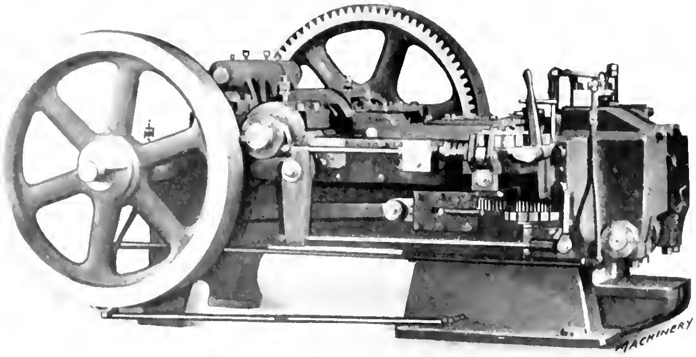
WATERBURY FARREL NUT MAKING MACHINE

To meet the demand for a large machine for use in the manufacture of nuts by the cold process, the Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., is now building an automatic cold pressed nut machine which has a capacity for hexagon or square nut blanks ⅝ inch in size. The machine produces the blanks from bar stock and either hexagon or square blanks are finished complete, being chamfered and re-sheared and provided with a pierced hole ready for tapping, which is done on another machine.

In operating this cold pressed nut machine, one bar of stock follows immediately after another, with the result that it is unnecessary to stop the machine between bars and no short ends are wasted. In order to facilitate starting the stock into the ratchet driven feed rolls and between the straightening rolls, the latter are made with a quick adjustment for opening and closing them. In starting the stock it is necessary to have the end practically square before it enters the machine. This precaution guards against the possibility of breaking the punches. After the end of the

stock is between the open straightening rolls and gripped by the feed rolls, the straightening rolls are brought together by a lever. When the machine is working on bars of stock that are straight, the straightening rolls may be left open, as they are not required.

While the different operations performed in the machine are taking place, the tools are thoroughly flooded with lubricant which is pumped from the tank and delivered through a suitable system of piping and valves. The tank and pump constitute part of the regular equipment. As the lubricant



Waterbury Farrel Machine for making Nut Blanks by the Cold Process

flows away from the tools it is caught in a retainer and carried back to the tank. The scrap produced in making square nuts consists of the piercings and trimmings from the reshearing operation; and in making hexagonal nuts the scrap consists of the piercings, trimmings and the scalloping of the stock which is taken from the sides of the bars. The scrap is automatically separated from the finished blanks, the scrap falling into an iron pan and the blanks being delivered through a tube at the end of the machine. The machine illustrated in connection with this article is for making nuts ⅝ inch in size, but the Waterbury Farrel Foundry & Machine Co. also makes these machines for nuts ½, ⅜ and ¼ inch in size.

NATCO NO. 26 MULTIPLE SPINDLE DRILL

The National Automatic Tool Co., Richmond, Ind., has just added to its line of multiple spindle drills the No. 26 machine illustrated herewith. This is a much larger and heavier machine than the other sizes built by this company and was designed to meet the demand for a multiple spindle drill having a capacity up to 1 inch. It is built along simple and sturdy lines and ample power is provided to drive high-speed drills at their maximum efficiency, regardless of the speed.

It will be seen that single pulley drive is employed so that the machine may be belted direct to the line-shaft if so desired. However, it is a very simple matter to apply individual motor drive. The driving pulleys are of large diameter and wide face and are mounted on Hyatt roller bearings. The speed box is located at the top of the column of the machine and three changes of speed are provided by the sliding gear transmission. The gears, which are of coarse pitch and wide face, are hardened. Any one of the three available speeds is obtained by shifting the hand lever to one of the positions marked *A*, *B* and *C*. For each speed obtained from the speed box, two changes of speed may be made by means of gearing in the head. These changes are made while the machine is running.

The bearings in the speed box are also provided with high-duty Hyatt roller bearings which insure a high transmission efficiency. The speed box and feed box gears are provided with the cascade system of lubrication and a sight-feed oil glass shows the operator at a glance whether the pump is working properly. There are three independent drill feeds which permit the use of any feed with either of the three double drill speeds that are available in the head. All of the feed changes can be made while the machine is running. The feed box is located at the base of the column of the machine and the feed gears are of hardened steel. They are of large diameter and run at moderate speeds. It will be noticed that the cover of the feed box is provided with a small tray that is particularly convenient for holding tools.

The machine is mounted on a heavy base which is provided with an oil channel for catching the overflow. This channel has a screened pocket through which the cutting lubricant must flow to enter the tank from which it is pumped back to the tools. The pumps employed for oiling the machine and delivering cutting lubricant to the drills are independent of each other. When so desired, the base of the machine may be provided with T-slots.

Several sizes of heads can be used on this machine and these heads may be equipped with various combinations of adjustable spindles and cluster boxes for carrying drills ranging from ⅛ to 1 inch in diameter. The head used on the machine is provided with power feed and a pilot wheel to facilitate advancing or returning it easily and rapidly. The power feed may be tripped either automatically or by hand. Referring to Fig. 1, it will be seen that the head is counterbalanced by two chains that support a counterweight contained in the column of the machine, which is of box section. The spindles are made of special steel, hardened and ground and provided with ball thrust bearings at the lower end, and lock-nuts at the upper end to take up any end wear that may develop. The spindles are made to carry either straight shank or Morse taper shank drills, as required. Individual flexible oil tubes deliver the cutting lubri-

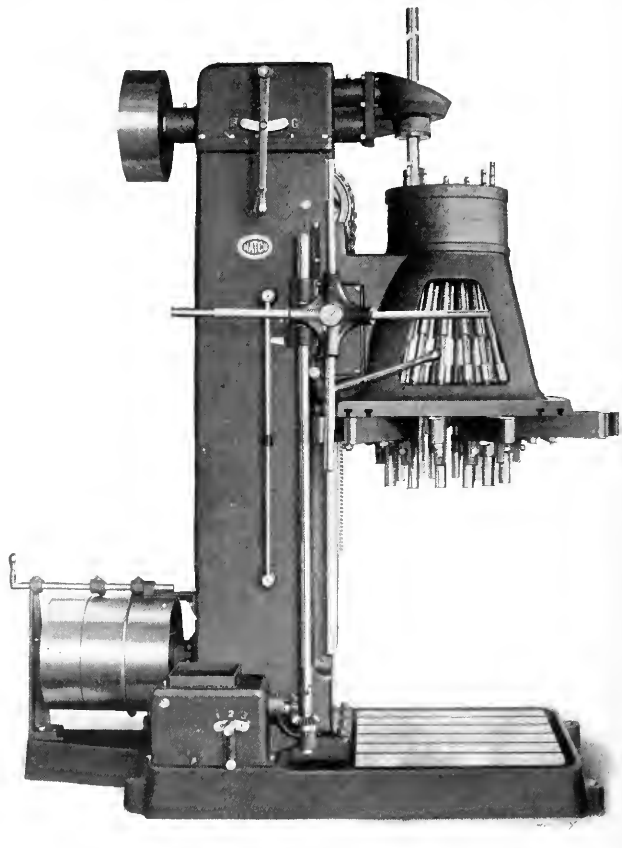


Fig. 1. The Natco No. 26 Multiple Spindle Drilling Machine

cant to each drill when the machine is working on steel or aluminum.

The bronze bearings which carry the drill spindles are provided with vertical adjustment to compensate for variation in the drill lengths. This adjustment is quickly and easily secured by simply loosening one nut which is always accessible, regardless of how close the spindles may be clustered together. This spindle adjustment—which is a patented construction—holds the bearing rigidly to the end of the arm, and the arm may be moved to cover any layout within the range of the head. The construction is illustrated in Fig. 2. In making the adjustment, it is only necessary to loosen the nut *A* as mentioned. This allows the steel beam *B* to rock on its fulcrum and loosen the bearing to provide for making the adjustment. The ball thrust bearing on this spindle is shown at *C* and the lock-nuts and washer for taking up end wear are illustrated at *D*. It will be seen that an oil chamber is provided in the bronze bearings in order to insure adequate lubrication of the spindles.

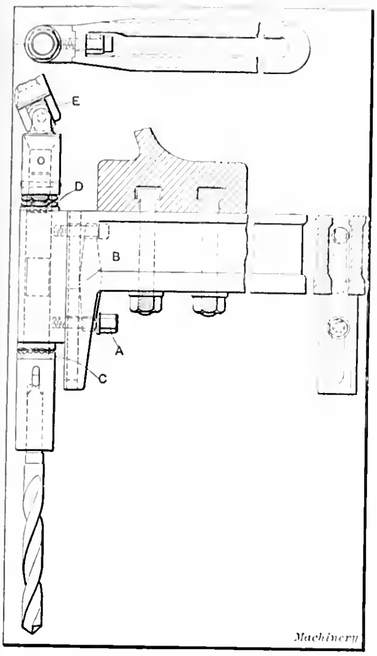

Fig. 2. Quick-acting Device for making Vertical Adjustment of Spindle Bearings

The universal joints used on the Natco multiple spindle drills are milled from the solid and carefully hardened. One of these joints is shown at *E* in Fig. 2. This is composed of only five pieces and does not depend upon a cross-pin that may be broken, or upon screws that may work loose. These universal joints are guaranteed to stand up for two years.

One of the most important features of this machine is the independent drill speeds in the head, which give two independent changes of speed to each spindle for each of the three changes of speed obtained in the gear box. It is well known that it is impractical to drive drills of different sizes at the same speed and feed per revolution, and the Natco independent drill speed feature gives approximately the correct speed and feed for each size of drill that comes within the range of the machine. For example, using ½-inch and 1-inch drills in cast iron, it is possible to secure a feed of 4.72 inches per minute. For this purpose the speed box lever is shifted to station *B* which gives 547 revolutions per minute or 71.5 feet per minute as the peripheral speed of the ½-inch drills which are fed at 0.0086 inch per revolution. By shifting the driving pinion in the head which drives the 1-inch drills these drills can be driven at 271 R. P. M. or 71 feet per minute, with a feed per revolution of 0.0174 inch per revolution. It will be noted from the preceding that the peripheral velocity of the drills in feet per minute is practically the same, while the feed of the ½-inch drills is only one-half as great as that of the 1-inch drill. Experience has led the National Automatic Tool Co. to believe that cone pulleys for driving and feeding machines of this type are unsatisfactory, while very gratifying results have been obtained with the powerful single pulley drive with geared feeds now employed.

* * *

More than 32,000 tons of aluminum was consumed in the various industries in the United States during 1913.

NEW MACHINERY AND TOOLS NOTES

Pinion Rod: Meisselbach-Catucci Mfg. Co., 27 Congress St., Newark, N. J. The pinion rod recently placed upon the market by this company is made in any length and with the teeth either straight or helical, and of either regular or odd shape.

Baling Machine: Famous Mfg. Co., East Chicago, Ind. A machine for baling sheet metal scrap which is arranged for either belt or motor drive. The sides and ends of the box in which the material is pressed are built of rolled steel sections bolted together.

Sensitive Drilling Machine: Berghauser Machine Co., Cincinnati, Ohio. A sensitive single-spindle drilling machine equipped with a feed box which has a series of steel sliding gears running in oil. Nine changes of speed are provided, ranging from 225 to 1850 R. P. M.

Link Grinder: Newton Machine Tool Works, Inc., Philadelphia, Pa. A radius link grinder for finishing the slots in hardened locomotive links. For narrow slots and those with little end clearance, small wheels are used, while on larger sized links the entire face is ground at one time.

Milling Attachment: Cincinnati Pulley Machinery Co., Cincinnati, Ohio. A milling attachment for use on the lathe which is particularly adapted for the use of jobbing and repair shops. It will do various classes of work which are ordinarily handled on standard milling machines.

Drilling and Tapping Chuck: Victor Tool Co., Waynesboro, Pa. The collets of this chuck are driven by a key which is released when the sleeve of the chuck is raised. The tapping chuck is provided with an adjustable friction which may be set to the desired tension so that the drive will be released before the tap can be broken.

Baling Press: Logemann Bros. Co., Milwaukee, Wis. A hydraulic press for baling scrap brass, copper, aluminum, sheet steels, etc., into compact bundles ready to be remelted. These machines are built in three sizes. The pressure is obtained from a double system of hydraulic rams which compress the scrap in a covered box.

Radial Drill: Cincinnati Bickford Tool Co., Cincinnati, Ohio. A radial drill which is driven by a Westinghouse adjustable speed motor with the controller mounted on the head of the drill. Compressed air is used to bind the column and lock the arm in position, the air control lever being conveniently located for the operator.

Tapping Attachment: Hoefer Mfg. Co., Freeport, Ill. The reverse motion of this tapping attachment is either controlled by the hand lever or by an automatic trip secured to the front of the machine. The automatic trip is operated by the collar on the quill, which is set to reverse the tap when it has reached a predetermined depth.

Drill Chuck: Wahlstrom Tool Co., 346 Carroll St., Brooklyn, N. Y. In the October, 1912, number of MACHINERY the automatic Wahlstrom drill chuck for straight shank drills was illustrated and described. The company has now brought out a similar chuck, the design of which has been modified to adapt it for handling taper shank drills.

Sand-blasting Outfit: Carter Metals Cleaning Co., Philadelphia, Pa. A sand-blasting outfit which uses air at a pressure of from 80 to 100 pounds per square inch. The compressed air passes through the upper hose connection of the nozzle and the sand from the lower hose meets the air inside the head and is projected from a ¼ inch orifice in the nozzle.

Automatic Drilling Machine: Standard Mfg. Co., Bridgeport, Conn. This machine is equipped with automatic cam feed so that the operator has to simply load and unload the jigs. The cams are so timed that the drilling operations performed by the four spindles proceed progressively. Adjustment is provided for the depth of hole and the range of drilling.

Drilling Machine: Taylor & Fenn Co., Hartford, Conn. The important feature of this machine is the provision of safeguards which protect every part of the mechanism. The only possible way in which the operator could be injured is by putting his hand under the drill. This machine is known as the type C. Each spindle has independent automatic feed and quick return.

Combination Shear and Punch: Schatz Mfg. Co., Poughkeepsie, N. Y. A combination shear and punch which combines three separate units. The first of these is a plate shear for cutting plates of any desired length or width. The second unit is a punch for punching sheets, plates and structural shapes and the third unit is a shear for cutting structural material at right angles or on a miter.

Power Press: Max Ams Machine Co., Mount Vernon, N. Y. A line of double crank cutting and stamping presses which are adapted for handling a great variety of work for which machines of this type are used. The machines are made in four sizes with capacities of 15, 25, 50 and 100 tons, re-

spectively. Each size is made in a number of different widths between the housings, ranging from 24 to 120 inches.

Multiple Spindle Drill: Baush Machine Tool Co., 200 Wason Ave., Springfield, Mass. A high-speed multiple spindle drilling machine in which each spindle has independent vertical adjustment controlled by an outside clamping screw. The drive is through helical gears which are enclosed in a case and immersed in oil. The main driving shaft slides up through the yoke or down through the head, thus economizing in overhead space.

Abrasive Wheel Cutting-off Machine: Nutter & Barnes Co., Hinsdale, N. H. In the December, 1910, number of MACHINERY, the abrasive wheel cutting-off machine of this company's manufacture was illustrated and described. This machine was equipped with a handwheel and screw for clamping the work in a V-block. This was a slow method and has recently been improved by the substitution of a lever-operated device which can be manipulated much more quickly.

Tapping Chuck: Cincinnati Bickford Tool Co., Cincinnati, Ohio. A tapping chuck designed for use in upright, horizontal or radial drilling machines, which are not provided with a tap leading mechanism. With this device, the danger of stripping the threads or reaming out the hole while drawing to start the tap is eliminated. The chuck consists of a driving spindle and a floating outer sleeve which have two rectangular ball bearings in place between them that drive the outer sleeve. The tap holder and tap are attached to this sleeve.

Screw Plates: Russell Mfg. Co., Greenfield, Mass. Two screw plates known as styles A and B, respectively. Style A plate is very simple to adjust, adjustment being accomplished by a single screw, while the die is in the stock ready for use. In the style B plate, the screw guide forces the beveled edges of the die against the beveled surfaces of the collet. As these beveled surfaces are identical in form, a combined screw and taper fit is effected which compensates for wear. The adjustment of the cutting size is accomplished by turning screws located back of the die.

Drilling Machine: Kern Machine Tool Co., Hamilton, Ohio. Two types of drilling machines. One of these is a tilting table machine on which the table may be swung to any angle. The table is rigidly held on the saddle by four bolts. The second machine is a heavy-duty drilling machine, the design of which combines a number of interesting features. There are nine changes of speed and eight changes of feed. Double back gearing is provided through gears which may be slid into engagement without stopping the machine. A feature of the machine is a ball thrust bearing under the bevel gear which is used to elevate the table arm.

Double Seaming Machine: Charles Leffler & Co., Brooklyn, N. Y. An automatic square double seaming machine primarily adapted for use in the manufacture of double seamed tin cans of the kind used in packing tobacco, talcum powder, etc. The machine is driven by a two-step cone pulley and friction clutch. The operator is merely required to place the can on the chuck and depress the treadle which causes the lower spindle to rise and engages the clutch, thus starting the driving shaft and the chuck spindle. The double seaming rolls are brought into action automatically while the can is making the required number of revolutions. The clutch is then disengaged automatically and the work is released.

OCCUPATIONS OF ENGINEERING GRADUATES

The College of Engineering of the University of Illinois has collected data relating to 2165 graduates in order to ascertain the branches of work in which they are engaged. It is of interest to note that 89 per cent are engaged in one way or another in engineering work, while 8 per cent have gone into other fields, the remaining 3 per cent having passed away. Out of every 100 engineering graduates of the University of Illinois, we thus find that 63 per cent are employed by corporations engaged in one way or another in engineering work; nearly 15 per cent have become architects; 6 per cent hold executive positions with engineering companies; 4.5 per cent are teachers in engineering colleges and nearly 1 per cent are consulting engineers. Of those engaged in non-engineering occupations, 2.4 per cent have turned to farming; 1.4 per cent are merchants; 0.9 per cent hold executive positions with mercantile companies; and a comparatively small number are lawyers, physicians, bankers, army officers, salesmen, real estate and insurance brokers and editors of non-technical journals. The percentages represented by these various occupations vary from 0.24 to 0.9 per cent.

NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION CONVENTION

The twelfth semi-annual convention of the National Machine Tool Builders' Association was held at the Hotel Bancroft, Worcester, Mass., April 23-24. The place of meeting was first fixed in New York City, but the fact that the convention of the National Metal Trades Association, whose membership includes some of the machine tool builders, was to be held in Worcester the same week, caused the management to make the change of place shortly before the meeting. That Worcester did herself proud in providing entertainment and accommodations was heartily conceded by all.

The meeting was called to order by President W. A. Viall of the Brown & Sharpe Mfg. Co., whose address of welcome sounded an optimistic note. He was confident that normal conditions of prosperity in the machine tool trade would be soon restored and counseled the members to plan for the future and take steps to improve manufacturing and selling facilities.

Charles E. Hildreth, the manager of the association, begged the members to respond to letters of inquiry and promised to see personally all of them in their places of business. He pleaded for more personal acquaintanceship and cordiality.

J. H. Drury, of the Union Twist Drill Co., reported the name of one new member, Williams White & Co., Moline, Ill. The committee report on standardizing grades of grinding wheels was a resumé of the factors to be considered and was decidedly discouraging as to the feasibility of establishing a uniform grading system. The number of abrasives, the sizes of grain, the varieties of bond and other factors to be considered make a vast number of possible combinations. That it will be possible to establish a system of grades which will be uniform for all makes of wheels seems doubtful.

Charles Fair, of the General Electric Co., presented an analysis of the conditions that must be met in standardizing electric motors for machine tools. This problem, too, seems difficult of solution, but something may be accomplished in establishing a near standard from which many differentiations of equipment must necessarily be expected.

The paper by J. C. Spence, superintendent of the Norton Grinding Co., "How Can We Induce Ourselves and Our Men to Earn More Money," was enthusiastically received and discussed. Mr. Spence got down to the fundamentals of personal relationship between employers and employes and pointed out how necessary it was to engender confidence of the men in the management to obtain the highest production. This paper will appear in a later number.

The afternoon of the first day was given over to committee meetings. In the evening a "Good Fellowship" dinner was given in the Hotel Bancroft which was attended by about 280. It was marked by no toasts or speeches, but a unique and most enjoyable entertainment was provided by talent of the Norton Grinding Co. The farce and minstrel show called "High Speed Steals," which concluded the evening, was received with uproarious applause.

Friday forenoon was given to committee meetings and the fourth session in the afternoon was occupied principally by an illustrated paper, "Safety as Applied to Grinding Wheels," by R. G. Williams, safety engineer of the Norton Co., and committee report on safeguarding grinding wheels.

The number registered in attendance to the convention was 169, which is more than was ever before registered at a semi-annual meeting.

* * *

The rack-and-pinion-type locomotives that haul cars to the top of Mount Washington, N. H., take water from a pipe along the track instead of carrying it in a tender. The water is pumped to the top of the mountain by duplex pumps near the base, which pump against a pressure of 2250 pounds per square inch. The pumps are located at 2540 feet above sea level and pump water to the summit at an elevation of 6280 feet. The pipe line to the summit is two inches in diameter and one-half inch thick for half its length and three-eighths inch for the remainder of the distance.

MAKING THE OSGOOD OIL-HOLE COVERS

The operations involved in making the Osgood oil-hole covers are interesting for two reasons: First, because the operations of turning and cross-slotting the brass shells, assembling the ball and retaining spring in place, spinning over the edge of the shell and cutting it off, are all performed in the turret lathe, without requiring the spindle to be stopped. Second, in developing this sequence of operations, a special cross-sawing attachment was designed for cutting the slot in the bottom of the brass shells.

The first operation consists of feeding the stock up to a stop, and the second and third operations are those of spotting, drilling and forming the seat for the ball. After the work has progressed to this point it must be slotted, and the cross-sawing attachment illustrated in Fig. 1 is used for this purpose. Referring to this illustration the barrel *A*, of which the flange *B* is an integral part, is screwed onto the nose of the turret lathe spindle. The four pins *C* which guide the plate *D* are secured in the flange *B*. The plate *D* is normally held in its outermost position by spiral springs *E*.

The tool *F* is clamped to the turret, the working parts of the tool being free to turn on the shank. The friction wheels *G* and *H* are carried by bearings at right angles to the turret-

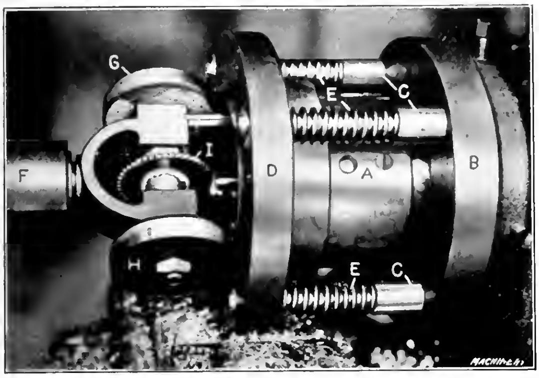

Fig. 1. Cross-sawing Attachment for slotting the Brass Shells

tool shank. These wheels are made to revolve through their contact with the plate *D*, which is revolved on the end of the lathe spindle. The friction wheel *G* simply acts as a balancing idler for the other wheel *H*. When the turret tool is brought up to the work, a lock on the turret tool engages a lock finger on the spindle nose attachment and causes the tool *F* to rotate in unison with the spindle. Pressure of the turret tool against the plate *D* causes this plate to move back

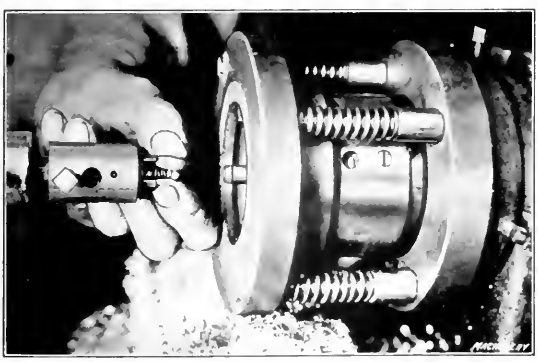

Fig. 2. Assembling the Ball and Spring in the Shell

against the tension of the springs *E*. At the same time the wheel *H* drives the saw *I* which cuts the slot in the brass shell.

After completing the slotting operation, the ball and spring are assembled, as shown in Fig. 2, and the edge of the shell is spun down to retain the spring in the shell. While this spinning operation is being performed, the slots in the shell are closed so that the work is not distorted. The cutting-off operation illustrated in Fig. 3 is next performed by operating the cam lever. This causes the cutting-off tools to move in and sever the completed oil-hole cover from the bar. As cut from the bar, the cover is ready for use and the time required to make a complete cover is about fifteen seconds. From this it will be readily seen that the operation of the slotting tool is quite rapid. The J. L. Osgood Co., 43 Pearl St.,

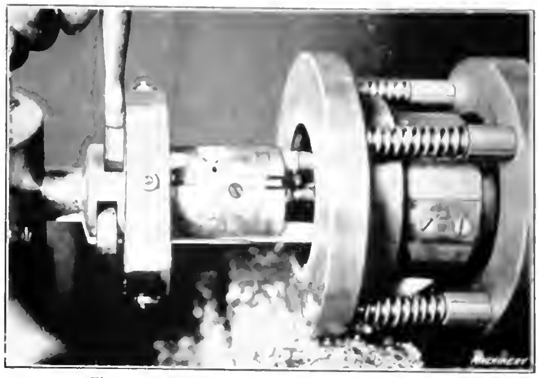

Fig. 3. Cutting off the Completed Oil-hole Cover

Buffalo, N. Y., is prepared to furnish the cross-sawing attachment described in this article to manufacturers who have turret lathe work for which it is adapted. The Osgood oil-hole cover is described in the New Machinery and Tools section of this number of MACHINERY.

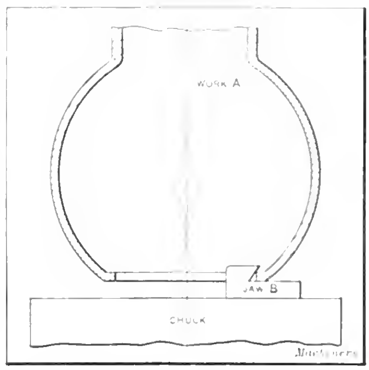
HOLDING DEVICES FOR FIRST-OPERATION WORK

BY ALBERT A. DOWD*

Answering the criticism by F. H. Bullard in the February number of MACHINERY, regarding my article on "Holding Devices for First-operation Work" which appeared in MACHINERY for November, 1913, I wish to say that he is correct in regard to the expense of some of the fixtures shown. The first cost of a fixture is a minor item, however, in comparison to convenience and rapidity of operation when a large number of pieces are to be machined. Referring to the fixtures described in the article mentioned, it will be noted that Figs. 1, 2, 4, 5, 6, 7, and 10 are either component parts of an automobile or they are portions of accessories used in automobile construction. The smallest number of pieces in this group is 5000 and the largest 100,000 for a year's production. It must therefore be admitted that the first cost of the fixtures shown is a negligible item, when compared to the saving in time effected by their use. The manufacturer of today is looking for production first, last, and all the time, and he would not for a moment consider the use of a fixture which would involve any great amount of labor in setting the work in position, no matter how cheaply the fixture might be made.



Special Form of Jaw for Holding Ball Joint

Regarding Fig. 3, the fixture for which is rather harshly criticised by Mr. Bullard, the writer stated in the last paragraph describing this fixture that "a method of holding this work by the interior undoubtedly would have been more satisfactory," meaning some device similar to that shown in Fig. 6. Perhaps a slight explanation will make this matter somewhat clearer and will show why the device illustrated was used in this particular instance. A number of castings were sent by a foreign government, as sample castings for which

No. 5B Heavy Plain Milling Machine

Heavy Service Milling Machines Designed for Easy Operation

In addition to the Automatic Fast Feed, our Heavy Service Plain Milling Machines are provided with many other features making them easy to operate.

The knee is efficiently clamped to the column from a single point at the front, saving time on shifting from roughing to finishing cuts.

All hand wheels and levers for controlling movements of the table are grouped at the front.

All feeds are started, stopped or reversed by a single lever on the side of the knee.

Gears which are often thrown into engagement have special pointed teeth so they always slip easily into mesh without bruising.

We should be glad to advise methods of handling your work.

PROVIDENCE, R. I., U. S. A.

CANADIAN AGENTS: The Canadian Fairbanks-Morse Co., Ltd., Montreal, Toronto, Ottawa, Winnipeg, Calgary, Vancouver, St. John, Saskatoon.
FOREIGN AGENTS: Buck & Hickman, Ltd., London, Birmingham, Manchester, Sheffield, Glasgow; F. G. Kretschmer & Co., Frankfort a M., Germany; V. Lowener, Copenhagen, Denmark, Stockholm, Sweden, Christiania, Norway; Schuchardt & Schutte, St. Petersburg, Russia; Fenwick Freres & Co., Paris, France; Liege, Belgium, Turin, Italy, Zurich, Switzerland, Barcelona, Spain; The F. W. Horne Co., Tokio, Japan; J. A. Vail, Melbourne, Australia; F. L. Strong, Manila, P. I.

Read page 67

fixtures and tools were to be designed; and in view of the fact that the location of the plant to which machines and tools were to be sent was nearly half way around the globe, it is evident that it would have been out of the question to suggest changes in the pattern, as this would have necessitated a delay of two months at the very least. It will, therefore, be readily apparent that it was essential to handle the castings *just as they were*, without taking liberties with the design. The method suggested by Mr. Bullard of holding by the inside of a flange in a three-jawed chuck would hardly be practical on account of the narrow gripping surface provided for the jaws, unless these were of special design as shown at *B* in the accompanying illustration. This design would then have a tendency to crowd the work back against the face of the jaw so that it would be securely held. Even under these conditions, it is highly probable that there would be more or less "chatter," for with the method described in the original article there was a slight tendency to "chatter," although the manner of gripping was such as to prevent this to a great extent on account of the metal-to-metal holding method, which killed vibration of the casting to a considerable extent.

Regarding the use of the "bull center" as a support; this is obviously out of the question, as the casting is in the rough at the end where the center is used. This is used merely to approximate the cored center of the work while the hook-bolts are being tightened. Regarding the use of clamps for holding on internal lugs, as mentioned by Mr. Bullard, it would give the writer great pleasure to have the method fully described, showing how the clamps would be operated and set up firmly on the internal flange. This would be possible on a special fixture or by the use of a socket wrench for tightening, but I fail to see how the work could be centered by the plug at the same time. It would also be a difficult matter for the operator to see what he was doing, even if the work were set up on blocks to let in the light at the ball end of the work.

In connection with suggestions regarding desirable pattern changes, this matter can be very easily arranged when the factory designs the work for which it also makes the tools, but when an outside customer's castings are involved it is sometimes inadvisable to suggest changes, as a number of castings may be already on hand. The writer will not soon forget a pattern change which seemed desirable for chucking purposes, the work in question being a pot casting for a large automobile factory in the middle west. The suggestion was made and the answer came back: "10,000 castings on hand. Cannot change pattern." There was also an intimation that if we could not design a fixture to hold the work as it was, some other firm might be able to do so. Needless to say, the fixture was designed for the sample casting sent us, and nothing more was said about changing the pattern. It may be seen from this that it is not always wise to suggest changes, as some manufacturers do not take kindly to it. A knowledge of the number of castings on hand is valuable when changes are to be proposed and this information is not always available.

I fully agree with Mr. Bullard's statement that the "designer of any piece of machinery should not only be capable of designing mechanism that will perform the functions desired, but should so shape the various parts that they may be readily machined in ordinary machine tools with the least possible outlay for special equipment." I think, however, that he has not considered the matter from the point of view of the machine tool builder who is called upon to furnish machines and equipment for a great variety of work in which changes in patterns would not be permitted on account of the number of castings which might already be on hand. For this reason the writer does not quite see how he "has failed in just this respect," especially as the customers who received and used the devices illustrated were perfectly satisfied with them, and in several instances duplicated their orders within a short time after their receipt and trial. If this is a sign of failure, most of us would be glad to fail continually.

In regard to handling the larger ball joint shown, by either of the methods suggested by Mr. Bullard, I will say that as the weight of a single one of these castings would approximate 2300 pounds or something over a ton, it would be an expensive proposition to "scrap" one of them. Suppose there are two or three on hand which must be either machined in some way or "scrapped." It would undoubtedly be a difficult matter to hold the work with the flange side up, in any sort of standard equipment with which the writer is familiar. Neither a three- or a four-jaw chuck would have sufficient gripping surface to hold the piece securely unless very light cuts were taken. If, on the other hand, the work was held with the ball end up by means of clamps and dogs, then the second setting would present some serious difficulties in the matter of holding and driving. Again, supposing that it was permissible to change the pattern, as suggested, before any castings had been made, the jaws could then be brought up on the inside and additional screw dogs used to assist in driving. How could the screw dogs be tightened unless a special wrench were provided? And even then it is doubtful whether the work could be held securely. The fact of the matter is that so little frictional surface can be obtained on the ball end (due to its shape) that some sort of a seat which will conform to the shape of the casting is needed in order to provide the necessary surface. The use of ordinary clamps would be difficult and would be open to the same objections as those already mentioned. A set of cast-iron blocks could be bored out in position on the table of the machine and clamps used to draw the casting down upon them, thus providing frictional surface enough to hold the work, but even if this were done the clamping would be attended with some of the difficulties previously referred to.

In conclusion I will say that I believe the method shown in Fig. 12 is thoroughly practical and not excessively expensive in spite of the adverse criticism regarding it. Sketches illustrating the exact method proposed by Mr. Bullard would be greatly appreciated and would perhaps make clear some of the points which at present do not seem entirely logical or practical.

* * *

NOMENCLATURE OF ALLOYS

A committee of the Institute of Metals which was appointed in 1912 to report upon the question of the nomenclature of alloys has presented a report embodying its first series of recommendations. The work has been approached in a practical manner and the demands of industry and commerce have been borne in mind. It has been attempted to adhere, as far as possible, to existing names sanctioned by long usage, to avoid coining new names or adopting recently coined names, and to employ simple English names throughout. The committee has, in the first instance, confined its attention to the alloys of copper, and the terms defined in the report are "brass" and "bronze." When the word "brass" alone is used, it denotes an alloy of zinc and copper only, containing over 50 per cent of copper. When an alloy containing a third metal, such as tin, is to be denoted, the name of the additional element should be used as a prefix; thus, an alloy containing 1 per cent of tin, 29 per cent zinc, and 70 per cent copper would be called "tin-brass." The word "bronze" denotes an alloy of tin and copper containing more than 50 per cent of copper, additional metals being denoted as above. These two names represent by far the most widely used alloys, and the general adoption of the terms thus defined would do much to remedy the state of confusion which exists at the present time.

* * *

A material called "elianite," which has been produced in the electric furnace by Dr. C. Rossi, manager of a nitrate acid works at Legnano, Italy, is claimed to be proof against all acids. This material has about 75 per cent of the tensile strength and from 25 to 75 per cent of the compressive strength of cast iron. Its hardness is about 60 per cent greater than that of cast iron and its melting point is 2500 degrees F. Elianite can be cast and is suitable for use in large apparatus used in the acid-producing industries.

EFFICIENCY TEST OF A STOCKBRIDGE SHAPER

In connection with the experimental engineering work of the Worcester Polytechnic Institute, Worcester, Mass., tests were recently conducted with the view of determining the mechanical efficiency of a Stockbridge shaper and also the number of cubic inches of metal which the shaper was capable of removing for each horsepower hour of power supplied to the tool. For this purpose, it was necessary to equip the shaper with a special table upon which the dynamometer was mounted. The shaper equipped in this way is shown in Figs. 1 and 2 and Fig. 3 is a chart showing the results of the test.

The work upon which the tool was engaged during the test was held in a special chuck. This chuck had to be carefully lined up with the direction of travel of the tool in order that the full pressure might be applied to the dynamometer. The first table which was used to support the dynamometer was a little wider and considerably longer than the regular table of the shaper. This arrangement left a large part of the auxiliary table unsupported, with the result that vibration was set up which would have materially affected the accuracy of the results obtained. Several methods of overcoming this difficulty were considered, such as the use of a supporting chain secured to the ceiling. A number of people in the shop, who had not given the matter careful attention, suggested the use of jack-screws, overlooking the fact that the cross-feed of the shaper table was used during the conduct of the test. The difficulty was finally overcome by modifying the design of the table to reduce its length and the amount of overhang, with the result that vibration was eliminated.

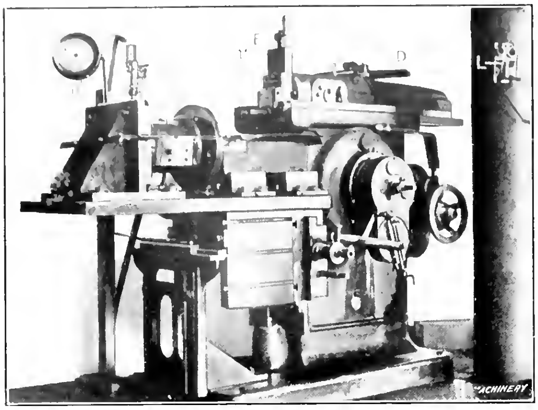

Fig. 1. Stockbridge Shaper equipped for conducting an Efficiency Test

The form of dynamometer *A* finally adopted for measuring the effective pressure of the tool consisted of a cylinder and piston, the cylinder being partially filled with oil. This simple though accurate dynamometer was used in connection with a pressure gage *B* and steam engine indicator *C*, as shown in Figs. 1 and 2. No calibration tests were necessary and it was a very simple matter to refill the cylinder with oil without admitting any air. This was done by removing the indicator, compressing the oil in the cylinder until it commenced to flow out, and then slowly drawing the piston back and pouring oil in rapidly enough to keep the cylinder filled at all times. The indicator was attached to the dynamometer cylinder in the same way as in the cylinder of a steam engine, and indicator cards were taken to determine the mean effective pressure. The results obtained were more accurate than those that could have been secured by reading the gage, as the latter fluctuated considerably, owing to variations in the hardness of the cast iron operated upon. A pantograph *D* was used as a reducing motion for the indicator and another difficulty was experienced in connection with this part of the apparatus. The indicator moved with the table when the cross-feed was in operation, and if the length of the indicator cord were adjusted when the table was in one extreme position, it would have been out of adjustment when the table was fed over two or three inches. Therefore a hook was fastened to the cord about 2 feet from the indicator, and instead of having one loop on the end of the cord attached to the pantograph, a number of small rings *E* were tied to the cord at intervals of 1 inch. It was then merely necessary to secure the hook to any one of these rings that gave the proper length of cord while a card was being taken.

One more difficulty experienced in connection with the dynamometer was that of providing means for rotating its piston to overcome the effect of static friction, the reason for taking this precaution being the same as that which leads one to spin the piston of a dead weight gage tester. The first method that was tried consisted of wrapping a wire around the piston rim, with one end terminating in a heavy weight and the other end carried over a series of pulleys and secured to the cross-feed reciprocating motion. This was a failure for three reasons: First, the sharp turns over the pulleys eventually caused the wire to break, and cord of any kind could not be used because it stretched; second, the reversal of the direction of motion of the cross-feed being slow, there were periods when the turning motion imparted to the piston was not active; third, the power required to rotate the piston could not be measured and so could not be considered in the results of the test. The next method that was considered consisted of placing a small pulley on a shaft directly above the dynamometer and carrying a belt from this shaft to the countershaft. A second belt from this intermediate shaft was connected to the rim of the piston *K*, in this way causing the piston to be rotated at a suitable speed. This rig would have required a considerable amount of time to set up and was replaced by a method which proved entirely satisfactory. This consisted of taking power from the platen of a planer *F* which moved at right angles to the shaper ram, to rotate the dynamometer piston. The mechanism employed for this purpose consisted of a piece of flat steel *G* bent to the shape shown in Fig. 2. One end of this link was bolted across the planer table and a straight flat link *H* was secured to the other end by means of a pin joint. The opposite end of this link was connected to a flat link *J* secured to the rim of the piston *K* by means of another pin joint. By running the planer on short stroke, the desired rolling of the piston was accomplished in a very satisfactory manner.

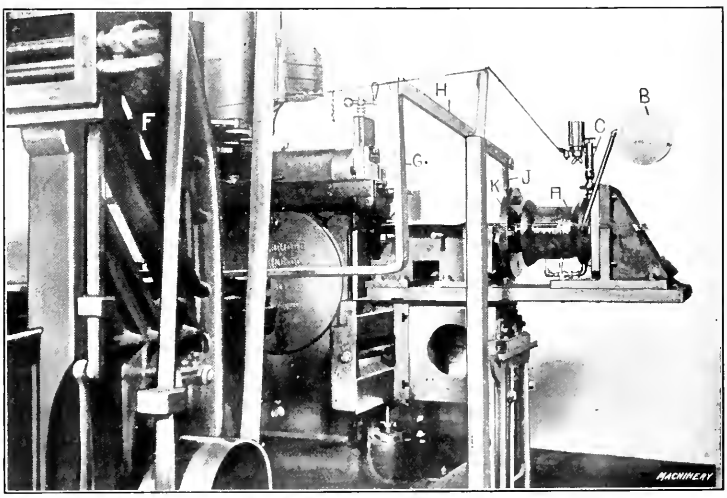

Fig. 2. Apparatus used for rotating the Dynamometer Piston

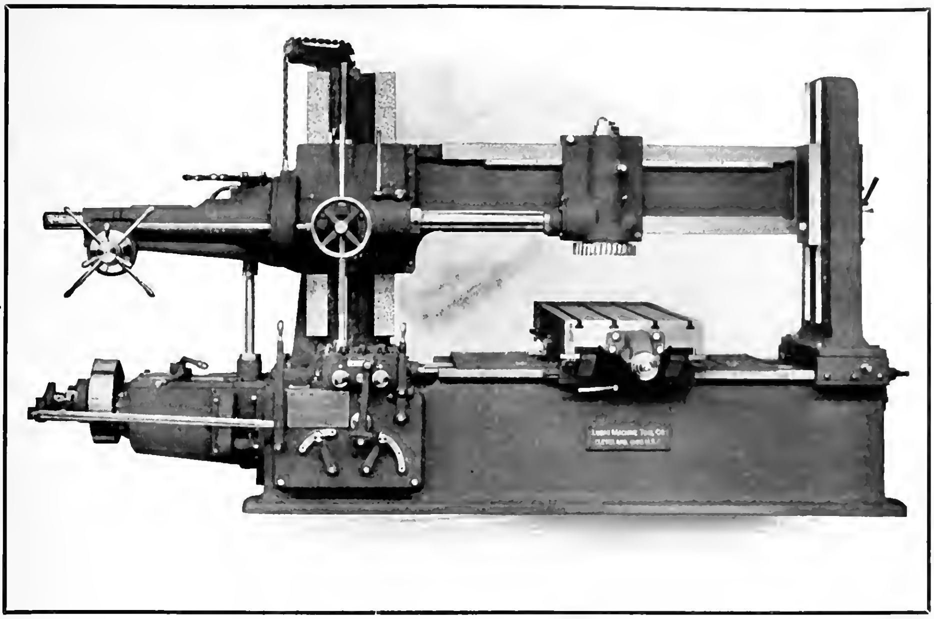
The shaper was driven by a 7½-horsepower direct-current Westinghouse motor, which was run at 975 revolutions per minute and belted to the shaper by a 3-inch double belt. The motor operated on 31 amperes at 220 volts. The center dis-



tance between the motor and shaper pulleys was 11 feet and the shaper pulley was of a size to run at 300 revolutions per minute. A brake test of the motor was made to determine its efficiency.

The integrating watt meter used to determine the power supplied to the motor was intended for a 110-volt circuit and the motor for 220 volts. Therefore, the necessary resistance was connected in series with the resistance already in the meter, so that the power in a 220-volt circuit could be measured after the meter had been calibrated to determine a new constant. The constant determined in this way was checked while the brake test of the motor was being made. The meter was so connected that it could be switched in or out without requiring the motor to be stopped, the switch L being provided for this purpose.

After preliminary tests had been made, it became evident that a more solid foundation than is ordinarily required for

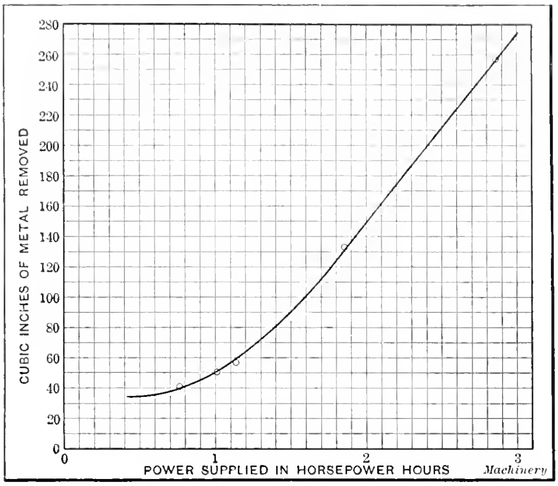


Fig. 3. Chart showing Relation of Horsepower Hours to Cubic Inches of Cast Iron Removed

a shaper was absolutely necessary if accurate results were to be obtained. The first foundation employed was not satisfactory, so a planer was moved in order to obtain the support of the brick piers under it, and the shaper set up in its place. Wedges were driven between the top of the piers and the beams to which the flooring was nailed and the shaper fastened in place by four ⅝-inch lag screws. The foundation provided in this way was perfectly rigid and enabled very satisfactory results to be secured.

The power supplied to the shaper was determined in the following manner. The total electrical power supplied to the motor during the test was recorded by means of the integrating watt meter and a brake test was made to obtain a curve of the watts-input to the motor as compared with brake horsepower. There was evidently a power loss in the belt drive but owing to the impossibility of reproducing the conditions of loading, a belt test was out of the question. Therefore this loss was assumed to be 4 per cent of the power at the motor pulley and a new curve was plotted, taking this belt loss into consideration. This gave the watts-input against horsepower delivered to the shaper pulley.

The power expended at the tool point was measured as follows: The pressure of the tool point against the work was obtained from indicator cards which, theoretically, should be rectangles. Owing to variations in the hardness of the cast iron, however, the upper part of the cards varied in height. The mean effective pressure in pounds per square inch was obtained from the cards, and knowing the area of the piston to be 20 square inches, the total force was calculated. The number of strokes per minute were recorded and also the duration of the test. This gave the force, the distance and the time, from which the horsepower was figured. For a given depth of cut and cross-feed, a number of short tests were made because five minutes was sufficient to feed the tool across the work. Therefore, at the beginning of a test the time was noted and the meter switch thrown in. Just before finishing the cut, the switch was pulled and the exact time noted. After completing such a test another cut of the same depth and cross-feed would be employed for a subsequent test, the operation being repeated until enough power was registered on the meter to insure accurate reading of the dials. The mechanical efficiency of the shaper was obtained by dividing the power expended at the tool—as determined by the dynamometer—by the power supplied to the machine by the motor. The number of cubic inches of metal removed was figured, and knowing the number of horsepower hours, the number of cubic inches removed per horsepower hour was figured. The results of this part of the test are shown in Fig. 3.

NATIONAL METAL TRADES ASSOCIATION CONVENTION

The sixteenth annual convention of the National Metal Trades Association, held at the Hotel Bancroft in Worcester, Mass., April 20-22, was one of the most successful in point of attendance ever held. The registration of members and others attending was 294, a number considerably larger than that registered at the last New York meeting. President W. A. Layman of the Wagner Electric Mfg. Co., St. Louis, Mo., presided, assisted by John D. Hibbard, the commissioner succeeding Robert Wuest, who had so ably conducted the affairs of the association for years. The report on industrial education by F. A. Geier was discussed by C. A. Prosser of the National Society for the Promotion of Industrial Education, Louis H. Buckley of the Worcester Independent Industrial Schools, and W. B. Hunter, who presented the Fitchburg plan of industrial education.

W. H. Van Dervoort presented a report on industrial accidents which was discussed by M. W. Alexander and W. H. Doolittle. The cause of accident prevention is growing and the movement is being greatly accelerated by educating the workmen to use their intelligence in avoiding dangerous acts. Justus H. Schwack of William Sellers & Co., Inc., Philadelphia, Pa., discussed the general subject of publicity.

The program for Wednesday forenoon and afternoon comprised "Results of Applied Scientific Management," by George D. Babcock of the H. H. Franklin Mfg. Co., Syracuse, N. Y.; "Basic Principles of Industrial Organization," by Prof. Dexter S. Kimball, Sibley College, Cornell University; "Work of the Bureau of Foreign and Domestic Commerce and the Plans of the Department for Its Development," by Albertus H. Baldwin, chief of the Bureau of Foreign and Domestic Commerce, Washington, D. C.; "Labor Legislation," by Walter G. Merritt, American Anti-Boycott Association, New York City.

The following officers were elected: President, Herbert H. Rice, Waverly Co., Indianapolis, Ind.; first vice-president, L. H. Kittredge, Peerless Motor Car Co., Cleveland, Ohio; second vice-president, George Mesta, Mesta Machine Co., Pittsburg, Pa.; treasurer, F. C. Caldwell, H. W. Caldwell & Son Co., Chicago, Ill.

The convention was closed with a banquet in the evening at the Hotel Bancroft, attended by over 250, at which W. A. Layman was toastmaster. Dr. J. Lawrence Laughlin of the University of Chicago and Dr. W. H. P. Faunce, president of Brown University, made the addresses of the evening.

* * *

Filing machines, while designed primarily for filing the clearance in dies, are used advantageously for lapping and filing parts to size. One well-known maker of drafting instruments employs filing machines for reducing German silver parts to size and shape. The parts are held in simple jigs and a boy runs the machine, moving the jig up to a stop and sliding it along until the work is finished. The filing machine is required to remove but little material and is especially advantageous on such work. The parts could not be held firmly enough to be milled without marring and distorting them, and the amount to be removed would make a milling operation almost absurd even if it were practicable. The same type of filing machine is used in armories for filing gun sights and similar parts.

PERSONALS

W. H. Sherman has been made superintendent of the W. P. Davis Machine Co., Rochester, N. Y.

Ralph E. Flanders has been made manager of the Jones & Lamson Machine Co., Springfield, Vt.

N. K. B. Patch has been appointed superintendent of the Lumen Bearing Co.'s plant at Buffalo, N. Y.

H. P. Parrock, manager of the Lumen Bearing Co., Buffalo, N. Y., has completely recovered from his recent illness.

J. B. Slagle, who worked in Harrisburg, Pa., and Muskegon, Mich., is requested to communicate with the Lyons Machine Works, Lyons, Iowa.

F. H. Brown, formerly sales manager of the W. P. Davis Machine Co., Rochester, N. Y., has been made secretary and treasurer of the company in place of C. F. Davis, who has resigned.

A. S. Baldwin, formerly general manager of the Alberger Pump & Condenser Co., Newburg, N. Y., has resigned his position, and will become manager of works of the Best Mfg. Co. of Pittsburg, Pa.

Leroy M. Curry, who was with the Aurora Automatic Machinery Co., Chicago, Ill., as tool designer, has resigned and taken a similar position with the Wood Turret Machine Co., Brazil, Ind.

Robert Wilde has resigned as superintendent of the gear department of the Warner Gear Co., Muncie, Ind., to become a consulting gear engineer. Mr. Wilde will give his attention to all classes of gear work.

Ludwig Swenson, for several years in the special machinery department of the Barber-Colman Co., Rockford, Ill., has been made secretary and general manager of the Rockford Lathe & Drill Co., Rockford. C. W. Holmquist, who formerly held this position, has resigned to take charge of his coal and lumber business.

Walter C. Allen has been elected vice-president of the Yale & Towne Mfg. Co. Mr. Allen has been general manager of the company for the past five years, and as such, has had charge of the sales policy and management in all departments of the business at home and abroad excepting the bank lock department. As vice-president and general manager, he will continue to perform the same duties as heretofore.

Frederick L. Hickok, formerly sales manager of the Ingersoll Milling Machine Co. of Rockford, Ill., has joined the staff of MACHINERY, and will devote his time to field service work for advertisers, cooperating particularly with them for the development of business. Mr. Hickok was born in Ashtabula, Ohio. He is a graduate of the Case School of Applied Science, Cleveland, and has an all-around mechanical experience that especially qualifies him for the line of work he has taken up.

* * *

OBITUARIES

John S. McLean died of pneumonia at his home in Readville, Mass., March 26, aged fifty-four years. Mr. McLean had been in the employ of the Prentiss Tool & Supply Co. at its Boston branch as selling representative for twelve years. He was a man of estimable character, well and favorably known in the machine tool trade.

COMING EVENTS

May 1-October 31.—Anglo-American Exposition, London, England, to celebrate the centenary of peace between the United States and Great Britain. American executive offices: Woolworth Bldg., New York City. Charles J. Kiralfy and Albert E. Kiralfy, commissioners general.

May 19-20.—Annual convention of the International Association of Manufacturers, at the Waldorf-Astoria Hotel, New York City. George S. Boudinot, 30 Church St., New York City, secretary.

June 10-12.—Annual convention of the Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill.

June 15-17.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill.

June 15-17.—Annual convention of the American Supply & Machinery Manufacturers' Association at White Sulphur Springs, West Virginia; New Green Brier Hotel, headquarters. General offices of the association, Woolworth Bldg., New York City.

June 16-19.—Spring meeting of the American Society of Mechanical Engineers, Minneapolis and St. Paul, Minn. Calvin W. Rice, secretary, 29 W. 39th St., New York City.

June 30-July 4.—Annual meeting of the American Society for Testing Materials, Atlantic City, N. J. Hotel Traymore, headquarters. Edgar Marburg, secretary, University of Pennsylvania, Philadelphia, Pa.

July 15-22.—Second International Congress of Consulting Engineers, to be held in Berne, Switzerland.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

SOCIETIES, SCHOOLS AND COLLEGES

Clarkson College of Technology, Potsdam, N. Y. 1914 catalogue. 56 pages, 6 by 9 inches.

Northwestern University, Chicago, Ill. Annual catalogue 1913-1914. 485 pages, 6 by 9 inches.

Syracuse University, Syracuse, N. Y. Bulletin of the university for March, 1914. 503 pages, 5½ by 8½ inches.

Beloit College, Beloit, Wis. Beloit College bulletin for March, 1914, being the sixty-seventh annual catalogue issued by this institution. 168 pages, 5½ by 8 inches.

University of Vermont and State Agricultural College, Burlington, Vt. Catalogue for 1913-1914 and announcements for 1914-1915. 260 pages, 5¼ by 7¾ inches.

Columbia University, New York City. Bulletin containing announcements of the summer session which extends from June 3 to September 23. 175 pages, 6 by 9 inches.

Armour Institute of Technology, Chicago, Ill. Bulletin for May, 1913, containing general information on the calendar, curriculum, etc., of the institute. 192 pages, 5¾ by 8½ inches.

Massachusetts Institute of Technology, Boston, Mass. Bulletin containing 1914 reports of the president, treasurer and other administrative officers. 142 pages, 5¾ by 8¾ inches.

Rensselaer Polytechnic Institute, Troy, N. Y. Rensselaer Polytechnic Bulletin for December, 1913, giving general information on the undergraduate and graduate courses and student organizations.

University of Wisconsin, Madison, Wis. An engineering experiment station has been created by the board of regents. The organization will be established in the College of Engineering and will have general charge of the testing and research work of the college. The staff of the station will consist of the dean as director, and the members of the instructional staff in the various departments of the College of Engineering. In addition to these will be fellows, scholars and assistants who may be engaged in experimental and research work.

Department of Education, City of Waterbury, Waterbury, Conn. Form 51-B, giving information concerning the continuation school for machine shop apprentices. Apprentices from the various shops are eligible to membership provided their employers insist that they comply with all rules and agree to pay them while in attendance at the school. The subjects covered during the four years course are: shop mathematics, reports and discussions of special topics, articles from trade journals, etc., shop talks, history and civics, hygiene, drawing, mechanics and strength of materials.

Tri-state College, Angola, Ind. Annual catalogue 1913-1914. 125 pages, 5¼ by 7¾ inches. The Tri-State College comprises three branches, viz., the Tri-State Normal College, the Tri-State College of Pharmacy and the Tri-State College of Engineering. The college of engineering offers courses in civil, electrical and mechanical engineering, each of which requires but two years for graduation. A student may enter with an ordinary common school education. In addition to the regular courses, special courses are given in shop practice, wood, bench and lathe work, patternmaking, foundry work, forging, and tool-making.

Pratt Institute, Brooklyn, N. Y., holds its annual exhibition Thursday, April 30, from 2 P. M. to 10 P. M.; Friday, May 1, from 10 A. M. to 10 P. M., and Saturday, May 2, from 10 A. M. to 5 P. M. The exhibition is open to the public and a cordial invitation is extended to all interested in industrial and technical education. The students will be engaged at their regular work and an opportunity will thus be afforded to visitors to inspect the methods, equipment and general facilities of the school as well as the work of the students in the various courses. The School of Science and Technology should prove of special interest to men engaged in technical and trade pursuits. This school provides instruction in applied mechanics and machine design, applied electricity, applied chemistry and tanning, machine work and tool-making, carpentry and building, patternmaking, plumbing, foundry and forge work and sheet metal work.

University of Wisconsin, Madison, Wis. The demand for professionally-trained mechanics to teach in industrial schools has led the regents to create fifteen industrial scholarships. Each scholarship carries with it a special honorarium of $40 and the holders are to be organized into a mechanics' institute. The purpose of the institute, which will be held on the campus of the university from March 9 to April 9, will be to give intensive practice in special lines of shop work and drawing, and to give a detailed consideration of organization and teaching problems that confront industrial schools. The need for such an institute is manifested by the fact that men enrolled in the special industrial and trade teachers' courses given in Milwaukee and in Madison by the university for mechanics interested in teaching, have in many instances been urged to accept appointments to teaching positions before completing their preparatory work.

NEW BOOKS AND PAMPHLETS

Mechanical Drawing, Part I. Third revised edition. By Oscar E. Perrigo. 44 pages, 6 by 9 inches. Published by the Industrial Press, New York City. Price, 25 cents.

Mechanical Drawing, Part II. Third edition. By Oscar E. Perrigo. 44 pages, 6 by 9 inches. Published by the Industrial Press, New York City. Price, 25 cents.

Report of the Director of the Bureau of Mines for the Fiscal Year ended June 30, 1913. 118 pages, 5¾ by 9 inches. Published by the Bureau of Mines, Washington, D. C.

Gage Making and Lapping. MACHINERY'S Reference Book No. 64. Second Revised Edition. 40 pages, 6 by 9 inches. 39 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

Tariffs on Machinery, Machine Tools and Vehicles. Published by the Bureau of Manufactures of the Department of Commerce and Labor, Washington, D. C., as No. 3 A of the Tariff Series. 34 pages, 6 by 9 inches.

Industrial Research in America. By Arthur D. Little. 23 pages, 6 by 9 inches. Reprinted by Arthur D. Little, Inc., chemists and engineers, Boston, Mass., from the "Journal of Industrial and Engineering Chemistry," October, 1913.

The Law of Patents for Designs. By William L. Symons. 300 pages, 6 by 9 inches. Published by John Byrne & Co., Washington, D. C. Price $3.

This work was prepared with particular reference to the practice obtaining in the prosecution of applications for design patents in the United States Patent Office as shown by the rules and decisions. It treats of the Design Patent Statutes; Subject Matter for Design Patent; Inventions; Novelty and Infringement; Applications and Letters Patent; and Procedure in the Patent Office.

Hydraulics. By Ernest H. Sprague. 184 pages, 4½ by 7¼ inches. 89 illustrations. Published by Scott, Greenwood & Son, London, England, and sold in the United States by D. Van Nostrand Co. New York City. Price $1.

This work was compiled chiefly from the author's lecture notes at the University Club, London. The aim has been to present the subject in a concise and useful form. Many examples illustrating the principles are given and the answers have been carefully checked. The work would appeal particularly to those studying at home were it not for the fact that the author has used the calculus quite freely. The contents by chapter heads are: Introduction and the Principles of Fluid Pressure; Liquids in Motion; Discharge through Orifices, Weirs, etc.; Flow in Pipes and Channels; Pressure of Water and Application to Motors; Pumps, Miscellaneous Examples; Useful Data; Mathematical Tables.

The Steel Foundry. By John Howe Hall. 271 pages, 6 by 9 inches. 37 illustrations. Published by the McGraw-Hill Book Co., New York City. Price, $3.

This book deals with the metallurgy of the steel foundry from the point of view of the engineer. It considers the classes of steel castings in general commercial demand and their characteristics from a manufacturing point of view. It deals with the common steel-making processes and their characteristic features, and explains the procedure in the shop, such as molding, coring, annealing, etc., in the light of its influence on quality and cost. The chapters of the book are headed as follows: General Considerations Governing the Choice of a Method of Steel Making; The Crucible Process; The

Bessemer Process; The Open-hearth Process; The Electric Furnace; Summary—Special Deoxidizers—Ladles; Molding, Pouring and Digging Out; Heat-treatment and Annealing; Finishing, Straightening and Welding; Laboratories; "Building up" Impurities in Steel.

Engineers' Costs and Economical Workshop Production. By Dempster Smith and Philip C. N. Pickworth. 248 pages, 5½ by 8½ inches. Illustrated. Published by Emmott & Co., Ltd., Manchester and London, England. Price, 4s. 6d., net.

The effort of this work is to give clearly and simply the principles of manufacturing costs with various problems and methods of solution. Particular attention has been given to methods of correct time fixing in determining the cost of machine operations. The contents by chapter heads are: Pig Irons; Wrought Irons and Steel; Copper and Copper Alloys; Specification of Materials; Wage Systems; Shop Organization and Management; Considerations Affecting Standard Times for Machine Operations; Considerations Affecting Standard Times—Machine Capabilities; Standard Times for Hand Operations; Inspection of Work and Classes of Fit; Establishment Charges; Reserve, Maintenance and Depreciation; Selling Expense; Railway Rates; Shipment of Goods; Cost Keeping; and Estimating.

Alloy Steels—Their Composition, Characteristics, Strength and Heat-treatment. By E. F. Lake. 47 pages, 6 by 9 inches. 16 illustrations. 13 tables. Published by the Industrial Press, New York City. Price, 25 cents.

This book is No. 118 of MACHINERY'S Reference Series. The important part which alloy steels play, at the present time, in the machine building and manufacturing trades will make a book descriptive of these steels especially valuable to the mechanical world. The book contains a number of comprehensive treatises on the most commonly used alloy steels, including nickel steel, nickel-chromium steel, vanadium steel, manganese steel, titanium steel, and natural alloy steel. In the case of each, their characteristics and peculiar properties are reviewed, and the uses for which they are adapted referred to. Their strength and the methods of heat-treating in order to obtain the best results from each steel are given. As there is no book on the market treating of these classes of steels in a similar manner, it will be especially welcome to all interested in this subject.

The Modern Gasoline Automobile. By Victor W. Page. 816 pages, 5¼ by 7½ inches. 575 illustrations. Published by Norman W. Henley & Son, New York City. Price, $2.50.

This is the third, or 1914, edition of this work, which treats of the design, construction and maintenance of the gasoline automobile. The major portion of the previous edition remains unchanged, but much additional matter has been included in order to keep pace with the progress of the automobile industry. Supplementary matter has been added relating to ignition and magneto-generators, as well as entirely new material on many important subjects. Mechanically interesting sections that have been augmented are those on the skew-bevel gear and two-speed, direct-drive rear axle, as well as the discussion on several new forms of worm-gear drive. It may well be said that, in general, this book presents a most comprehensive treatise on the gasoline automobile and may well be recommended both to owners and users of automobiles and to students, mechanics and repairmen. The treatment of the subject makes it also especially valuable as a reference book for draftsmen, designers and engineers.

Gear Cutting in Theory and Practice. By Joseph G. Horner. 391 pages, 5½ by 8½ inches. 367 illustrations. Published by Emmott & Co., Ltd., Manchester and London, England. Price, 7s. 6d., net.

Mr. Horner is a well-known British authority on machine shop practice and mechanical engineering work generally, of indefatigable enterprise. The number of articles and books annually produced by him is remarkable. In offering this book on gear cutting to the public, the author refers to the rapid developments of machine shop practice during the past ten years. Form planing and generating planing methods have come to be applied chiefly to bevel gears and the hobbing practice is widely used as a means of generating spur gears. The growth of automobile practice and the development of all-geared machine tools have brought the high carbon steels and the alloy steels to the front. The difficulty of cutting gears of these steels and the requirements for hardening have increased the demand for expert knowledge on the part of the modern gear maker. The work treats of: Elements of Tooth Forms; Tooth Curves; Pitches; Tooth Proportions; Gears Related to the Spurs; Bevel Gears; Method of Cutting; Form Cutters; Form Planing and Generating Methods; Machines Using Form Cutters; Form Planing; Machines that Generate by Planing Tools; Machines that Generate Bevels by Planing; Generating by Hobbing; Generating by Milling; Materials, Manufacture and Strength of Gears. The work treats modern gear making comprehensively and will be generally acceptable to the mechanical public interested in gearing.

NEW CATALOGUES AND CIRCULARS

Colburn Machine Tool Co., Franklin, Pa. Bulletin 54 on D-3 heavy-duty drill press of 24 inches swing.

E. J. Willis Co., 85 Chambers St., New York City. 1914 catalogue A, offering special cut-rate prices for automobile supplies.

Waterhouse Welding Co., Boston, Mass. Catalogue on welding and cutting plants, listing the parts that comprise the different equipments and prices of each.

Merrell Mfg. Co., Toledo, Ohio. Catalogue comprising bulletins 11 to 22 on pipe threading and cutting machinery of both hand and power types. 35 pages, 6 by 9 inches.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Leaflet giving price lists and dimensions of Hess-Bright ball-bearing ceiling hangers, floor stands, post hangers and pillow-blocks.

Cutler-Hammer Mfg. Co., Milwaukee, Wis. Pamphlet on push-button operated controllers for printers' machinery by which it is claimed a large increase of production can be obtained without increase in cost.

United States Electrical Tool Co., 6th Ave. and Mt. Hope St., Cincinnati, Ohio. Bulletin of electric polishing and buffing machines made in six sizes, ¼ to 5 horsepower, with alternating- or direct current motors.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Bulletin E-31 of Duntley electric sensitive drilling stand, and Bulletin E-32, superseding E-28, on Duntley electric tools for street and interurban railways.

Julius King Optical Co., New York City. Leaflets entitled "Don't Lose Your Eyes" and "Should Workmen be Compelled to Wear Safety Goggles," advertising the "Saniglas" shop goggles for protecting the eyesight of workmen.

National Machinery Co., Tiffin, Ohio. Circular 1010-B on National semi-automatic nut tappers built in 1- 1½- and 2-inch sizes. A special feature of this machine is the automatic raising and lowering of the spindles which eliminates the item of fatigue from treadling and allows an increased production.

Sprague Electric Works of General Electric Co., 527-531 W. 34th St., New York City. Bulletin 41010 on direct-current motors, types C and D. Folder 853 on laboratory ozone apparatus, describing ozonators, ozone mixers, air filters, etc. Folder 330 on electric fans, direct and alternating current.

Ironton Punch & Shear Co., Ironton, Ohio. Catalogue 12, descriptive of Ironton punches and shears. 48 pages, 6¼ by 9¼ inches. The line of machines illustrated and described includes vertical punches and shears, horizontal punches, universal shears, straightening rolls, bending rolls and multiple punches.

Sprague Electric Works of General Electric Co., 527-531 W. 34th St., New York City. Bulletin 242 entitled "Sprague Electric Control Systems for Newspaper and Rotary Magazine Presses." 31 pages, 8 by 10½ inches. Installations of the Sprague control system in a number of printing plants are shown.

Allen-Bradley Co., 495 Clinton St., Milwaukee, Wis. Bulletin B-531, describing Allen-Bradley Type G starting switches intended for use with small alternating-current motors that can be connected directly to the line without a starting resistance to limit the current. They are of the drum type, entirely enclosed in a dustproof case.

Charles H. Besly & Co., 120 N. Clinton St., Chicago, Ill. Card on the advantages of 15-30-C Besly grinder, showing the machine in operation. It is claimed that this machine so increased production as to save one-sixth of the pay roll in a large railroad patternshop. The card has a hole punched in the top and is intended to be hung up for reference.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletins 152, 153, 154 and 172 on "Chicago gatling" drills, the "Chicago sinker," the "Chicago stoper" and the "Chicago" plug and feather drill. The bulletins show clearly the application of these various types of pneumatic drills and their several advantages, and gives dimensions and prices for each.

Watson-Stillman Co., 192 Fulton St., New York City. Catalogue 91, descriptive of the Watson-Stillman line of hydraulic jacks. 96 pages, 6 by 9 inches. This line comprises plain hydraulic jacks, horizontal and swivel claw hydraulic jacks, pulling jacks, pit jacks, motor lifts and battery lifts. A miscellaneous section is devoted to repair parts and includes tables giving dimensions, prices, etc.

American Blower Co., Detroit, Mich. Bulletin 35, Series I, dealing with the pitot tube and fan testing. The construction, operation and application of the pitot tube are described and comparisons are drawn between "ABC" pitot tubes and other types. Tests show that very accurate results are obtained in measuring air pressures and volumes in fans by the use of "ABC" pitot tubes. The method of conducting fan tests with these tubes is also described.

Wiener Machinery Co., 50 Church St., New York City. Circular of "Hercules" bending machines for bending angles, beams, channels, rails and other shapes. The material is bent cold and perfect rings can be bent from angle iron, with legs inward or outward. These machines are especially adapted for the use of boilermakers, structural shops and manufacturers of mining equipment. Railroads and street railway companies should find the rail bending machines of interest.

Brown Instrument Co., Philadelphia, Pa. Catalogue 9 treating of the complete line of indicating and recording pyrometers made by this company. 64 pages, 8 by 10½ inches. This book is virtually a treatise on pyrometers, taking up their construction, descriptions of the various types and their installation in plants throughout the country. The catalogue is well printed and illustrated, and attractively made up. A leaflet containing 100 letters of recommendation of Brown pyrometers is also being distributed.

Russell Mfg. Co., Greenfield, Mass. Bulletin A on screw plates. 32 pages, 5 by 7½ inches. Screw plates include a set of stocks, dies and taps consisting of from one to twelve sizes or more. A new feature of the Russell plates is the double die which is made to cut from both faces. This allows the die to be reversed when worn, bringing into action a new set of cutting edges and thus materially increasing the life of the die. Attention is also called to the opening-die screw plate which greatly facilitates the work of threading bolts by hand.

Graton & Knight Mfg. Co., Norfolk & Suffolk Sts., Worcester, Mass. Catalogue No. 5 on leather belting and leather products. 114 pages, 5½ by 8½ inches. This catalogue supersedes all previous editions and contains a complete description of the various brands of leather belting manufactured by this company. There are also included many mechanical rules, tables, etc., suggestions for the proper care of belts, points on ordering belting, selecting the best belt for special conditions, and other information which should be helpful to all belting buyers or users.

Starrett Pump & Mfg. Co., Salt Lake City, Utah. Booklet entitled "A Modern Method of Pumping," describing the Starrett system of pumping by compressed air. In this pump the air is used expansively, that is, the power put into the air by compression is changed from pressure into speed by expansion in the discharge pipe. It is claimed that the Starrett pump will lift water any height with any desired pressure, which makes it particularly adapted for well pumping and mine work. Tests of these pumps conducted at the University of Utah showed a very satisfactory performance.

Wagner Electric Mfg. Co., St. Louis, Mo. Bulletin 104 entitled "A Manual of Electrical Testing." 48 pages, 8 by 10½ inches. Besides describing the line of portable instruments manufactured by this company, this publication describes various types of electrical instrument movements, the errors to which they are subject, and gives suggestions for their handling and care. The methods of making electrical tests on alternating-current and direct-current motors and generators and on transformers are described at length and illustrated by comprehensive and instructive diagrams. The publication is one that should be in the hands of everyone who has to do with electrical testing. Copies may be had upon application to the Wagner Electric Mfg. Co.

Colburn Machine Tool Co., Franklin, Pa. Catalogue on Colburn boring mills arranged in the form of a binder in which the new bulletins can be inserted as received. Bulletins thus far included are Nos. 46, 58, 60, 61, 63 and 65 which cover Colburn vertical boring and turning mills of 30 inches, 34 inches, 54 inches and 72 inches capacity. Bulletin No. 63 is devoted to special features of this line of machines, among which might be mentioned the helical gear table drive which, it is asserted, gives a smooth rolling effect that entirely eliminates vibration and chatter. The Colburn Machine Tool Co. is the first to use this type of table drive for boring mills, and considers it superior to the ordinary spur gear drive. These bulletins have the usual typographical excellence of this company's publications.

Max Ams Machine Co., Mount Vernon, N. Y. Year Book for 1914 entitled "The Seal of Safety." 206 pages, 6 by 9 inches. This is a book which should be of particular value to those engaged in the canning or food packing industry, but the information contained is of considerable general interest as well. A brief history of the canning industry from its inception is given, and it will probably be a surprise to many to know that the preserving of food began as long ago as 1795, and that packing in tin cans was done in 1810. It is even asserted that various kinds of preserved foods have come to light in the excavations of ancient ruins by archeologists. The Max Ams Machine Co. was started in 1868 as a canning and packing business, and this company made many improvements in the cans then being used. From this beginning was developed the present business of building can-making machinery, and the last section of the book shows the improved types of machines made by this company for producing the modern sanitary solderless sealed can. Articles are also included on "The Canning of Vegetables and Fruits," by Dr. A. W. Bitting, "New Method of Canning," by Dr. Koch, "Process of Salmon Canning," by the secretary of the Salmon Packers' Association, etc. Other sections of the book deal with the associations in the canning and packing industries, and legal matters of interest to canners. In the latter division is the Sherman anti-trust law, an article on U. S. patent law, by Oscar E. Perrigo and other matters of much interest. This book shows considerable care in its compilation and the result is a valuable and attractive publication.

TRADE NOTES

Detroit Steel Cooperage Co., Detroit, Mich., has been succeeded by the Detroit Steel Cooperage Works of the Pfaudler Co., Detroit, Mich.

Western Tool & Mfg. Co., Springfield, Ohio, has just completed a drop-forge plant and is now in a position to take on business in this line.

C. & C. Electric & Mfg. Co., Garwood, N. J., announces the removal of its Cleveland agent, Charles S. Powell, to new headquarters at 711 Illuminating Bldg., Cleveland, Ohio.

Norma Company of America, New York City, maker of "Norma" ball, roller, thrust and com-

JUNE, 1914

VIBRATION IN MACHINERY AND ITS ELIMINATION*

THE BENEFICIAL EFFECT OF HERRINGBONE GEARS IN RUBBER WORKING

BY WALTER J. BITTERLICH†

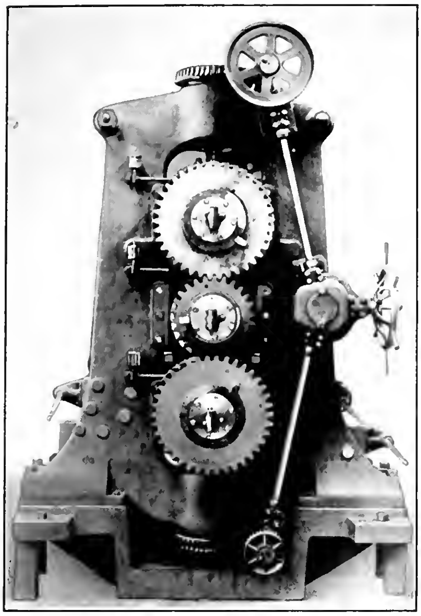

Fig. 1. Housing of Heavy-duty Calender and Roll Pressure Control

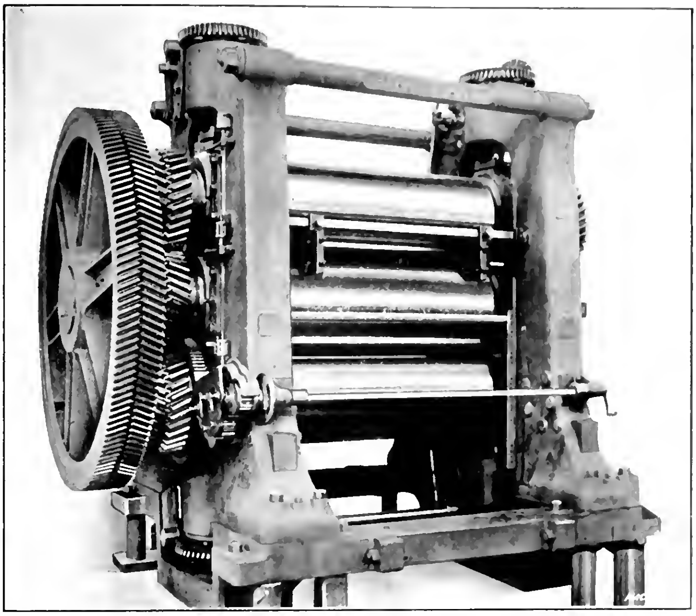

Fig. 2. Heavy-duty Three Roll Calender for Rubber Tire Work, equipped with Herringbone Gears

WERE the average person asked what feature of the mill-room in a rubber factory is the most distressing, he would undoubtedly reply "the odor." But this is not the case, as in the average rubber factory the vibration and noise are by far the most distressing features to be encountered. The sense of smell soon becomes accustomed to the disagreeable odors, while the effect of vibration and noise on the individual tends to increase rather than decrease as time passes. The noise in some departments of large rubber plants is nerve-racking, and at times one can feel the entire building tremble, even though the machinery is mounted on massive foundations, the power required to masticate the rubber being enormous. There are various sizes of calenders and mills, and the power required varies directly in proportion to the sizes of the rolls, all other conditions being equal. They are in almost all cases worked to their maximum capacity, making the noise very disagreeable.

Noise is produced by vibration, and in rubber machinery equipped with heavy spur gears it is due to the intermittent hammering action of the gear teeth. The use of pinions of rawhide or other soft material has lessened the noise considerably, but even these, when worn, produce noise. Everyone is aware of the effect of noise on operatives; it must naturally reduce their efficiency, decrease the output, and consequently increase the cost of production.

* See also "Power Transmitted by Herringbone Gears," MACHINERY, June, 1913, and "Herringbone Gears," January, 1912.

† Address: 27 Irving St., Watertown, Mass.

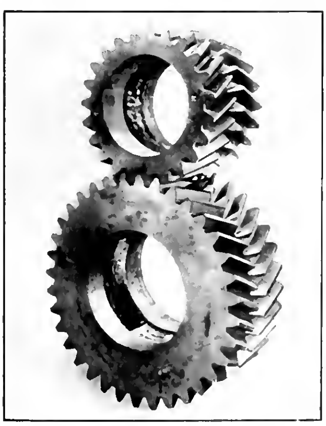

Fig. 3. Special Herringbone Gears

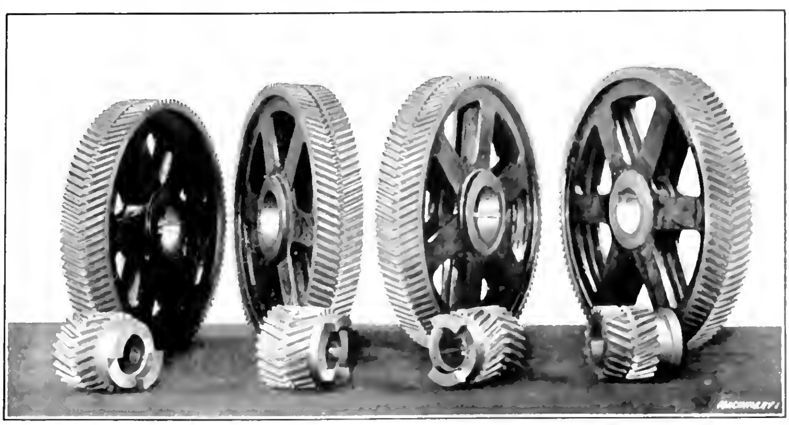

Fig. 4. Group of Wuest Herringbone Gears for Rubber Mills

Noise in buildings of slow burning construction is not so apparent as in the concrete building; this is because the wood of the former construction acts as a shock absorber, while the rigidity of the concrete building tends to enhance the noise. Since the progress of modern building is toward concrete construction, the elimination of noise should be given careful consideration.

The effect of vibration on rubber calenders and mills is detrimental to the life of the machines, as it causes rapid wear in the bearings, throwing them out of alignment and thereby increasing the frictional losses. There are also premature renewals of broken parts due to shocks, and since all the mills and calenders are equipped with steam and water pipe connections, these become leaky from the vibration. To sum up, the vibration causes increased depreciation, and adds to the maintenance and operating costs.

There is no type of chain or gear drive for transmitting heavy power that will entirely eliminate noise, although, by proper design, the noise and vibration can be minimized to a great extent. The best means for eliminating noise is by the use of properly cut herringbone gearing. Herringbone or double helical gears have been developed to such a stage in the last few years that with accurately generated teeth they cause less vibration than any other type of mechanical transmission. The principle that makes for superiority over other types is the smooth, continuous action of the teeth during engagement instead of the intermittent hammering action occurring in nearly every other type of drive. Worm-gear drives have been tried on rubber mills, but owing to their low efficiency when transmitting very high powers even when well designed, they are not a commercial success.

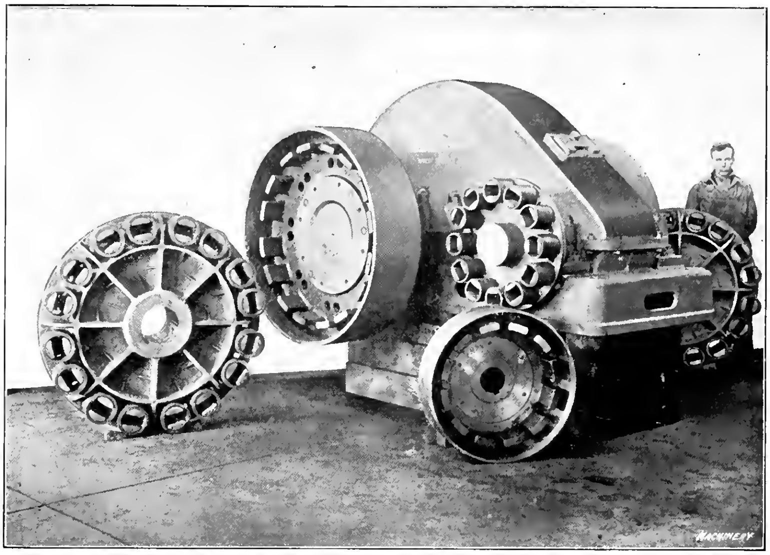

Fig. 5. Enclosed Herringbone Gears for Rubber Mill. Illustration shows also Flexible Couplings used in connection with Rubber Mills

The advantages of the herringbone gear in rubber machinery are as follows: Greater efficiency (98 and 99 per cent having been obtained in actual practice); noise reduced to a minimum; wear evenly distributed over entire tooth face, which cannot be obtained on straight spur gear teeth; reduced depreciation, maintenance and operating costs; the only positive drive possible where great speeds are used, due to its smooth action (the safe limit of spur gears and chain drives is far below the limit of speed permissible for herringbone gears); saving in power consumption; maximum output of machine because highest speed practicable can be obtained from the calenders and mills; use of higher speed motors without additional countershafts, due to the very high ratios possible in reducing with this type of gear, resulting in reduced initial cost of installation; smaller size teeth for same amount of power transmitted, because the maximum bending moment of any tooth under load is far less than that to which a spur pinion is subjected under equal conditions, owing to the fact that more teeth are in engagement in herringbone gears at the same time; and a better quality of the finished product in calendering.

It is absolutely essential that the connecting gears of the calender rolls be of the herringbone type, otherwise marks would appear on the finished product, due to backlash and vibration. These gears have until recent years been cast tooth herringbone gears, which were a development of the cast staggered tooth spur gear. The accurately generated herringbone gear is now displacing the cast tooth gear. Through the courtesy of the Falk Co. of Milwaukee, Wis., the writer is enabled to show some of the principal applications of the herringbone gear drives in the rubber industry. Many of the large rubber manufacturers of both Europe and America are now adopting this form of drive exclusively and equipping the calenders and mills throughout, from motors to the rolls, with herringbone gears. There seems little doubt but that herringbone gears, properly designed and cut, form the smoothest and most efficient drive known, and through their use and development we may hope for really silent machine drives. The field for the machined herringbone gear is great, its application being only in its infancy.

Figs. 1 and 2 show a complete herringbone equipment on a 26 by 72 inch three-roll calender. These calenders are usually driven by individual motors and the motor gear and pinion, together with the second motion pinion which meshes with the bull gear, are not shown. The effect of these gears on calenders is to entirely eliminate vibration and to enable the calenders to be run at much higher speeds and outputs than was formerly the case. With these gears it is impossible to produce flats on the calender rolls, a thing which quite frequently occurs on some classes of work where one roll has to be made of vulcanized rubber instead of cast iron.

The gears used for connecting the rolls of both calenders and mills are of special design and are illustrated in detail in Fig. 3. The teeth are longer than is usually the case for this class of gears and are generated in such a way that they are actually wider at the base than at the pitch line. This allows the rolls to be separated to any required extent up to a maximum of about 1¼ inch, while the gears work with absolute smoothness and without interference in all positions of the rolls within these limits. The peculiar shape of the teeth illustrated is of great value for resisting the heavy bending stresses imposed by carrying the drive near the tips of the teeth when the roll centers are extended.

Fig. 4 shows a group of Wuest herringbone gears that were applied to driving a number of mills on one lineshaft. The pinions are not keyed to the lineshaft, but are bushed so as to float freely thereon. The drive is taken through jaw couplings, as shown, meshing with corresponding jaws cut in the ends of the pinion hubs. The driving half of each coupling is keyed to the shaft and the drive is transmitted through the jaws, but allows the pinions a free end movement which enables each pinion to align itself correctly with the gear which it drives. This arrangement prevents binding of the pinions on one side of the teeth, which might otherwise occur through longitudinal expansion of the lineshaft.

Fig. 5 shows a completely enclosed gear unit as used for driving the main shafts of rubber mills from high-speed electric motors. The illustration also shows the Falk leather-link flexible couplings which are used for connecting these units to the motors and lineshafts. These couplings absorb all shock and give a certain degree of elasticity to the transmission which is desirable for this class of work. They also take care of slight defects in alignments of bearings.

ELECTRICAL SOLDERING

PRINCIPLES APPLIED IN OPTICAL FRAME MANUFACTURE

BY WARREN E. THOMPSON*

THE application of electricity in welding is understood by most metal workers, as it plays an important part in the manufacture of automobiles, wagon-tires, chain and other articles made of one or more different kinds of metal. There are two methods of welding in which the electric current is employed, *i. e.*, the arc and resistance methods. The arc is used to a limited extent for welding large broken parts and its application is considered more economical than any other process, but the danger of handling current at the high voltages that are necessary makes its scope limited. The other welding process, as invented and developed by Dr. Elihu Thomson, consists of causing a heavy current of electricity at a low voltage to flow through the abutting ends of the pieces of metal to be welded. This heats the metal at the joint to a welding temperature, the joint being the point of greatest electrical resistance, and by forcing the ends of the work together until the molecules of the metal, or metals, flow together, the pieces become as one. This method of welding is generally carried on without the use of any flux, the pieces having been previously cleaned of all scale, grease, or other foreign substance detrimental to the process.

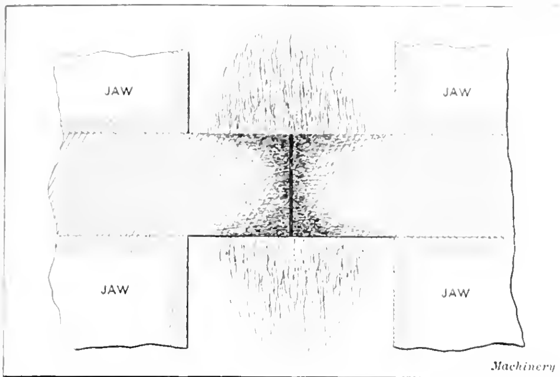

Fig. 1. Diagram showing Relative Volume of the Work that is heated by the Current

The underlying principle of this method of welding is based on the fact that any conductor of electricity offering resistance to the passage of the current will be heated if sufficient current is applied. This process is used extensively and the general advantages of cleanliness, simplicity, accuracy, economy, uniformity of product, safety to the operator, and general utility, tend to make it very popular wherever it can be applied. Exhaustive tests have proved that the electrically welded joint is from 75 to 95 per cent as strong as the original metal, and in cases where the upset or fin is not removed, the strength of the weld can be increased to above 100 per cent. It is also known that the electrical welding process is no more harmful to the homogeneity of the metal than any other heating process; probably less so, as the danger of overheating is eliminated.

What is true of welding is also true of the electrical soldering process about to be described, as in both processes the heat is developed by the same action, *i. e.*, the passage of a large current of electricity through the joint. This soldering process is a mechanical one and in operation the apparatus used is not likely to give any more trouble than any simple machine will. The wear on the clamping jaws makes it necessary to replace them periodically, but as they are comparatively inexpensive and constitute the only replacement necessary, the operating expense is very low. The amount of the current used in optical framework averages 1 K.W. hour per 1500 joints. This current can be purchased from the local lighting company or a generator can be installed which would probably reduce the current expense.

How the Process is Conducted

The general method of soldering consists of holding the pieces to be joined by clamping jaws with the ends of the work in firm contact. A heavy current of electricity, regulated to heat the joint sufficiently to melt the solder, is next passed through the work. The solder, in the form of tape or wire, is then applied to the joint. It flows in and around all parts heated to the proper temperature, as when using a gas flame, but an important difference is noted: the "life" or temper is retained in pieces that have been electrically soldered, instead of their being left in an annealed condition as when heated with a flame. One theoretical reason for this is based on the fact that alternating current electricity travels on the surface of a conductor, and so the core of the work does not heat to a temperature sufficient to become annealed. This condition is illustrated in Fig. 1. The heat varies from a maximum at the joint to the normal temperature of the machine at the jaws, and the heated section would take some such form as shown. As the length of the work that is heated is relatively short, the distance between the clamps usually being twice the diameter of the work, the heat has not had time to run into the work before the joint is made and the current shut off. This is shown by the fact that two highly tempered wires soldered together by the electrical process offer the same resistance to being bent at any other point as at the joint. The yield point or bending strength of the metal is practically as high as before heating.

Range of Electrical Soldering

Practically all the metals such as brass, copper, steel, German silver, gold, and silver can be soldered successfully in this way, and it is without doubt the most economical method for a continuous run of work. There are no noxious fumes or smoke produced in making an electrically soldered joint, and windows can be opened in warm weather without affecting the process in the least. The operator is thus able to do a full day's work each and every day, instead of experiencing the fatigue that is caused by breathing the carbonic acid gas caused by the gas flames. The joint is made almost instantly, the time required to heat the joint, apply the solder, and shut off the current being approximately from three to five seconds, depending on the cross-sectional area of the joint. As the gripping jaws of the holders are made as large as possible, the heat is drawn from the work almost the instant that the current is shut off, allowing the work to be removed immediately.

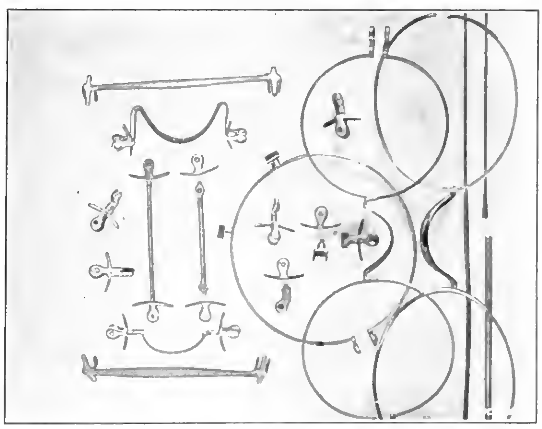

Fig. 2. Examples of Eyeglass Parts joined by Electrical Soldering

Examples of Electrically Soldered Optical Frames

A few samples of parts of eyeglass frames joined by this process are illustrated in Fig. 2. At the extreme right is shown a "cable-temple" before and after the joint is made. These

* Address: 42 Sayles St., Southbridge, Mass.

cable ends are wound in a special machine and consist of two coils, right- and left-hand, one inside the other. The inner coil is made of brass wire wound on a steel wire arbor and then swaged to a specified diameter. The outer coil is made of German silver, gold filled, or any other stock that is desired, and it is pushed over the inner coil. After the assembled cable is soldered to the "temple," which is a solid wire with the center reduced, it is swaged to the final finished diameter. This leaves a very smooth and flexible earpiece, and at the same time a stiff connection to the lensholders. The soldering of the brass-German-silver cables caused some trouble through the brass fusing before the German silver would heat enough to flow the solder, but this was stopped by using a larger wire in making the secondary coil of the transformer.

Two specimens of "nose-pieces" soldered to "eyes" are shown to the left of the cable-temples. These eyes are formed by rolling a round wire to form a groove in it; they are then wound on an arbor and sawed apart. The end-pieces are sawed, assembled and peened in one machine, and they were formerly soldered by gas. Previous to soldering the "bridges" on by electricity, a long space was annealed on the eyes. This made a joint that could be easily bent, and various methods of striking in dies were resorted to in order to get back some of the temper. In all cases of soldering by electricity, the eye wire is left with nearly all of the original temper. Another eye with studs attached is shown encircling samples of "straps," "studs" and "end pieces" before and after assembling and soldering, and to the left of this eye are shown different forms of bridges and nose-pieces with straps, before and after soldering. Such parts, that have about the same cross-sectional area at the joint, are very easily handled. Electrical soldering is very valuable for straps, as considerable strain is brought on them by the lenses when worn or handled. This tends to bend them out of shape and the value of a strap with a high temper cannot be overestimated. Straps that are soldered by this process and struck inside have nearly the spring of tempered steel. Another noticeable feature is that the solder flows freely at a lower temperature than when heated by gas, as practically no oxidation takes place at the joint.

The Utilization of High Voltage Alternating Current

In the process of electrical soldering, alternating current is invariably used, although there is no fundamental reason why direct current can not be employed. For mechanical and economical reasons, however, direct current is not to be considered. To make this clear, suppose a joint having a cross-sectional area of 0.125 square inch requires a current of 130 amperes at a pressure of 3 volts to heat it properly, and that an ordinary plating dynamo rated at these figures is used to furnish the current. It will be noticed that the work heats practically solid from jaw to jaw. Then suppose a joint having a cross-sectional area of one-half the first one, or 0.063 square inch, is to be heated by the same dynamo. A suitable resistance must be interposed in order to reduce the current to a point where the joint will heat properly without melting. This resistance will use current as though it were doing useful work and the small joint will cost practically the same as the large one, as regards the amount of power consumed. On the other hand, it is claimed that the heating action of alternating current is more uniform, as it flows more on the surface; the heat is thus more intense on the surface and is evenly conducted to the core of the pieces, offsetting the effect of radiation and conductance.

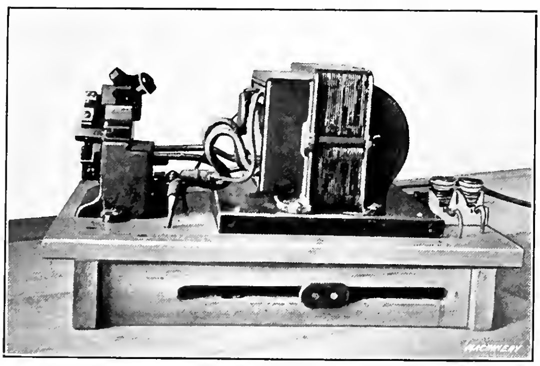

Fig. 3. Example of Unit Equipment for soldering Optical Frames

The current used for electrical soldering should be a single phase alternating current of any frequency between 40 and 60. A higher frequency could be used, but it is not good practice for various reasons. A step-down transformer of the shell-core type is preferably used to reduce the 110 or 220 volt feed pressure down to the $1\frac{1}{2}$ to 5 volts required at the machine jaws. It has been found that a pressure of from $1\frac{1}{2}$ to 5 volts is sufficient for all optical frame work, and from 75 to 500 amperes of current is consumed. The use of a large transformer for small work is wasteful, as, although the current can be regulated as desired without much loss of energy, the work heats much more slowly than when a transformer of the proper capacity is used. The machine transformer is usually connected in series with a single phase generator, but it may also be connected to one phase of a polyphase circuit or to either phase of a two phase generator.

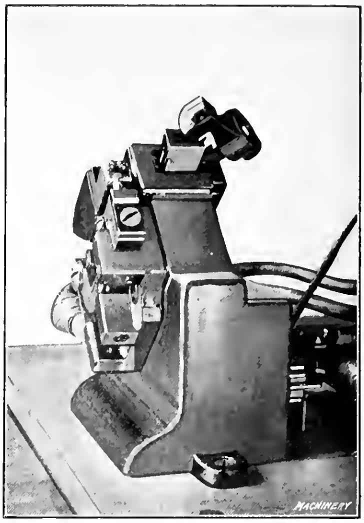

Fig. 4. Closer View of Work-holding Jaws shown in Fig. 3

The transformer is made by winding a coil of very large insulated copper wire around a core built up of iron sheets cut to shape by dies, each sheet being insulated from the others by shellac or some other medium. This coil, known as the secondary coil, is carefully insulated from the primary coil, which consists of a large number of turns of smaller wire wound around the secondary coil and its core. The number of turns of fine wire depends upon the number of turns of heavy wire and the current to be taken in and given out; also on the rules governing transformer design. The type of transformer illustrated in Fig. 3 is particularly well adapted for use in electrical soldering, as it can be used without changes with other work holders; and this would not be the case if it were built into the machine. As shown, it has the coils protected by an iron cover which not only acts as a case, but also as part of the magnetic field. Transformers of this type are very efficient—from 95 to 97 per cent of the current taken in being given out—and they are particularly suited for constant work.

Unit System of Electrical Soldering

The writer has developed a "unit system" of soldering and applied it very successfully in the manufacture of optical frames. This system consists in mounting all the working parts of the machine for each particular operation on a base-board or stand. Figs. 3 and 4 illustrate this idea; the transformer is mounted at the center, with a fuse box at the rear and the work holder at the front of the board. Under the base-board is located the adjustable rheostat operated by a sliding plate shown at the side. To set this machine up at any position in the shop, it is only necessary to run two wires from the feed circuit and attach a foot treadle to operate the clamp jaws and switch. This system allows the same transformer and other parts to be used with another machine in case of a change or the discarding of the original machine.

There are two practical methods of controlling the heat obtained at the joint; one is by introducing an adjustable rheostat into the primary circuit, as illustrated; and the other method is to introduce a reactive or "choke" coil into the same circuit. Of the two, the reactive coil is undoubtedly the better, as there is practically no loss of power and an infinite number of adjustments may be made, whereas the rheostat is limited to the number of contact points used. The difference in loss of current is an inappreciable amount more with the rheostat, but it can be made for little expense and for that reason has been used more than the choke coil. The writer uses the rheostat control on nearly all of his equipments on account of its simplicity, the ease with which it may be built and the simplicity of operation.

A machine for soldering straps to eye-pieces and bridges is shown in Fig. 5. This machine or holder consists of a base *A* with a vertical slide *B* working in a slot at the rear. A second slide *C* also works in another slot at the rear, the slot being inclined at 45 degrees to the base. This slide *C* is operated through a lever *D* which receives its movement from the slide *B*; the lever *D* is pivoted in the base. The slide *B* is provided with a spring tension which allows the lever *D* to keep a constant pressure on the slide *C* while the slide *B* continues to move. The lever *D* works in a slot cut through the slide *C*, this slide carrying a cam-operated swinging arm at its upper end to which the clamping jaws *G* are attached. This upper jaw is designed to swing away from the work and leave it clear to facilitate handling.

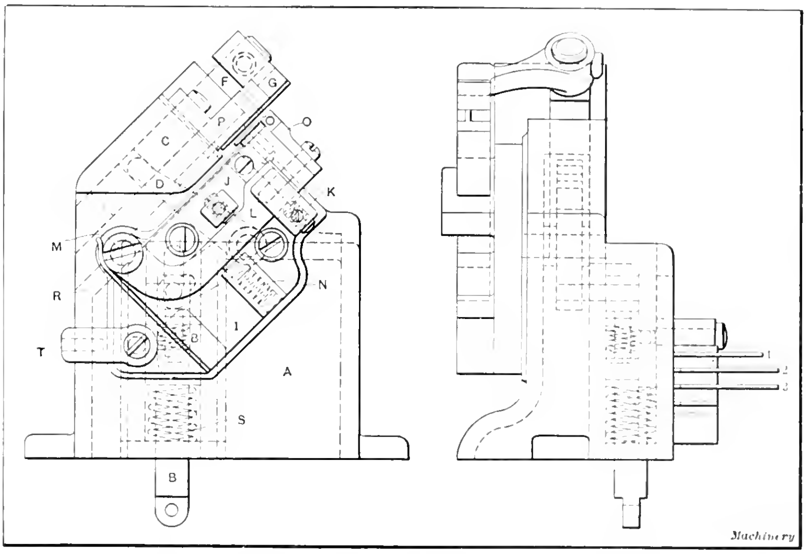

Fig. 5. Machine for soldering Straps to Eye-pieces and Bridges

At the rear of the machine and attached to the base there is a switch which is operated by a pin in the slide *B*. At the front of the base and insulated from it is the casting *I* which is milled to receive an arm *L* that is free to move on a pivot, but the motion of the arm is limited by the adjusting screws *J* and *K*. The arm is held against the screw *J* by means of an adjustable spring tension *N*. There is a jaw *O* at the upper end of the arm, which, in this case, holds the strap in the proper relation to the other part to which it is to be soldered. The contact of the jaw *O* with this strap is made by the pressure of the spring *N* against the arm *L*, and the strap is held against the part to which it is to be soldered, which is carried between the jaws *P* and *G*. The jaws are made interchangeable for different classes of work and may be easily replaced.

At the lower end of the casting *I*, one end of the secondary or low pressure circuit is connected by means of the terminal *T*, and a spring brush *R* is used to insure a low resistance contact between the casting *I* and the rocker arm *L*. The lower clamping jaw *P* is attached to the base *A* and the jaw is provided with a gage for aligning the part held in it. The slide *B* is held at the top of its movement by means of the spring *S*. Two points of the switch control the primary or high pressure circuit, and the other two points operate on the secondary which is in the circuit with the jaws of the machine. A chain connects the lower part of the slide *B* with a foot treadle which is placed under the bench in a convenient position for the operator.

The operation of this holder is as follows: Two pieces to be joined, previously covered with a non-scaling or protective mixture, have the joint end of one piece dipped into the flux. They are then assembled in the proper relation to each other in the jaws of the holder, which are so arranged that the rocking arm is away from its stop when the work is in place. The foot treadle next is depressed until the upper clamp jaw grips the work; in this case only one part is held rigid. The other piece—which is a strap—is guided by its form and a teat on the piece held in the rigid jaws. The solder, in the form of wire, is then placed on the junction and the foot lever depressed further until the current is connected. Almost instantly the solder flows and runs around the joint, when the foot treadle is released entirely, and the work, which is left free, is taken out with a pair of tweezers. On work which is very small and difficult to handle with the fingers, tweezers are used; but such work as soldering temples together, bridges to eyes, bridges to straps, or eyes to studs, is handled with the fingers. The heat is held at the joint instead of spreading as it does when heated with the flame, so it causes the operator no discomfort to take the joined pieces out as soon as the jaws are opened. The jaws are brushed clean at intervals, using a short hair stiff bristle brush for this purpose.

The idea of using a spring tension jaw was developed by the writer after having had considerable trouble caused by particles of dirt or burrs getting into the junction, also by not having the two ends fit together properly to form a contact of low resistance. When both pieces were held rigid, these particles or points would fuse and in most cases necessitated refinishing the points before a joint could be made. In some cases it was possible to release the parts, push them together with the fingers, and get the solder to take, but the method of clamping both parts rigidly always caused trouble and kept the actual production factor at a low point. By the use of the movable jaw, all of this trouble was eliminated as the constant spring pressure holds the ends in firm contact, automatically keeps the ends together in the case of burrs or other points fusing, and prevents any break in the contact while the current is being applied. In the welding process, the ends are forced together while at a welding temperature, but this changes the form of the ends and shortens the pieces; consequently it could not be applied to optical work, as there must be no change in the size or form of the pieces to be joined. The spring behind the rocking arm *L* in Fig. 5 is adjusted to provide just sufficient tension to keep a constant pressure on the junction without deforming or upsetting the ends, thus forming the joint when the ends become hot. The jaws of the holder are made as large and heavy as possible to allow of their working continuously without heating. These jaws are made of copper, which has been found best for this purpose on account of the low resistance of the contact made between them and the metal to be operated on. Copper is one of the best conductors of heat and electricity that is possible to use commercially, and for this reason will not only heat less by the passage of the current, but

will draw the heat away from the work quicker than any other metal.

Preparing the Work to Prevent Scaling

To prevent gold-filled metal from scaling or "burning" at the joint, it is customary to cover the work with some preparation to prevent oxidation. Probably the best, and at the same time the simplest, method of preparing the work is to place it in an ordinary flour sieve, cover it with commercial boracic acid, and then shake all loose powder out. This leaves the parts covered with a thin coating of dust which becomes liquid at a low red heat and prevents the air from coming into contact with the surface of the gold. Another method is to make a solution of the boracic

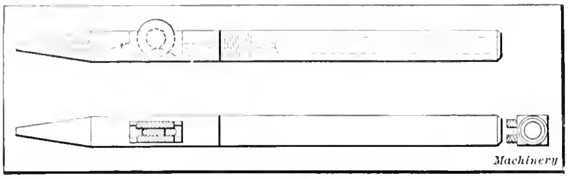

Fig. 6. Holder for applying the Solder by Hand

acid and water, dip the pieces into this solution, drain off the surplus and allow them to dry. In no case, however, should any solution be used that will leave a hard film over the parts, as this would prevent a clean contact with the clamping jaw, create a resistance that would cause an arc to develop, and spoil the surface of the work. The flux generally used is borax and it is prepared in the following manner: A piece of genuine slate, the green colored variety which is the hardest being the best, is thoroughly cleaned; a few drops of water are placed in the center and a thick, creamy mixture of borax is made by rubbing a piece of crystalline borax in the water on the slate until the desired consistency is obtained. The proper mixture is best determined by actual trial; a mixture that is too thin or too thick will either cause the solder to remain in one spot, instead of flowing through the joint, or create an unclean contact and interfere with the heating.

The solder in the form of wire may be held in the hand in a holder, as shown in Fig. 6, or some such arrangement as the one shown in Fig. 7 may be employed. This consists of a chuck at the top of a wire, bent about as shown, and having a metal ball at the lower end heavy enough to balance the wire and chuck in an upright position. This wire is held by a screw in one member of a universal joint which allows the chuck to be moved freely to any position in front of the clamping jaws and take a convenient position to allow the solder to be grasped by the operator. When a holder of this type is used, both hands are free to place and adjust the work and apply the solder quickly.

Considerable trouble, owing to the overheating of the joint, has been experienced and overcome by the rocking arm of the work holder. This heating caused the metal to become porous or "rotten" and the parts would break at either side of the joint upon the application of the slightest pressure. Some trouble was also overcome at the switch by making the contact points of pure silver. These points would fuse and weld together when copper was used, but the silver points stopped this trouble at once. Electrical soldering is a comparatively new process and has not been applied extensively as yet. It is the opinion of the writer, however, that this process is to become more popular and will be taken up by all large concerns that have a large number of interchangeable parts to braze or join.

SAM AND HIS TROUBLES

BY A. P. PRESS

I have been forty years in the shop, twenty-five of which was passed as foreman and superintendent. Now my two boys are growing up and going "through the mill" themselves, and the troubles they run up against in their everyday work are usually brought home in some form or other and put up to "dad." In thrashing out what is new to them but old to me, it struck me that perhaps I might help out some other man's kid who is trying to fight his way through the ranks to the top, but hasn't any "dad" to fall back on. Although, to tell the truth, a boy who builds his own foundations has a better rest under his feet than one whose dad stands back of him. However, I will give you a few of their troubles and remedies, and the boy who seems to need the coat can put it on if it fits.

One of the boys is foreman in a large pattern shop, and the questions that come up are very similar to those that came up to me twenty or more years ago, except they seem to be a little more acute, and you have to be a little broader minded and use a little more diplomacy and "horse sense" in handling them now. One is the labor question. This I well know is a delicate subject, and should only be spoken of in whispers, but in spite of this fact it is eternally coming up. Sam came home one day, his face as long as his arm, and said:

"Dad, it's no use. I've got to have some advice whether you've got it to give or not. We have four big patterns half finished in the shop and the boys have all been working every night until 9 o'clock, and I've heard you say many a time you can't reason with a man whose worked thirteen hours a day. Now they've all hit me up for double pay for overtime, and the job won't stand it. What shall I do?"

"Are they all union men, son?"

"No, not yet, but soon."

"Well go back, and in the morning get the boys together, and put it up to them; tell them how the case is, just where you stand on the pattern work, what you're going to get for them, what they're costing you, and how much you'll lose if you have to pay them double time; and if they stand by you and see those patterns out, you stand by them; but if they won't, why 'buck' them."

Sam went back and took my advice. He had a heart-to-heart talk with the men. There were only ten of them, and out of the ten eight were willing to help him pull them through on the time-and-a-half basis, but the other two were not that kind. Well, you know. Anyhow, no need of my telling. It ended in the boys all walking out and leaving Sam with the errand boy, a helper, one good patternmaker who "wouldn't jack up his job for anyone," also, four half finished patterns on the floor. Sam was very solemn when he came home that night. He did not say a word, and I let him alone. Sometimes contemplation is good for the soul. But the next morning he got busy, and sent out some twenty letters to all the different patternmakers whom he knew to be good men and good workers, and, to cut a long story short, five of them came on and went to work and helped him out of the hole, and the next lot of patterns was taken at a price that would take care of the overtime work.

Before starting in on the new work, however, he had another talk with the men.

"Boys, it's like this: You are demanding the utmost of me in the way of wages, now I am going to demand the utmost of you in the way of work. Seven o'clock is going to mean seven o'clock right at the bench, and overtime means that there isn't going to be fifteen minutes out for lunch and your pay going on. It's going to mean, not only double time, but that every hour means sixty minutes of work." And so far it has worked out very well.

The moral of it, as I told Sam the other night, is this: Treat the men like men, and draw them if you can, but if they won't be drawn and want to be driven, well then drive.

EXTERNAL HOLDING DEVICES FOR SECOND-OPERATION WORK*

CHUCKS, FIXTURES AND LOCATING DEVICES USED IN LATHES AND BORING MILLS

BY ALBERT A. DOWD†

IN the majority of cases, work which is to be handled in more than one setting is so treated in the first of these that an interior surface can be used from which to locate the piece in the second setting. For work of this nature some kind of internal holding device, such as an expanding arbor or locating plug with clamps, is conceded to be of the greatest utility. (See "Arbors for Second Operation Work," October, 1913.) Frequently there are instances, however, which require an entirely different method of holding, namely, by some form of contracting device such as a set of collet jaws, a step chuck, soft jaws or some other scheme of a kindred nature. Obviously, one of these devices would only be found necessary when an outside finished surface was to be used as a locating point.

There are a number of conditions which affect the design of arrangements of this sort and a number of vital points in construction which should not be overlooked. In the first place, the form of the work itself and the material from which it is made, together with the thickness of the walls used as locating surfaces, are prominent factors which have a strong influence on the method of holding. The size and weight of the casting naturally determine to a certain extent the type of machine most suited to the work. The degree of accuracy required in the finished piece is also a factor in determining the type of holding device to be used. The types of machines most frequently employed on work requiring fixtures of this kind are the horizontal screw machine or turret lathe, the vertical turret lathe, and the vertical boring mill. A few of the most important points in the design and construction of this class of fixtures are given in the following paragraphs.

* For articles on this and kindred subjects see MACHINERY, November, 1913, "Holding Devices for First-operation Work"; October, 1913, "Arbors for Second-operation Work," and "Work Holding Arbors and Methods for Turning Operations"; August, 1913, "Knock-off Arbors for Threaded Work."
† Address: 84 Washington Terrace, Bridgeport, Conn.

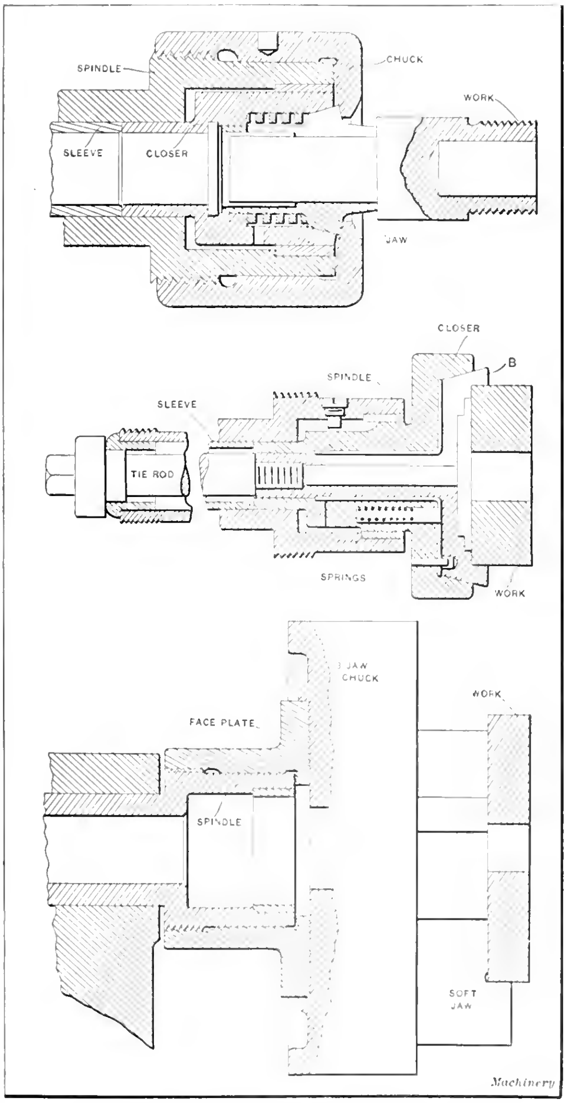

Fig. 1. Collet Chucks and Soft Jaw Chuck for External Holding of Small Work

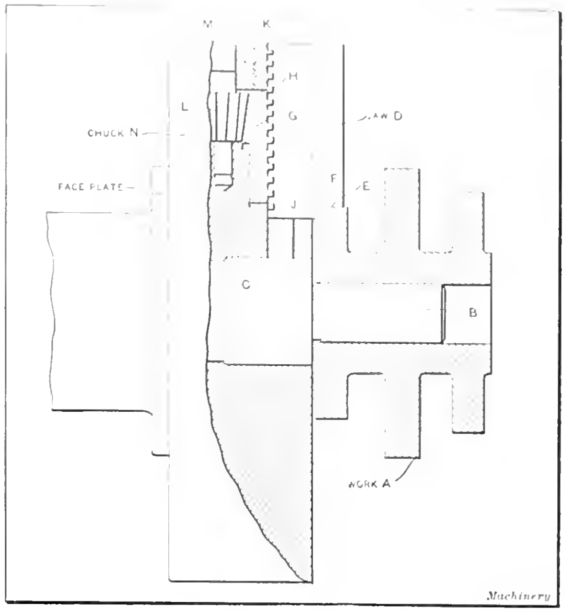

Fig. 2. Holding Device employing a Three-jaw Chuck with a Floating Scroll

Points in Design

1.—Decide on a method of holding which will not produce distortion in the finished work. Consider the thickness of the metal at the holding points, and note whether there is danger of crushing if considerable pressure is applied. Use a driver of some kind whenever possible, as this will be of great assistance in taking the thrust of the cut, and will therefore do away with the necessity for excessive pressure in holding. It may be permissible in some cases to drill a hole in the work for the express purpose of furnishing a place in which a driver can be inserted.

2.—Decide on the type of machine to be used, selecting that most suited to the work, taking into consideration the diameter and weight, and the speed at which it should be run to secure maximum production. In this connection it is well to bear in mind that the diameter to be cut determines the speed, irrespective of the outside diameter of the work itself. For example, a comparatively small hole in a hub might be machined when the outside diameter requires no machining whatever at this setting. In a case of this sort it would be advisable to select a machine capable of sufficient speed to produce maximum cutting speeds at the point where the cut is to be taken.

3.—Rapidity of operation is important; this requires accessibility of various clamps, screws, or other adjustable por-

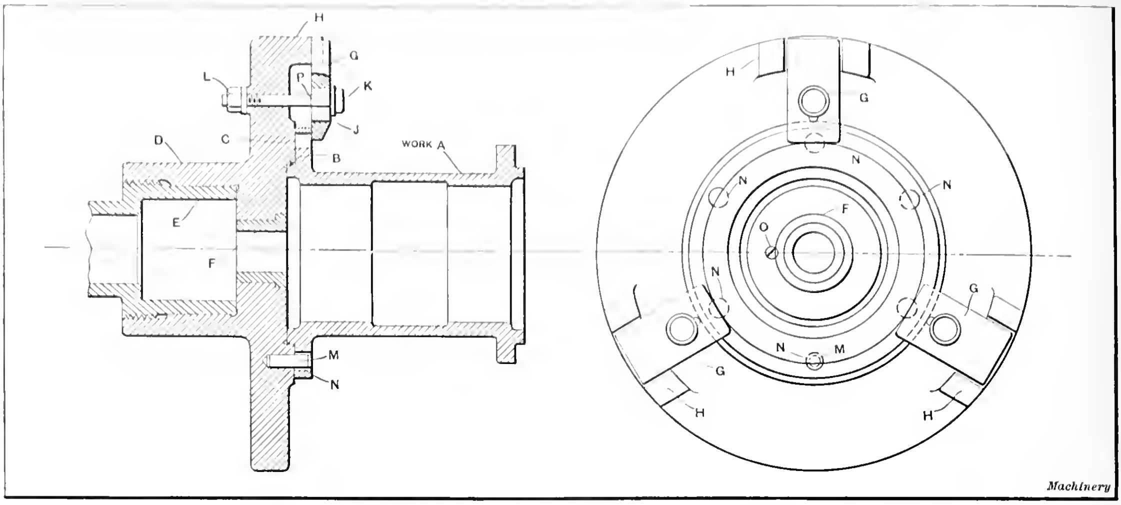

Fig. 3. A Fixture for Second Operation on a Motor Frame

tions necessary to the proper holding of the work. If a number of nuts are to be tightened, see that they are made of such a size that one wrench can be used for all of them. It is a very good idea to make nuts of the same size as some of the nuts on the machine itself, so that the regular wrench which goes with the machine can be used.

4.—Provide for positive location for the work, so that variations will not occur in shoulder distances when the piece is completed. It is well to make the locating points conveniently accessible so that they can be easily kept free from dirt and chips. Separate points, pads or studs should be used for locating, whenever possible, rather than unbroken surfaces.

5.—The accuracy required in the finished work should be carefully considered. When very close work is called for it is well to make suitable provision for wear in the moving parts and also to allow for grinding or lapping when making the fixture.

6.—Rigidity of design is important. It is well to remember that the closer the work can be held to the end of the spindle the less the overhang will be. Less overhang means less liability to chatter and also greater rigidity. Extra strength should be provided at points where there is excessive strain, and ribbing may be put in where needed. The balancing of the fixture should also be looked into, especially if it is to run at high speed.

7.—Safety of the operator should be considered and care taken in the design to provide guards over projecting lugs, set-screws, etc. Various methods will suggest themselves to the designer during the progress of the drawing, and a little thought on this point will be greatly appreciated by the operator. Projecting set-screws, exposed gears, etc., are growing more and more out of favor in machinery, and it is time that such things were done away with on fixtures also.

8.—The cost of the fixture should bear a certain relation to the number of pieces for which it is to be used; by this is not meant that it should be in a certain exact proportion to it, but that it should be taken into consideration while designing, so that the cost will not be too great as compared with the number of pieces to be machined. For example, if a fixture is to be used for only a hundred pieces, it should be designed as cheaply as possible, so that when the fixture cost is distributed among these pieces it will not increase the cost of production any more than can be helped. On the other hand, let us suppose the fixture is to be used for a lot of 10,000 pieces. It is then evident that an elaborate fixture having all possible provisions for rapid clamping, etc., would be in place, for the cost distributed among this number of pieces would be very small and the time saved would more than make up for the extra cost.

Outside Holding Devices for Small Work

There are several methods by which small work can be successfully machined when a second setting is necessary in

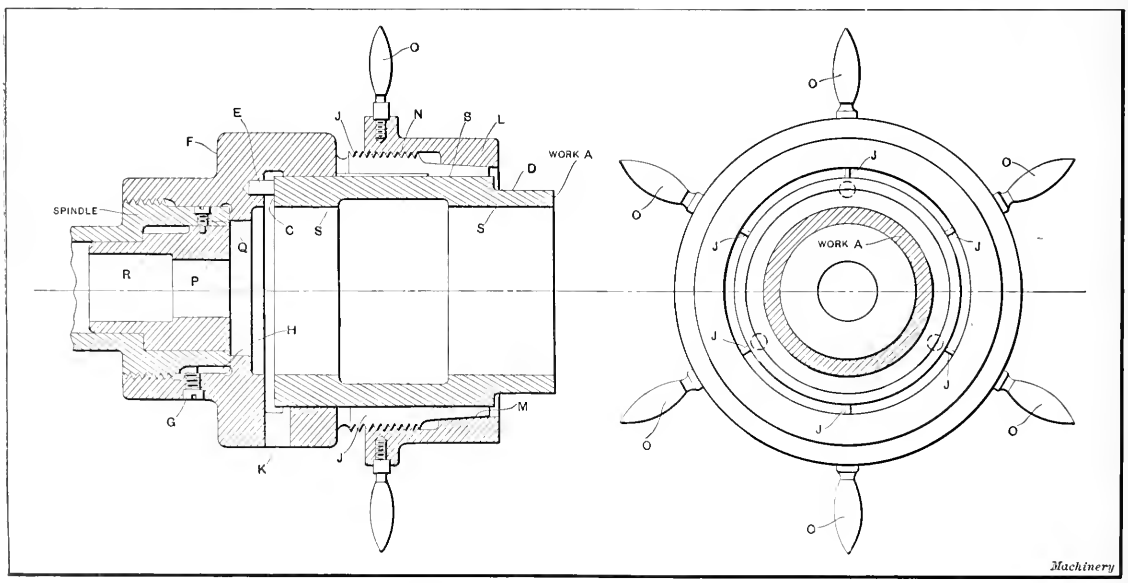

Fig. 4. Split Chuck used for a Bearing Sleeve

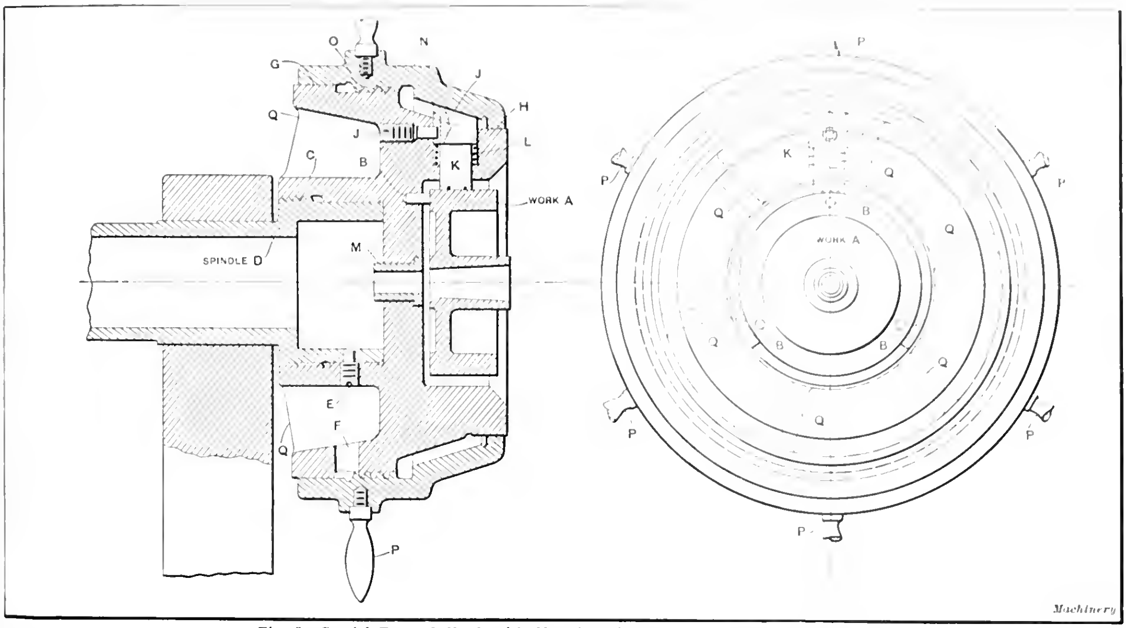

Fig. 5. Special Type of Chuck with Clamping Pins for a Small Flywheel Casting

which the work is held by the outside previously finished surface. The device most used is probably some form of collet jaws, such as is shown in the upper portion of Fig. 1. For second-operation work on bar stock, a method of this kind gives very satisfactory results and is too well known to require a detailed explanation. The collet jaws are closed in on the work either by drawing them back into a tapered body or by forcing a tapered body over them, thereby causing them to contract; the operating lever or wheel is at the rear end of the spindle. In the case shown in the illustration, the second of these methods is used. The machines supplied with this type of collet mechanism are the horizontal turret lathes made by the Pratt & Whitney Co., Hartford, Conn. A noteworthy feature of this collet chuck is the fact that the operation of the closing mechanism does not tend to move the stock lengthwise. It is therefore especially valuable for second-operation work.

Another method employing a step-chuck is shown in the second illustration of the same figure. This method is often used for second-operation work on gear blanks or pieces of a similar nature. The steel blanks *B* can be stepped out for several sizes, as indicated. The closing operation is performed by means of the collet mechanism, and it may be noted that, as in the case of the collet jaws, there is no longitudinal movement of the work. This method is less frequently used than the collet jaws, but it is very useful for many kinds of comparatively small pieces. This device is also a product of the Pratt & Whitney Co.

One other very widely used arrangement is shown in the third illustration, Fig. 1. This is a set of soft steel or cast-iron jaws which are bored out to the proper size, and then clamped onto the work by means of the regular chuck mechanism. Jaws of this kind are used for a great variety of work, both small and large. They are adapted for use in two-jaw, three-jaw, and four-jaw chucks, and are made up in a great many forms to suit peculiar conditions. In the two-jaw variety they are frequently formed to fit some odd-shaped piece. In the three-jaw type they are usually simply bored out and shouldered; the four-jaw style is not as common as the other two. In the operation of a four-jaw independent chuck with soft jaws, two of these are left set while the other two are used for clamping. One of these methods is in use in every shop or factory in the country.

Holding Device using a Three-jaw Chuck with a Floating Scroll

The work shown at *A* in Fig. 2 is an alloy steel jack-shaft gear for an automobile, part of which has been machined both inside and outside in a previous setting. As the size of the hole was too small to permit the use of an expanding arbor, the arrangement shown was decided upon. A regular three-jaw geared scroll chuck *N* of a standard make was selected

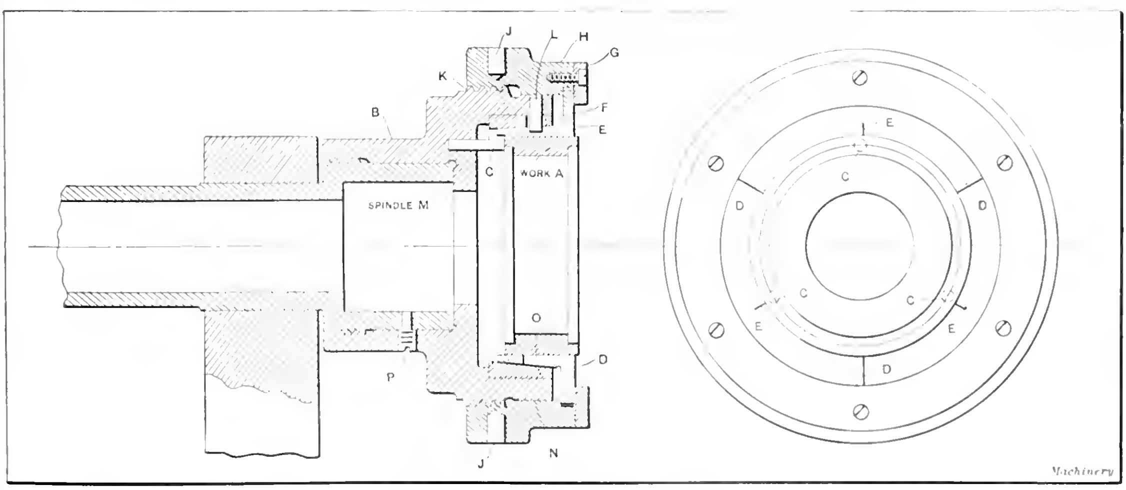

Fig. 6. Collet Chuck for a Steel Forging

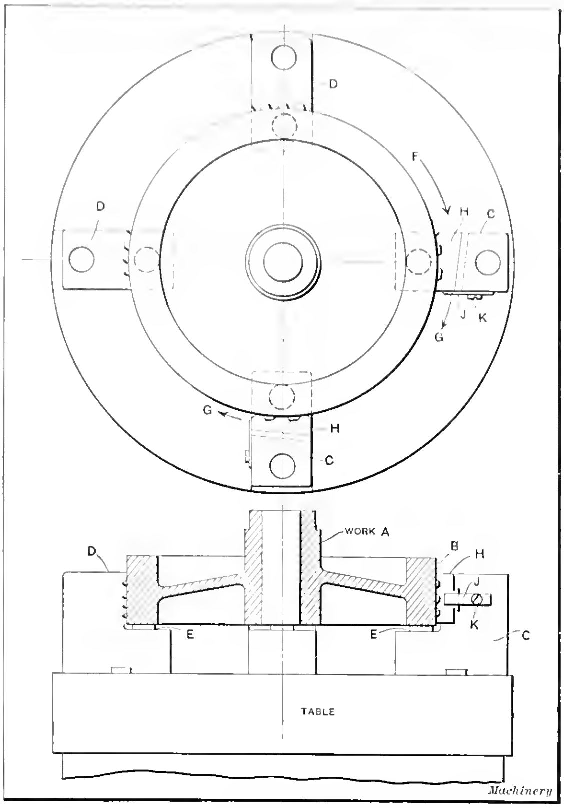

Fig. 7. Chuck for a Boring Mill having Special Secondary Jaws

for the work. The body of the chuck was bored out at *H* and *J* to a dimension 1/16 inch larger than the width of the scroll ring *G*, thereby permitting the scroll to float radially. The revolving motion of the scroll is accomplished in the usual manner by means of the pinion *L* which is squared at the end *M* to receive a socket wrench. The bushing *K* acts as a retainer. The radial movement of the jaws *D* is obviously accomplished by the revolution of the scroll ring which meshes with teeth cut on the under sides of the jaws in the regular way. The body of the chuck is bored out at *C* to fit the locating plug *B* which is ground to the size of the hole in the work. The jaws *D* are bored out at *E* to the diameter of the gear blank at this point, and they are recessed at *F* as a precaution against chips or dirt. It will be seen that while the locating is done by the plug, the jaws grip the work firmly and act as drivers without any tendency to throw any strain on the plug. The scroll, having a floating action, takes care of any inaccuracies. This arrangement is rather unusual, but its action was very satisfactory in this instance.

Locating Fixture for a Motor Frame

The work *A* in Fig. 3 is a casting of a motor frame which has been previously rough-bored and faced and shouldered on one end. This fixture was designed for finish-boring and facing the other end, and sizing the shoulder. This type of fixture is not uncommon for various kinds of work requiring a second setting. After the first setting, a drill jig is used to drill the flange holes *N*, so that a means for driving is provided. This is always an advantage, as less strain is imposed on the clamps. The body of the fixture *D* is screwed fast to the spindle *E*, and is recessed at *B* to receive the shoulder on the casting, which acts as the locating means. The body casting is also faced off at *C*, and the driving pin *M* inserted as a driver. This pin is made 1/64 inch smaller than the drilled hole to allow for slight inaccuracies in the drilling of the flange. The bushing *F* acts as a guide for the tools used. A screw *O* (shown in the end view), prevents the bushing from pulling out or turning around. The three clamps *G* are of the ordinary flat type, slotted at *J* so that they can be pulled back out of the way when placing the work in position. The bolt *K* passes through the clamp and body and is drawn up by the hexagon nut *L* on the other side, the portion *P* of the screw being squared up where it passes through the clamp to prevent its turning around when tightening. The lugs *H* are slotted so that the ends of the clamps will not tend to twist out of position. This type of fixture is quite effective, but depends for its accuracy on the fit obtained at *B*. When used for a great number of pieces it is advisable to make a hardened and ground steel ring instead of depending on the cast iron for accuracy at this point.

Split Chuck for a Bearing Sleeve

Fig. 4 shows a bearing sleeve which has been turned at *B* and *D* and faced at *C* in a previous operation. The fixture shown was made for facing the other end and boring the two surfaces *S*, but it was not entirely satisfactory, due partly to a tendency to remain closed after the clamping ring was unscrewed. A lack of spring in the chuck body was the cause of this; as it was made of machine steel, a great deal of elasticity could not be expected. Another bad feature was the position of the thread *N* which was so situated that considerable trouble was experienced in keeping it free from chips and dirt. This example is given to illustrate some of the faulty points in its construction, so that "what-not-to-do" may be clearly seen. The body of the chuck *F* was made of machine steel and was pack-hardened to obtain as much spring temper as possible. This body was screwed onto the spindle and held in place by the teat-screw *G*, which enters a slot *H* in the end of the spindle. Three pins *E* act as longitudinal stops for the work.

The inside of the chuck body is bored out to fit the work. It is threaded on the outside at *N* and tapered at *M*. Six saw cuts *J* are equally spaced around the periphery to allow for expansion and contraction. An operating collar *L* is threaded and tapered to fit the body, and six handles *O* screwed into place for operating purposes. These handles were afterward

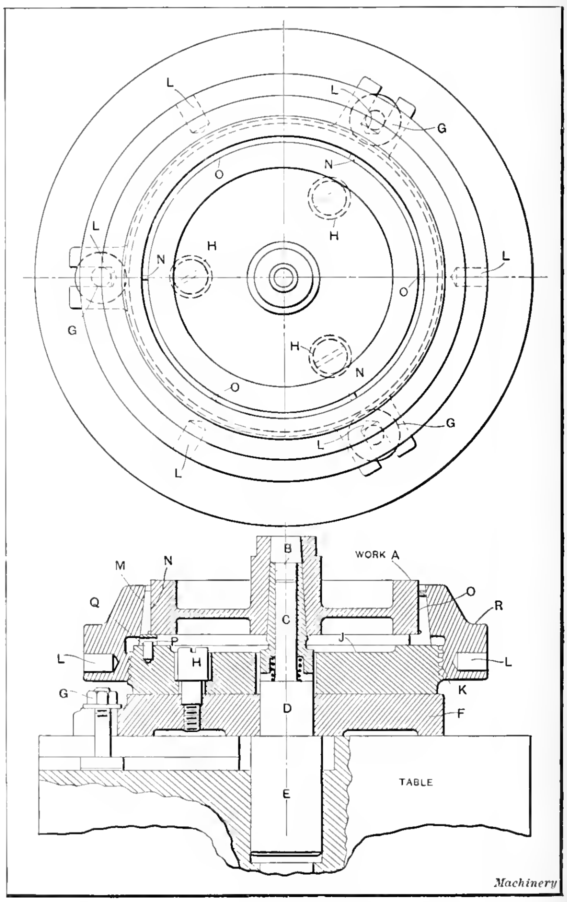

Fig. 8. Collet Chuck for Boring Mill having a Floating Action

removed by the operator (as a precaution against being injured by them) and a piece of drill rod used in the holes in place of the handles. A tool steel bushing was fitted to the spindle and held in place by screw *Q*. This bushing was relieved at *R* and ground to a running fit for the boring-bar pilots at *P*. Three holes *K* were drilled in the body so that accumulated chips and dirt could be readily brushed out. This entire chuck exhibits a lack of forethought in its design and forms an example of a poorly constructed device. As it was designed by the writer, he has no hesitation in condemning it rather forcibly, but would add that it was made a number of years ago. The recognition of its shortcomings has been of great assistance in subsequent designs.

Contracting Pin Chuck for a Small Flywheel Casting

A somewhat expensive device is shown in Fig. 5 for handling the small casting *A* on a horizontal turret lathe. It will be noted that the arrangement of the chuck is such that the weight is kept well back near the spindle bearing, so that excessive overhang is avoided. The body *C* is made of cast iron and is screwed onto the spindle *D*, where it is secured by the teat-screw *E*, access to which is obtained through the hole *F*. Three pins *B* serve as longitudinal stops for the work, and these are so placed that they can be very easily kept free from dirt and chips. The three jaws *K* are cylindrical, and are forced outward by the coil springs *L*. The teat-screws *J* enter slots in the jaws and prevent them from turning. The jaws are hardened, ground and lapped cylindrically, after which they are assembled in the chuck body and ground on the taper and also at their bearing points on the work. The operating collar *N* is a steel casting which is ground to a nice running fit at *H* and *G*, and threaded with a coarse pitch Acme thread (double) at *O*. It is ground to a taper at *J* corresponding to the taper on the ends of the jaws. It is well to note that the construction and accuracy of the chuck would have been materially improved by making a tool steel taper ring and inserting it at this point in order to minimize the wear and provide for means of adjustment. The handles *P* are a rather dangerous feature, but they permitted the operator to use both hands in tightening the jaws; this was

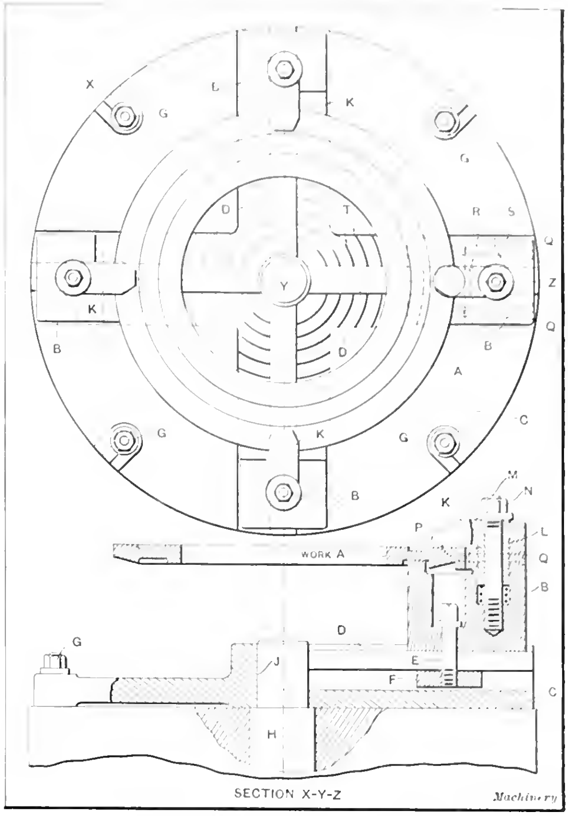

Fig. 10. Special Fixture for holding a Number of Different Sizes of Bevel Gear Blanks on the Boring Mill

of considerable advantage, as the power required took about all the strength he had. A more acute angle on the pins in their relation to the collar would have been of some assistance, but the thread diameter and frictional surfaces were large, so that ease of operation could not be readily attained. The bushing *M* acted as a guide for the tools used in generating the tapered hole. It should be noted that the threaded portion is made somewhat free and the fitting done at *H* and *G*. These closely fitting surfaces are also of assistance in keeping chips and dirt out of the mechanism.

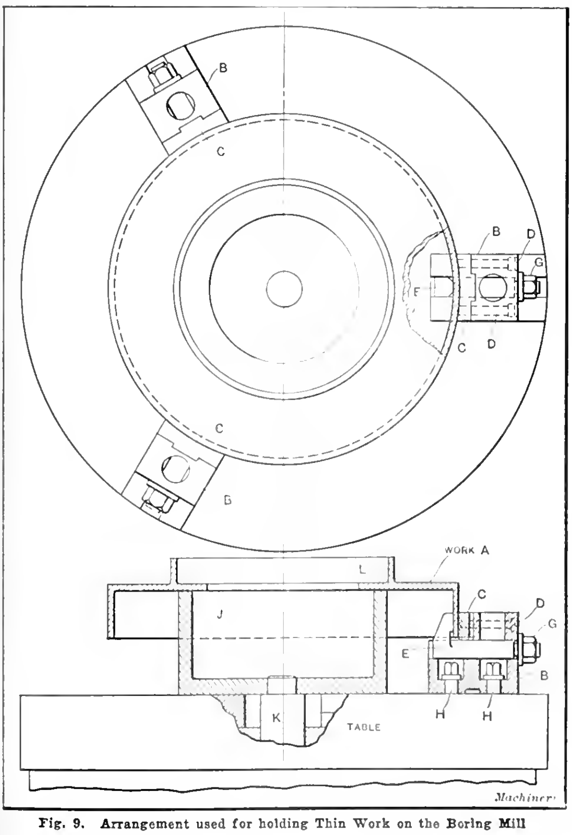

Fig. 9. Arrangement used for holding Thin Work on the Boring Mill

Spring Collet Chuck for a Steel Forging

The work shown at *A* in Fig. 6 is a steel forged collar which has been previously turned and faced on one end. The body of the chuck *B* is screwed onto the spindle *M* and is prevented from turning by the teat-screw *P*. A hardened and ground steel ring *O* is forced into the body of the chuck, and is tapered to coincide with the outside of the spring collar *F*, which is prevented from turning by the pins *L* that act as drivers in the elongated slots shown. Six slots are cut alternately at *D* and *E* to permit uniform contraction and expansion. It will be noted that the first-mentioned of these slots pass through the flange and part of the collar to a point close to the end, while the alternate slots are cut from the rear end toward the front but do not pass through the flange. In passing, attention is called to the fact that a slight tie is left at both ends of all the slots, this tie being cut out, at the end intended to be cut through, with a thin wheel after the grinding operation. If this were not done great difficulty would be experienced in grinding. The operating collar *H* is made of cast iron and is threaded at *K* with an Acme thread, 4 per inch. A recess is cut at the forward end to receive the flange of the spring collet. The cover plate *G*, made of steel, is screwed fast to the end of the operating collar. Six holes are provided around the periphery so that a piece of drill rod can be used to revolve the collar, thus forcing the collet in or out and causing it to contract or expand. The cylindrical bearing at *N* insures accuracy. Three stop-pins *C* are used to locate the work in the chuck longitudinally. One

of the disadvantages of this kind of a chuck is the difficulty of keeping it clean and free from chips. It must be taken apart occasionally and washed in gasoline and brushed out, after which it can be re-assembled and oiled on the wearing surfaces. A few moments time is all that is necessary, however.

Vertical Turret Lathe and Boring Mill Fixtures

As the class of work which is usually handled on machines of this type is of a heavier variety, it naturally follows that the fixtures required are much more massive, and also that they must possess ample driving means, on account of the heavier cuts taken. As the fixtures lie flat on the table of the machine, the weight is of no particular importance, but rigidity and proper protection against chips must be carefully considered in the design. In addition to this it is well to remember that outlets for chips are also of importance, so that the latter can be brushed out. If some provision is not made for this, it will be necessary for the operator to scoop out the chips from time to time, and this is an unnecessary waste of time. Outlets can nearly always be provided so that the matter will not be troublesome.

Special Jaws for a Large Motor Gear

The work *A* shown in Fig. 7 is a steel forging for an electric motor gear. Both the first and second settings of the pieces were accomplished on a vertical turret lathe; the operations were roughing cuts to within approximately 1/8 inch of the finished sizes. The blanks weighed something over 350 pounds and were rough-finished all over in these two settings, about eighty pounds of metal being removed. The blanks were composed of alloy steel containing a high proportion of carbon and manganese, thus making them very tough. The speeds used were about twenty to twenty-five feet per minute, and the feed from 1/16 to 1/8 inch per revolution. It will be seen from this that chuck jaws of the regular type would be put to their utmost capacity to hold the work without chance of slipping. A few of the blanks were machined in the regular type of jaw and there was more or less slippage of the work when the heavier cuts were being taken.

The method shown was suggested by the writer, but was not used on account of the few pieces to be handled at the time. The idea, however, is of some value. The two jaws *D* are of the regular type and are left set to form a sort of V-block arrangement for locating the work. The other two jaws *C* are of special design and are operated independently. Each of these jaws is fitted with a sub-jaw *H* sliding in a dovetail slot in the main jaw. This slot is cut at an angle of 15 degrees from the tangent to the work, and the jaw is kept in its normal position by means of the flat spring *J* which bears against it. The screw *K* holds the spring in place. The jaws are all provided with raised buttons on which the work rests. It may be readily seen that the pressure of the cutting tools would tend to move the piece in the direction indicated by the arrow at *F*, in case any slippage were to occur. Assume, then, that this takes place during the progress of the work; a wedging action would immediately begin at the points where these special jaws are, and this would prevent further slipping.

Large Spring Collet Chuck having a Floating Action

The flywheel casting shown at *A* in Fig. 8 represents a rather unusual condition, for the shoulder on the upper part of the hub is to be machined concentric with the tapered hole which has been machined in a previous setting. The rim, web and body of the hub are also to be machined in the second setting. A tool-steel, hardened and ground plug *E* fits the hole in the table and is a forced fit in the base *F* at *D*. The upper part of the stud is turned down at *C* to receive the sliding taper bushing *B* which is of the same taper on the outside as the hole in the hub. A coil spring supports the bushing and keeps it snugly in place in the hub. It will be noted that slight variations in the hole do not affect the locating, as the sliding movement of the taper bushing equalizes them. The base *F* is of cast iron and is fastened down by the three bolts *G* in the table T-slots. The upper portion *J* of the base is made of steel and is held down by the three special screws *H* which are fitted with clearance enough to permit a slight radial movement or "float" to the plate, and at the same time act as drivers. Acme threads, 4 per inch, are cut on base *J* to engage the operating collar *R*. A thin steel taper ring is slotted in six places *N* and *O* in the same manner as that shown in Fig. 6, and driving pins *Q* are provided which engage the slots *P* in the ring. The operating ring *R* is of cast iron, tapered at *M* to fit the spring ring. It is revolved by a drill rod handle set into any of the holes *L* in the periphery. In using the device, the work is dropped down on the spring tapered plug, which automatically adjusts itself to the hole and allows the rim of the flywheel to rest on the flange of the spring ring. It is then only necessary to revolve the operating ring, which clamps the work securely, the floating action taking care of slight inaccuracies.

Arrangement for Holding a Piece of Thin Work

The thin steel casting shown at *A* in Fig. 9 was held in the first setting by the thin flange *L* in a set of hook-bolt jaws. (See MACHINERY, July, 1913.) During this setting the large diameter was machined both outside and inside, the inside of the web faced, and the hole through the web bored. In the second setting a cast-iron pot *J* is located on the table by means of the centering plug *K* which fits the center hole. This pot is used as a support for the work while facing and turning, and also locates the piece vertically. A set of jaws *B* is provided with hook-bolts *E* which are drawn up against the work on the inside by the nuts *G*. The soft steel sub-jaws are inserted in place and fastened by the screws *D*. These soft jaws are bored out to the correct size to fit the finished work and are brought up lightly against the casting before the hook-bolts are tightened. The screws *H* enter shoes which fit the T-slots in the table jaws. It will be noted that the soft jaws can be easily replaced, thus making the life of the main jaws almost unlimited.

Special Fixture for Holding Several Sizes of Bevel Gear Blanks

The work *A* in Fig. 10 is one of ten blanks, ranging in size from 12 to 20 inches in diameter, and the fixture shown was made to handle all these sizes, by the simple expedient of moving the main jaws to an approximately correct position and inserting a set of soft jaws which are then bored to the exact size of the outside of the ring. The body *C* of the fixture is located centrally on the table by the plug *H* which fits the fixture at *J*. The four bolts *G* hold the casting down on the table. Four T-slots are cut at *D* and the main jaws are clamped in their proper positions by bolts *E* which enter the shoes *F* in these slots. Approximate locations are determined for the jaws by the radial lines *T* scored on the finished pads. Both the main and sub jaws are of machine steel, the former pack-hardened and the latter left soft. The main jaws *B* are tongued on their lower sides to fit the slots. The soft jaws *P* are made up in a long strip and then sawed up into separate pieces. They are tongued at *R* to fit the main jaws and jig-drilled for the screws *Q* which hold them in place. The hook-bolts *K* are of tool steel, hardened and drawn to a blue on the hook end, to lessen the chance for breakage. The body *L* fits the hole in the jaw and the coil spring supports it. The stud *M* is screwed tightly into the jaw and is threaded at its upper end to receive nut *N*, which operates the hook-bolt. Attention is called to the manner in which the hook-bolts are backed up by the jaw, thus greatly stiffening the clamping arrangement. The backing is partially cut away at *S* to allow the hook-bolt to swing clear of the work. This fixture was made within the past year and gave excellent results at the time of testing.

* * *

Some tests have recently been carried out at the works of Alfred Herbert, Ltd., of Coventry, England, to ascertain the comparative efficiency of ordinary and ball bearings for line-shafts. The tests showed that 5½ horsepower was required to turn over 62 feet length of 2½-inch shafting, running without belts in seven adjustable self-oiling bearings, with two ring-oilers to each bearing. In the new factory of the company, where ball bearings are fitted to all the shafts, only 2½ horsepower was required to turn a shaft of the same length. On this shaft there were seven ball bearings placed at 10-foot intervals.

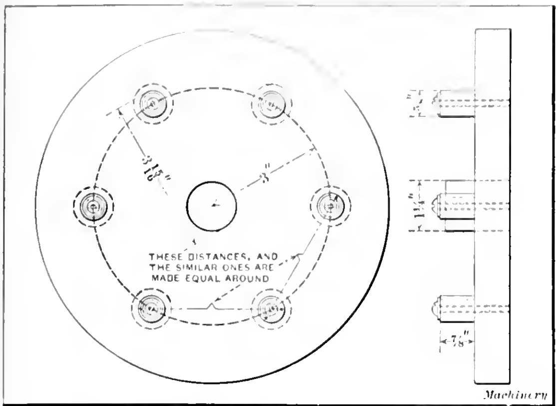

Fig. 1. Flange Templet showing Arrangement of Buttons

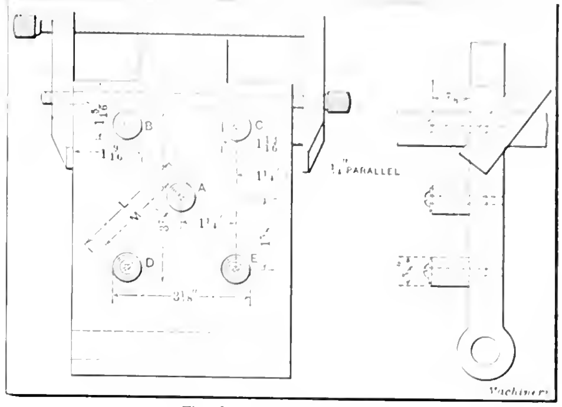

Fig. 2. Hinge Jig Templet

LOCATING HOLES IN TEMPLET PLATES BY THE BUTTON METHOD*

BY D. DALTON†

The use of buttons for locating holes in templet plates, or bushings in drill jigs, is a very accurate method even when only a fair degree of care is taken in locating the buttons; and when considerable care is taken, it is the most accurate method and, sometimes, the only one which can be employed. The increasing use of multiple spindle drills in the machine shop calls more and more for the application of this method when locating the holes for the drill bushings.

The Buttons

The buttons are shown in the side view in Figs. 1 and 2. A convenient size is from 1/2 to 5/8 inch outside diameter, and from 3/8 to 1/2 inch inside diameter. If a No. 10, 24 threads per inch screw is used this will allow plenty of adjustment. The length should be from 3/4 to 7/8 inch; it is well to have the buttons a good length, so that the indicator can be used conveniently.

The buttons should be made of tool steel and hardened. They should be ground on the outside, and both ends should also be ground off square. Care must be taken to see that they are ground to *exact* size. A 1/2-inch button must be 0.500 inch and not 0.499 or 0.501 inch, for these little errors cause considerable inaccuracy in the work. A set of buttons should be part of a toolmaker's kit.

Method of Using Buttons

Fig. 1 shows a templet plate which formed part of a fixture for drilling holes in flange plates. It was necessary to space the six holes equidistantly, so that the holes in the flanges would match up in any position and thus make the flanges interchangeable. First a plug was turned so that it fitted snugly in the 1 1/4-inch hole in the center of the plate, and projected above the top about 3/4 inch. A center was located in this plug, and from this center a circle of 3 inches radius was drawn; around the circumference six divisions were laid off. Small 1-inch diameter circles were then drawn at each of these points to indicate the outside circumferences of the bushings to be placed in the holes. These circles act as a guide when placing the buttons in position; they can be located much more quickly in this way.

The centers of the holes were next carefully prick-punched, and holes drilled and tapped for No. 10, 24 threads per inch machine screws. It is well to do this work carefully, so that the tapped holes are as near as possible in the exact center, as this will facilitate the starting of the boring of the holes for the bushings. Having now the six tapped holes around the circle, place a button at each point with a small washer on top, and fasten it approximately in the correct position; then tighten the screw sufficiently to hold the button firmly, but so as to allow it, at the same time, to be moved by tapping lightly. The radius of the circle being 3 inches, that of the plug 5/8 inch, and that of each button 5/16 inch, we find that the distance from the outside of the center plug to the outside of any button must be 3 15/16 inches. Also, since there are six buttons around the circle, the distance from center to center is equal to the radius, and the distance between the outside of any two buttons will be 3 5/8 inches.

We now have the distance each button should be from the center, and also the distance they should be apart. Then, by the use of micrometers, and by tapping the buttons gently all these distances can be correctly fixed. As each button is brought near to its correct position, it should be tightened down a little, so that it will finally be snugly located.

The work is next strapped on the faceplate of the lathe, and one of the buttons made to run true; this should be done accurately by means of an indicator. When the button is made to run true, the No. 10 machine screw may be loosened and the button removed. It will be found that in nearly all cases the small tapped hole will not be running true, and if a drill is used right away it will probably break off. A lathe tool can be used to cut away the front of the hole and so give a true start to the drill. This process is repeated for each button, and if care is exercised, the holes will be accurately located.

Fig. 2 shows a method of locating a button from the side of a plate. It will readily be seen from the illustration that the buttons *B*, *C*, *D* and *E* could not have been located with certainty from the center alone, for while they could have

* The following articles on this and kindred subjects have previously been published in MACHINERY: "Three-disk Method of Locating Holes," July, 1913; "Method of Accurately Locating Drilled Holes," May, 1913; "A New System for Locating Holes to be Bored on the Milling Machine," April, 1912; "Drill Jigs," January, 1907; "Drilling Jig Plates," October, 1902. See also MACHINERY'S Reference Book No. 3, "Drill Jigs."

† Address: 112 Cook St., Ithaca, N. Y.

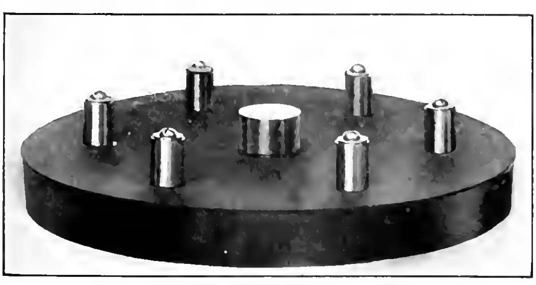

Fig. 3. Flange Templet shown in Fig. 1

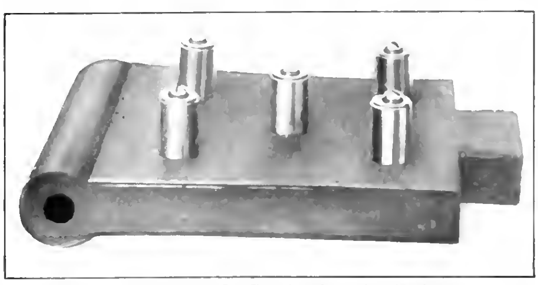

Fig. 4 Hinge Jig Templet shown in Fig. 2

been located the correct distance from the center, they probably would not have had their correct position with respect to the fixture as a whole. It was necessary, therefore, to work from the side and the center.

The width of the plate was carefully measured and found to be 5 inches; then, since the center to center distance of B and C was $2\frac{1}{2}$ inches, that left $1\frac{1}{4}$ inch from the center of B, C, D and E to the outside of the plate. A $\frac{1}{4}$-inch parallel was clamped against the side as shown in the illustration, and then the distance from the outside of each button to the outside of the parallel, 1 13/16 inch, was used in conjunction with the distance L. Distance L was obtained by first solving for M by the use of the right-angle triangle, as follows:

$M^2 = 1.25^2 + 1.625^2$ or

$M = \sqrt{1.25^2 + 1.625^2} = \sqrt{4.024}$.

Therefore, M = 2.050 inches, and L = 2.050 + 0.625 = 2.675 inches.

In this case the center button was first located correctly from the sides and end, screwed down tightly, and not moved while the other buttons were being located.

* * *

Steel passenger cars are built with double walls and insulation between. The insulation deadens the sound and acts as a non-conductor of heat, thus making the cars warmer in winter and cooler in summer than they would be without it. The application of the insulating material was formerly accomplished by attaching it to galvanized sheet steel strips with nails clinched. The strips were attached to the framing by stove bolts. The drilling of holes and placing of the bolts and strips was a slow, tedious and costly job. The method has been displaced by a much simpler, cheaper and neater one that depends on the electric welding process. The car is placed in a circuit of 220 volts, the circuit being completed when the workman applies the head of a special nail to the steel side of the car. The nail is held in a pair of pliers provided with insulated handles and connected to the electric cable. The speed with which the nails can be welded to the car is very great and the cost of fixing the insulation in this way is reduced to about ten per cent of the old method. The insulation is applied by pressing it against the nails which penetrate it, and they are then clinched to hold it in place.

HARDENING BOLTS BY THE TON

The best grade of carriage and machine bolts is made from a low carbon steel about 0.15 per cent carbon, low in sulphur and phosphorus. This steel, while it will not harden by heating and dipping in water, is made much tougher and its elastic limit considerably increased by the proper heat-treatment. In order to secure a uniform heat-treatment and to turn out large quantities of machine and carriage bolts, the National Screw & Tack Co., Cleveland, Ohio, has installed a very interesting hardening equipment that is used for this purpose. Fig. 1 shows two of the furnaces used and gives a general idea of the method of handling the bolts when hardening, dipping and washing. The bolts, before being conveyed to the heat-treatment department, are sorted and all those of similar sizes and styles are placed in boxes, each box holding about 75 pounds. They are then conveyed to the heat-treatment department, piled up beside the entrance to the furnace, as illustrated in Fig. 2, and gradually fed through the furnace, which is of the drum type and kept in continuous rotation. The inside of this tubular furnace, which is from 10 to 12 feet long by $3\frac{1}{2}$ to 4 feet in diameter, is lined with firebrick arranged in such a manner that a conveyor screw is formed by the convolutions of the firebrick. This drum is rotated by two friction rolls on one side, and rests on two rolls on the other side. The two friction rolls on the right-hand side of the furnace are driven by a shaft which, in turn, is driven through gearing from the overhead works. The drum is rotated at a speed of one revolution in fifty seconds.

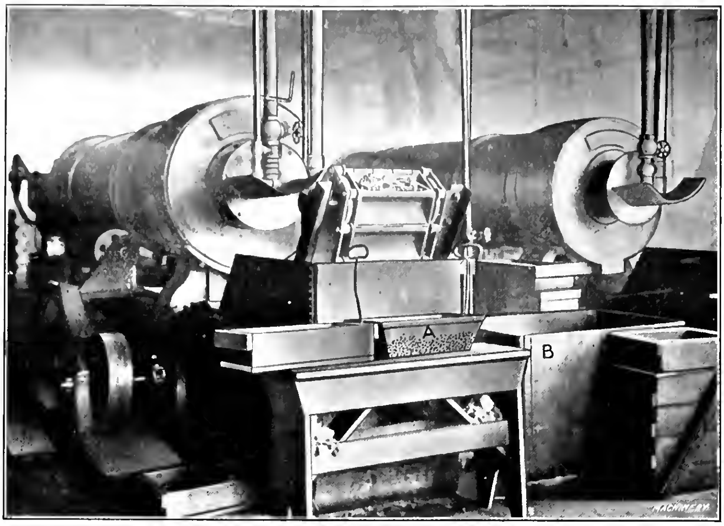

Fig. 1. Two Rotary Hardening Furnaces for heat-treating Carriage and Stove Bolts

Fig. 2. The Feeding End of the Rotary Furnace, showing Conveyor Method of carrying Bolts from Boxes to Screw in Furnace Drum

The inside of the furnace is kept at a uniform temperature of about 1400 degrees F., by a burner which burns natural gas. The bolts are started through the furnace in the manner shown in the illustration Fig. 2. The operator dumps the bolts into the hopper A, through which a conveyor B is continually passing that is rotated through belting and gearing from the overhead works. This conveyor passes down the other side and deposits the bolts in a chute, through which they pass into the screw or conveyor in the furnace.

This screw gradually carries them toward the other end and in passing they are heated to a temperature of about 1400 degrees F. It requires eight minutes for them to pass through the inside of the furnace. The smaller the bolts, the greater the number that can pass through at one time. On carriage bolts, ⅜ inch diameter by 3 inches long, about 1180 pounds are hardened per hour. The furnace, of course, is kept working continually for twenty-four hours per day, as it would require a considerable time to get it up to the proper temperature after it had once cooled down.

As the bolts gradually work to the emptying end of the furnace, they drop out into a bath of water which is heated to a temperature of almost 212 degrees F., that is, it is kept boiling. This cools the bolts off slowly, does not harden them,

Fig. 3. Conveyor used in taking Boxes from Hardening Room to Packing and Shipping Departments

but just toughens them. The conveyor works through this bath, carries the bolts up again as illustrated in Fig. 1, and deposits them in a steel pan *A*. When this is almost filled, the operator removes it and drops it in the bath *B*, which is composed of soda and oil mixed with water. The bath is also steam heated and is used to give a good finish to the bolts after hardening; that is, it brightens the bolts and gives them a dark glossy coating. This soda and oil bath also makes the bolts rust-proof and gives them a very good looking finish.

After the bolts have been dipped in the bath as previously mentioned, the steel pan is removed, the bolts deposited from it into a wooden box and the box then placed on the esculator shown in Fig. 3. This, as can be seen, is arranged to take a box of the desired width, which it carries up to the next floor, and as each box passes the point *A* it operates the counter so that every box passing from the hardening department to the packing department is kept track of. This method of handling bolts reduces the manufacturing cost to a minimum, and what is more, a uniform heating and hardening effect is secured at almost no cost. On a bolt that is ⅜ inch in diameter by 3 inches long, a production of 28,320 pounds, or almost 13 tons, is secured in twenty-four hours. D. T. H.

* * *

Trials have been made in Germany to ascertain the possibility of using the oxy-acetylene torch for removing the scale in boilers. These are reported to have been successful. The deposit is immediately removed without injury to the plate.

MANGANESE STEEL CASTINGS

Considerable secrecy has surrounded the making of manganese steel castings. Only a few concerns have been engaged in this industry and they have guarded the methods used with great care. In an article in the April number of *Foundry*, F. R. Zerhansen gives some information relating to the composition of manganese steel and the methods used in its production.

In making manganese steel castings, the metal is refined in a bessemer converter from which it is poured into a ladle in which the proper quantity of ferro-manganese has been previously placed. Either a standard bessemer or a tropenas or other modified type of converter may be used. The molding equipment is similar to that necessary for the production of unalloyed converter steel castings, and similar raw materials, including low phosphorus pig iron and selected steel scrap, are used. From a metallurgical standpoint there is nothing to prevent the successful production of manganese steel in open-hearth furnaces, and it is possible that there may be some developments in the future along this line, although at present the converter process is strictly adhered to.

The alloying material added is commercial, 80 per cent ferro-manganese, which is melted in crucibles in oil-burning furnaces. The quantity of manganese required varies somewhat with the nature of the castings, but 12.5 per cent is a good average figure. To produce castings that will show this amount of manganese upon analysis, it is necessary to add about 312 pounds of 80 per cent ferro-manganese to each net ton of steel. This is done, as previously stated, by placing the melted alloy in a hot ladle before the steel is poured from the converter. After the steel has been added to the alloy, the ladle is allowed to stand for a few minutes to permit the ferro-manganese to remove the oxygen and other gases and impurities from the metal, leaving it homogeneous and dense. The excessive accumulation of slag is then removed by skimming.

The shrinkage of the metal is unusually great, but otherwise the principles of ordinary steel foundry practice apply in making the patterns for manganese steel castings. The shrinkage amounts to 5/16 inch per foot. Ordinary steel shrinks only about 3/16 inch. Patterns, therefore, must be specially made for this material, as otherwise the castings will be under size. Abrupt changes in section are more objectionable with this steel than with other kinds. The molds must be made from sand containing a high percentage of silica, and are usually oven-dried, although in some cases skin-drying is sufficient.

Manganese steel castings are generally allowed to cool in the mold and are then annealed from three to twenty-six hours at temperatures ranging from 1800 to 2000 degrees F. At the conclusion of this process, they are removed red-hot from the annealing oven and are quenched suddenly in cold water. Some castings, however, need a preliminary treatment to remove cooling strains, and in this case they are taken from the sand while still hot and slowly cooled in an oven, after which they are reheated for annealing and quenching as described.

Unannealed manganese steel castings are exceptionally brittle and almost glass hard. After the heat-treatment, they are tough and ductile with a tensile strength of about 90,000 pounds and an elastic limit of about 60,000 pounds per square inch. The ductility of the metal is indicated by the elongation and reduction of area, frequently amounting to about 28 and 29 per cent, respectively. It is possible to satisfactorily anneal manganese steel castings having a thickness up to about 5½ inches. After the castings are annealed, they are cleaned and finished on grinders. Castings which must be accurately finished to given dimensions cannot be machined by ordinary methods on account of their toughness, but must be ground to size.

ON SETTING UP MACHINE TOOLS

Probably the builders of machine tools in general receive more complaints that are due to the fault of the purchasers than other machinery builders. The reason is that lathes, planers, boring mills and other machines of precision must be set level on even foundations in order to produce accurate work. A slight twist in a lathe bed will prevent it turning or boring straight. The user must set his machine up properly in order to obtain satisfaction. Not many machine tool builders, however, have as exasperating an experience as one whose machine was set on a foundation covered with rust cement.

Rust cement composed of iron borings and sal-ammoniac was much used in the early days of engineering in the construction and erection of machinery. A foundation covered with this cement might have been good when machines were small and not over-accurate, but today it is a different matter. This machine tool builder had furnished a boring mill to a customer who was very particular as to the accuracy of the work produced. The machine was shipped and set up, and after it had been in use a few days an urgent letter of complaint was received, stating that it was boring a taper hole and requesting that a man be sent to correct the fault.

The superintendent went to the plant and looked the machine over, including the foundation. When he saw that the purchaser had set the mill on rust cement he immediately suspected that the cause of the trouble was the slow expansion of the cement due to the rusting process, but could not convince the purchaser that this could be the cause. The table was lifted and the track scraped a little, the wedges under the machine readjusted, when the machine bored a perfect hole. In a week another complaint was received and again the superintendent went and corrected the fault. He again told the purchaser that the cause was the lifting action of the cement but was not believed. A third time was this episode repeated and then the purchaser was induced to remove the rust cement and float in a grout of hydraulic cement. This stopped the trouble as the superintendent had predicted.

It hardly seems necessary to say that any medium underneath a machine likely to change is undesirable. Ordinary cement is cheap, easily obtained and can be depended on to maintain its integrity under normal shop conditions.

EFFICIENT JIG DESIGN

A walk through many American manufacturing plants will demonstrate to one familiar with the best machine shop methods that there is still much to be done in cutting out useless and time-wasting movements. The superintendent who has to provide equipment for producing a comparatively small number of parts is likely to order jigs and fixtures made as simply as possible. This usually means primitive clamping devices—nuts and bolts, for example. Often these clamps are inconveniently placed and the operator loses time in making many unnecessary movements.

Now it does not require a highly trained efficiency expert to avoid such mistakes. Applied common sense is the secret of good engineering, whether it be the building of a jig or a great bridge. Both the jig and the bridge are but means to secure an end. A toolmaker can generally make a simple fixture convenient to use as easily and quickly as an unhandy trap. The first is efficient, the second may be a time-waster to such a degree as to be a costly device before worn out or superseded.

In general, a jig should be self-contained, requiring no detached parts or wrenches for operation. If, in addition to a wrench, a hammer must be used to set up the clamp firmly, it is a poor device.

* * *

BALANCED DRILL CHUCKS

A manufacturer of a very good sensitive drilling machine running at the usual range of speeds had been using a standard line of drill chucks for a good many years with satisfaction. Recently he developed a high-speed drilling machine operating at several thousand revolutions per minute. His concern prided itself on the good work it did in aligning its spindle bearings and every spindle was tested for alignment before leaving the factory. When the new type of machine was first operated, he applied chucks of the usual type, but found that under the high speed the spindles ran out considerably. With the drill chucks removed, the spindles ran perfectly true again, showing that the trouble lay in the drill chucks themselves. Out of a lot of fifty chucks, only three were found to run in balance at high speed. In a word, the chucks that ran satisfactorily at 1000 R. P. M. ran out badly at speeds of from 5000 to 10,000 R. P. M.

The chuck manufacturer when called in to examine the machine learned a new lesson in chuck requirements, and on the next lot of chucks special care was taken that the individual parts were balanced, the result being that no more trouble has developed from this source. The balancing of chucks for use on high-speed machines is highly important, though a point usually overlooked by machine builder and chuck maker alike.

* * *

AFTER THE MACHINE HAS BEEN SHIPPED

Not many hundred miles from New York City there is a manufacturing concern making a special machine which performs but one very simple operation—so simple that in the minds of the builders there could be no cause for complaint about its performance. In fact, they had been building the machine for years without receiving serious criticism.

Recently, a friend of the manager of this company, whose work takes him into many shops where the machine is in use, pointed out that whenever he saw one of these machines he noticed invariably that one of its bearings was kept covered with a heavy piece of paper tied on with a string. In every case this piece of paper was oil-soaked, so the visitor rightly concluded that the paper was to stop the spattering of oil from this bearing. The factory manager saw the point immediately, and the result will be a change in the design of this part of the machine.

The moral to this little incident is that no matter how simple a machine or specialty may be it is to a manufacturer's interest to follow his machines to the place where they are operating. An occasional trip around the trade to see how his product is working out will benefit him, his machine and the general users of his product.

HOMEMADE SCIENTIFIC MANAGEMENT

When "efficiency engineers" are employed to introduce methods of scientific management in a factory, their work is usually hampered by opposition from the employes. It is only natural for foremen and mechanics who have spent a number of years in acquiring a knowledge of the methods used in their work to feel that they are more familiar with the practical details than the so-called "efficiency experts" who are called in to improve them. The result often is that the men in the shop give little or no assistance to the efficiency engineers; but are rather inclined to throw obstacles in their way. This means that the engineers must spend a considerable amount of their own time and their client's money in cultivating the good will of the factory staff before they are able to get down to actual work.

Scientific management has been aptly defined as "the application of common sense in manufacturing methods with the view of increasing efficiency." The name sounds formidable, but the methods are often very simple. In most cases, efficiency engineers are called in to increase production rather than to improve the quality of the work; and their services are needed because the factory staff has devised carefully thought out ways and means for producing work of the required perfection, but has depended largely upon physical effort to keep the rate of production up to a satisfactory standard. The importance of eliminating lost motion and useless effort in turning out the maximum amount of product for a standard day's work has not been appreciated. This is what the efficiency engineer strives to do.

In efficiency engineering, as in other fields, experience is of value; but while the efficiency engineer may produce satisfactory results with his knowledge of general conditions, he is likely to fail through lack of specific information concerning the industry in which he is temporarily engaged. This lack of specific information often leads the efficiency engineer to recommend methods which he has applied successfully in one line of work, but which may prove a complete failure in another line because they conflict with existing conditions which have been overlooked. Men who have spent years in learning the details of one particular kind of work are naturally familiar with the practical conditions governing its production, and if such men could be taught to undertake the development of plans for increasing efficiency, there would be little danger of failure on account of their methods being unsuitable for the purpose for which they were intended.

One of the greatest drawbacks in the departmental method of factory administration is that it is responsible for killing ambition among the employes in a shop. Men are hired to run a drill press, milling machine or other tool and are kept on such work continuously, with the result that they lose interest and fail to develop the initiative which will fit them for more advanced positions. Any plan that can be adopted to remedy this difficulty directly benefits both the employer and the employe, and it appears that "homemade" methods of scientific management could be developed in this connection to very good advantage.

Some men in a shop have good ideas in regard to methods of reducing production costs, but diffidence prevents them from placing such ideas before the management. Other men are capable of developing valuable ideas, but lack incentive. Both of these classes could be reached by using a suggestion box in connection with some effective method of reward. In the case of shops working on a bonus system, the interests of employer and employe are both benefited by any method which increases efficiency, so that in such shops the necessary incentive already exists. In other cases, the reward might take the form of cash prizes for ideas of sufficient merit to be used in the factory, or better still—a record of useful ideas submitted by each man might be preserved in the office and this record made the basis of promotion. The application of this system would be the direct means of counteracting the effect of the departmental method of manufacture in killing ambition among the men in the shop.

The most effective safety appliance yet discovered is a careful man.

EXPORT AND IMPORT TRADE*

BY O. S.

Having been engaged in the export and import business both here and abroad for the last twelve years, I am almost daily confronted with questions from American manufacturers concerning the possibilities of exporting American manufactured goods to foreign countries in all parts of the world. With the present changes in tariff and the new democratic administration, this question of "export" has become more prominent than heretofore, and has attracted even the attention of the general public. A few remarks dealing with the fundamental principles of exporting are therefore quite timely.

It is a striking fact that whenever an American business man mentions export to foreign countries a considerable change takes place in his general attitude. No matter how confident and self reliant he may be about his business ability at home, his splendid system and organization, his up-to-date manufacturing methods, his efficiency, etc., his confidence in himself and the whole American nation seems to fail when it comes to the question of export. "Well," said one prominent American to me a few days ago, "look at the Germans; they are better business men than we, they are doing an export trade of manufactured goods to every little corner of the world. Why it is preposterous to think that even in countries like the Philippines, Cuba and the South American Republics, we depend on the German export houses to handle our own goods." Some blame it on the government; others attribute it to the fact that the young American has no liking for absorbing foreign languages.

Neither is the true cause. I venture to state at the outset that the average business man in America is at least equally, if not more progressive in all branches of business than his German or English cousin. The reason that his export trade is not developed in the same high degree is due to quite natural circumstances; in fact, it is due to an almost insurmountable natural law, as I will try to explain in the following.

I will begin with an explanation of the meaning of the word "export." Usually, for the manufacturer who has done no export business at all, or only a little occasionally, the word export has quite a charm. He pictures in his mind an order mailed to him from a foreign country with a strange looking envelope, stamp and order sheet. When he has that order, all that is left to do is box up the goods, follow shipping instructions on the order sheet, and collect money in New York by means of draft attached to bill of lading. No trouble at all, not even as much as is sometimes experienced at home when furnishing machines to a neighbor, where the superintendent is "the best mechanic in the country." Unquestionably, it is a desirable business with no expense attached, to speak of; and as a general rule, I must admit that the American manufacturer is very exacting about carrying out instructions properly, and boxing and carefully inspecting the goods he sends out into foreign countries. He is proud to do an export business. But the word "export" has an incomplete meaning; in fact, it signifies only half or third of the entire transaction. The other half is the word "import." That is to say, the foreign country to which the machine is shipped is importing it. Therefore the whole word should be "export-import." But this import part of the transaction rarely receives any consideration whatever; usually the manufacturer does not even know the name of the importer on the other side of the ocean, and is not interested in his general welfare after the goods are shipped and paid for. Here is one point at which the American business man can develop more action. If the prospects for selling many machines are not sufficiently large to warrant the expense of a personal visit, write your importer from time to time, calling attention to improvements made in construction; write him about the talking points of the machine; give him examples of production and examples of application to new lines of business. In short, teach him by mail how to handle your

* For additional information on export trade and allied subjects, see "Packing Machine Tools for Export" published in MACHINERY for February, 1906, and "Packing Machinery for Export," July, 1909.

line of goods the same as you would instruct one of your agents or traveling salesmen at home.

In case your line of goods has good selling possibilities in foreign countries on account of patent protection or superior features of either quality or lower price, a personal visit to your importer from time to time is by all means desirable. Do not hesitate to go because you cannot speak a foreign language. Your importer will speak English. It is part of his vocation to speak a few foreign languages, the same as you must know something about a planer even though you build a lathe. When there, convince yourself that your importer is the right representative for you; that he has the facilities to cover the country and the means to finance his deals. Importers have to give credit to their customers, and if your man is limited in capital, he will be limited in accepting orders.

After being fully convinced about these matters, do not leave your importer until you have injected into him and his salesman an enthusiasm about your machine, the same as you have yourself. Assist him wherever you can; consider carefully his suggestions; make changes, if required, to suit the particular wishes of the user. Do not think that if you sell it that way in the United States, it is good enough for other countries. Other people think differently from you, and you will have neither the chance nor the time to educate the importer and his staff after you have left. On the prices for export business do not figure all your overhead expenses and domestic advertising and selling expenses. Consider that your importer has to advertise and sell on his own account, and that he has to add his expense to his cost. No importer can expect to stay in business with 10 or 15 per cent commission and be successful, any more than you could be if you were to add 10 to 15 per cent to the actual manufacturing cost of a machine, and cover with this the salaries of your office force, salesmen, traveling, advertising expense, etc.

Anything more that I could offer in the way of suggestions would be details into which I do not intend to go at this writing. I will therefore answer now the question, "Why do we Americans mostly depend on foreigners to sell our goods even in countries like the Philippines, Cuba, Argentine, etc." As already indicated at the beginning of this article, the cause is a natural consequence of a natural law. Let us suppose that, starting from tomorrow, the American people would begin to teach foreign languages in public schools and succeed in making excellent linguists out of their youngsters. Would the export trade of the United States improve, and would the Americans do the business themselves? The answer is, "No." There would be, perhaps, other things being equal, a small increase in business due to a little more interest; but the majority of the business would still be done through foreign import houses, principally English and German. Why this is so is very simple indeed. There are almost no American born importers in foreign countries, and their number is not expected to increase in the near future. The young American is not going to foreign countries to work and be satisfied for any length of time.

By way of contrast, take as an example the German nation. You will find its representatives in every country in the world, even on the littlest island in the South Sea. These Germans, however, did not originally go there because they intended to make the Fatherland great by building up a large export for Germany. They went because they could earn more money and afford a higher standard of living there than at home. The Italian may go to Germany, the German to England, the English to the United States, but the American will stay at home. There is no country for him where he can earn more money (a few specialists or experts are paid high salaries) or get a higher standard of living. The stream is never flowing in the opposite direction. Take the conditions within the boundaries of our own country. If in Rochester, N. Y., a young mechanic is paid 30 cents an hour, and he reads that in Detroit the wage for his kind of work is 50 cents an hour guaranteed, and lots of people are in demand, he will pack up some day and go to Detroit. A farmer in the east, if he hears that raising corn is easier and more profitable in the west, will move some day. This is the natural order of things. English and German people have early begun to go to foreign countries, and they are now established and acquainted with conditions. Their governments have ably assisted them in every way, by means of brains and power.

If the voluntary emigration of German or English people becomes less, because of better wages and an improved standard of living at home, the established merchants will make efforts to get them by promising an even better salary than they are getting at home.. If the merchant cannot afford to pay more, the business will in time pass into the hands of the natives or the representatives of some other nation. If, on account of the new democratic regime, the United States' scale of wages should decrease and the standard of living become lower than in any other country, the young American, the same as the citizen of any other nation, would begin to emigrate to foreign countries. He would, the same as others, be satisfied with his better wage for three, five or ten years, as an employe for another firm, then establish himself as an importer.

As the matter stands now, I believe Americans have no reason to desire the emigration of their young people, if it would have to be at the sacrifice of the present high standard of living and good wages for everyone. Americans can increase their export trade by getting in touch with established export houses, regardless of what nationality the owners are. Importers are business men in the strictest sense and do not know any feeling of antagonism against any other nation, no matter what the newspapers write to the contrary.

* * *

MATERIAL IN CAST-IRON FLYWHEELS

Attention is called in *The Travelers' Standard* to the danger of using cast iron containing too much phosphorus for flywheels and pulleys. Flywheels sometimes burst, without any apparent cause, at low speed, the running conditions being normal at the time of the accident. When the material is examined, it may be that no defects can be discovered on the fractured surfaces, and that no cracks, blow-holes, nor discolorations can be found. Furthermore, when the fractured parts of the wheel are tested for strength, there is often no physical evidence of inferiority in the material.

An accident may sometimes result from internal stresses in the material, due to faulty design or to careless cooling of the casting; but severe internal stresses seldom occur except in wheels made in one piece. Some other explanation must therefore be sought for accidents of this nature, and the cause will often be found to be the use of improper raw material in the foundry. Chemical analysis frequently shows that the iron is not of a grade suitable for machine castings. This is particularly likely to be the case in wheels from small foundries that turn out all kinds of work, because in such places the same grade of raw material is likely to be used for castings of all kinds. A considerable part of the output of a foundry of this sort requires metal that will flow freely, so as to fill the forms well. In making ornamental work, for example, it is highly important to obtain a sharp impression. Such iron invariably contains a large percentage of phosphorus. Phosphorus lowers the melting point, but makes the iron brittle; and machine castings should never contain more than 0.4 per cent of it.

There is on record a case where a pulley burst under ordinary running conditions, and where no defects could be discovered in the broken wheel by a visual examination; but an analysis of the iron showed that it contained 1.37 per cent of phosphorus, or nearly 3½ times the maximum that should have been allowed. There is little doubt but that brittleness of the metal, due to this high percentage of phosphorus, was the cause of the break. From a safety point of view, it is exceedingly important to make cast-iron wheels of material with a low percentage of phosphorus.

* * *

Don't forget when drilling a hole on an angle, that the drill is going to come through on one side of the work first, and that care should be taken to let it through carefully or it is likely to be broken.

PRESSED VS. MACHINE FINISHED PARTS

BY P. O. URBANI-PUSCHMANN

In the manufacture of interchangeable parts such as are used in the assembly of adding and addressing machines, registers, scales, typewriters, etc., a large quantity of duplicate pieces of a tubular or hollow cylindrical form are used. These must not only be absolutely concentric but interchangeable and yet low in production cost; hence it becomes quite a problem for the shop superintendent to decide which is the best, quickest and cheapest way to produce such parts. If the quantities required are small, say not over one thousand pieces per lot, and the lots are far between, and if cheapness need not be a prime factor in his calculation, the superintendent will invariably decide in favor of screw machines, either automatic or hand operated. The percentage of perfect or interchangeable parts that will be obtained from a given lot depends largely upon the condition of these machine tools, the skill of their operators and the stringency of the inspection limits.

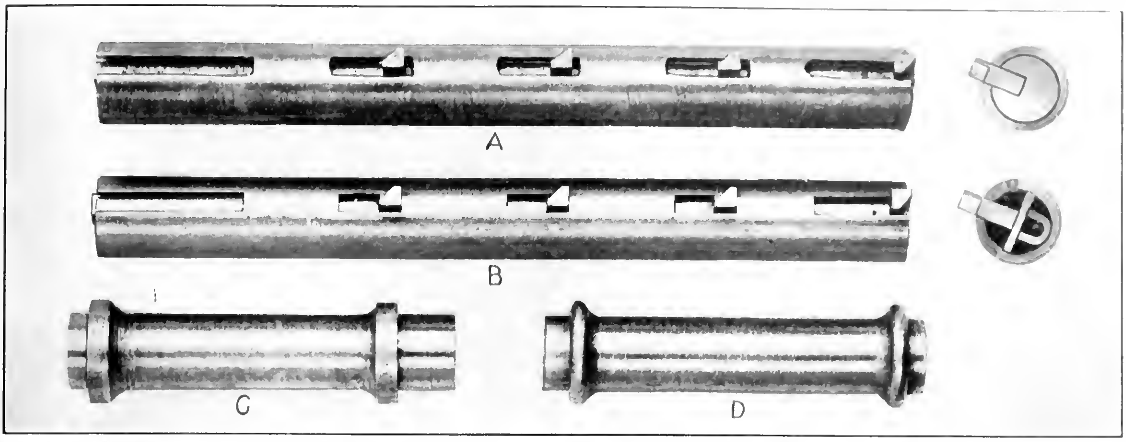

Fig. 1. (A) Part machined from Bar; (B) Same Part produced from Sheet Steel in Dies; (C) Machined Spacer Tube; (D) Die-formed Spacer Tube

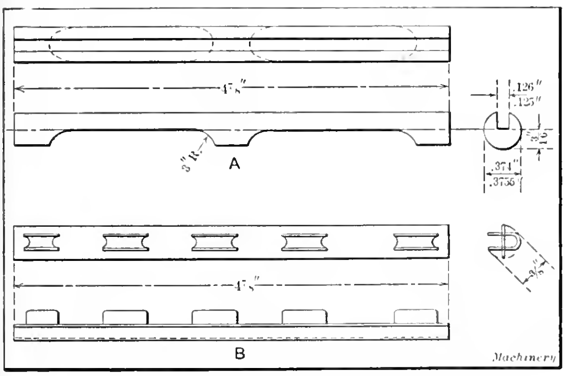

Fig. 2. (A) Slotted Rod for Hollow Shaft shown at A, Fig. 1; (B) New Method of producing Part to replace Solid Rod A

Another reason why screw machines are generally favored for this class of work is because of their adaptability to various forms of cylindrical work without a great investment for special tools, except a nominal figure for forming tools and reamers. This factor is perhaps the trap in which many otherwise shrewd shop managers are caught, because they see only the low initial cost for tools and overlook entirely the loss per lot due to slow production, to work spoiled or not passing inspection, and the fact that their screw machine department becomes overtaxed with work that could be done advantageously with special tools in punch presses or special machinery. Therefore they deprive themselves of the use of their screw machines and milling machines for work that cannot be done to advantage in any other way.

The accompanying illustrations show examples of work which will illustrate the idea referred to in the foregoing. Fig. 1 (View *A*) represents a hollow shaft with slots running parallel to its axis, and Fig. 2 (View *A*) shows a slotted filler for this shaft. Fig. 1 (View *C*) shows a spacer tube, and Fig. 3 (View *A*) illustrates a threaded housing for a ball race.

After a superficial examination of these illustrations, nearly every practical man would assign these parts to the screw machine for the first operation, to be followed, where required, by a slotting operation on the milling machine. The fact is that these parts have been made for years in just this way in our factory until we realized that they were costing considerably more than their allotted allowance in the assembly of the machines. On account of the very close limits on length and concentricity of the outside with the hole, the inspection loss had been very great and the time of production slow, so that the screw machines fell behind with other work. This necessitated working overtime and employing night shifts at higher wages, which meant an increase of pay roll, an increase of power and light bills and raised our entire overhead charge, affecting directly the production cost of the screw machine department in total.

The parts shown at *A* and *C*, Fig. 1, were first made of seamless steel tubing of sufficient wall thickness to allow machining the pieces both inside and outside. The hole was first bored and reamed to size, but since tubing having such a wall thickness coald not be secured absolutely true and the drill and reamer followed the old hole subject to the law of least resistance, we could not get concentric work until we finished the outside surface by a later operation. This was done by driving the pieces on arbors and turning them between collet and center. By this method the work was made true, but the finish depended, of course, on the sharpness of

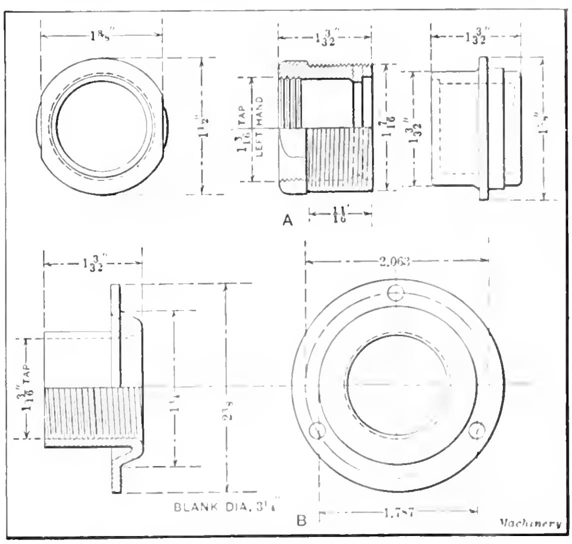

Fig. 3. (A) Ball Race Housing machined in Gridley Automatic; (B) Ball Race Housing pressed from Sheet Steel

the cutting tools and the cutting speed of the machine. Anybody acquainted with machining unpickled steel tubing knows what that means.

Finding this method unsatisfactory we changed the material and made the parts of cold-drawn steel shafting of the largest diameter of the finished pieces, depending upon the accuracy of the stock for the outside surface, the size of the reamer and copious lubrication for the size and smoothness of the bore, and on good luck for the truth with which the drill and reamer would come out on the other end, or rather meet in the center, inasmuch as our automatics have only a 2-inch feed and we had to add another drilling and reaming operation on a hand machine.

On account of the lower price for cold-drawn shafting, as compared with steel tubing, and because the machining of the outer surface of the hollow shaft *A*, Fig. 1, was omitted, the final cost of these pieces was about one-third lower when made of cold-drawn shafting, in spite of the additional drilling through the center. However, even at this reduction, the price was too high because of the large inspection loss due to eccentric work, as well as to rough or oversize holes. The part shown at *A*, Fig. 3, was also made of cold-drawn shafting on a Gridley multiple-spindle automatic. The thread had to be absolutely true with the bore and was chased on the lathe.

The part shown at *A*, Fig. 2, was made of special gaged cold-drawn shafting, cut off on a hand screw machine and then slotted and milled, at great expense, in two operations. View *B* shows how this part was produced by the new method. The appearance is somewhat modified, but it serves the identical purpose. In manufacturing this part by the new method we finally dispensed altogether with the expensive and unreliable screw machine and milling operations, leaving these machines available for other jobs, thus avoiding the expense of overtime and night work and, incidentally, reducing the cost of the products to a surprising extent.

All of these parts, with the exception of the one shown at *D*, Fig. 1 (which is die-formed of seamless steel tubing of a gage to give the correct diameter at the shoulders and requiring no machining or finishing) are now formed of cold-rolled open-hearth sheet steel in special dies and require either no machining or very little. In spite of their great cheapness, the pressed products are far more satisfactory, uniform, and, therefore, interchangeable, than the expensive machined pieces were. An added advantage of the pressed pieces is their smoothness and wearing qualities due to the rolled surface of the raw material. To produce these pieces from cold-rolled sheet steel, instead of from bar steel in the screw machines, required an investment of about five hundred dollars, but the saving on the first lots repaid for this expenditure and left a profit besides.

The examples referred to in the preceding, while based on facts, are by no means suggested as a criterion by which other conditions should be regulated. They merely indicate one man's opinion and illustrate how we dealt with perplexing conditions and remedied them to our entire satisfaction. If this article has suggested ways and means by which others confronted with similar troubles will be benefited, it has served its purpose.

* * *

COAL RESOURCES OF CANADA

From time to time sensational writers hold up to view the horrors of the conditions that will arise when the fuel supply of the world gives out, and many have placed the time when this will happen as only about a couple of centuries distant. However, as time passes on an increasing number of coal deposits are being found in districts at the time not suspected as coal bearing. The Geological Survey of Canada gives the following figures for the actually known deposits of coal in the province of Alberta alone: Anthracite, 668,000,000 tons; bituminous, 3,200,000,000 tons; semi-bituminous coal and lignites, 385,000,000,000 tons. In addition, there are *probable* deposits of 100,000,000 tons of anthracite; nearly 200,000,000,000 tons of bituminous coal; and close to 500,000,000,000 tons of semi-bituminous coal and lignites.

RENEWING DUMMY AND GLAND STRIPS IN A PARSONS STEAM TURBINE*

BY N. I. MOSHER†

The method of renewing the dummy and gland strips in a Parsons steam turbine presented in this article outlines the shop practice of the Boston Navy Yard, and a method of procedure is also described which can be followed with satisfactory results when it is not convenient to dismantle the turbine and send it to the shop for repairs. Part of the section of the rotor with the dummy rings is shown at *A* in Fig. 1, and the dummy ring strips are shown at *B*. The strips are made of hard bronze and act as a baffle and

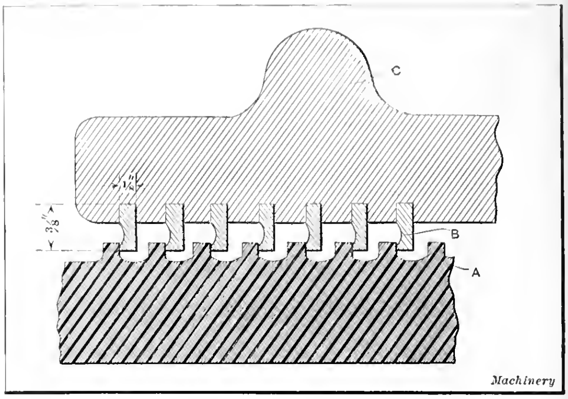

Fig. 1. Arrangement of the Gland Case Dummy Ring Strips and Dummy Rings

packing between the revolving rotor and the fixed cases. These dummy strips become worn from unequal expansion between the cases and rotor or from improper thrust adjustment, causing the strips to rub against the dummy rings. The adjustment between the dummy rings and the strips is ordinarily 0.012 inch. By the proper manipulation of a micrometer instrument, the correct location of the dummy rings in relation to the dummy strips can be determined while the turbine is in motion with a great degree of accuracy. The turbine considered in this article has thirty rings, which are cut into the rotor to a depth of 3/16 inch, and the rings are 3/16 inch wide on the steam entering end of the rotor.

The dummy ring strips are secured in a casting, which, in turn, is secured to the inside end of the turbine cases and machined diametrically true from the axis of the journals. These strips are 4 inches long and rectangular in shape. Fig. 2 shows a detailed view of one of the strips.

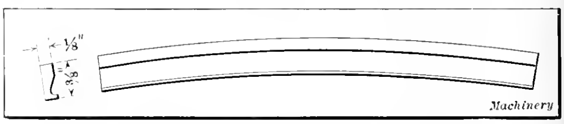

Fig. 2. Detail of one of the Finished Dummy Ring Strips

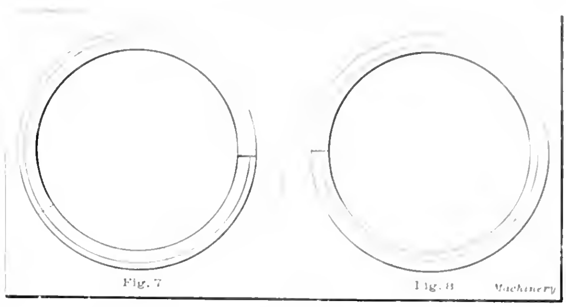
The following method of renewing these strips was adopted. Standard plates of bronze 24 by 48 inches in size were sawed into strips 4 inches wide, making eleven pieces 24 inches long by 4 inches wide. Eight of these pieces were next secured to the boring mill platen, running out radially from the center. Then a tool was forged and its end machined to the desired shape, as shown in Fig. 3; and the tool-holder was moved the required distance on the rail to give a diameter of 31 3/16 inches. The tool was then fed down into the revolving pieces on the boring mill platen, forming and cutting off eight of the required shaped strips. With the tool remaining in its original position, and by simply unstrapping the brass plates and moving them out the required distance, another set of eight strips was cut off, and so on until the plates were entirely cut up. This method wastes very little stock and the operator can easily cut 150 pieces in eight hours.

* For additional information on this subject, see "Re-blading a Parsons Steam Turbine" published in the December, 1913, number of MACHINERY.
† Address: 15 James St., Winter Hill, Somerville, Mass.

The variation in the thickness of the bronze plates was found to be from 0.001 to 0.007 inch, and to overcome this a sizing die was made which sheared the pieces all to one thickness, namely, 0.125 inch. This completed the machining operations, leaving the pieces finished all over to the proper thickness and diameter. The grooves in the gland casing *C*, Fig. 1, were approximately 0.123 inch wide, or just enough smaller to afford a snug driving fit when the finished strips were forced into them. For performing this operation, a set was machined to the same radius and length as the dummy strips, as shown in Fig. 4. These strips are set about 0.012 inch apart to allow for expansion. After having the 600 strips forced into the grooves, a set was used to calk the metal and fasten the strips more securely.

Having completed the dummy strips, we now turn to the gland strips. Fig. 6 shows the rotor spindle strips and the gland strip casing and strips. It will be noticed that the gland strips are of a different design (see Figs. 7 and 8) from the dummy strips. The edges are machined to a knife edge and the spindle strips just touch the inside of the case that supports the fixed strips; the fixed strips, in turn, just touch the spindle, less a clearance of 0.002 inch. The material for the gland strips is purchased from the mills in rectangular shaped pieces 1/8 by 3/8 inch in size, rolled up in coils about the diameter of the spindle and the gland cases. These coils are cut up into the required pieces, which are forced into the grooves of the spindle and gland cases. Ordinarily about five sections to each ring are set in with a clearance of 0.012 inch between each section, which is to allow for expansion. Having the sections securely calked in both the spindle and cases, they are then machined to the proper diameter and formed, as shown in Fig. 6. The casing that holds the gland strips is detachable from the main turbine case and can be set up in halves on either a horizontal or a vertical boring mill, enabling the machining operation to be performed very satisfactorily. The operation on the spindle is purely a lathe job.



Figs. 7 and 8. Fixed Gland Rings and Spindle Gland Rings

The preceding paragraphs describe the method followed when a turbine rotor and cases are delivered to the shop. When the work is to be done on board ship, however, without the use of a full equipment of power-driven tools, the following operations are required: First, cut the gland strip stock, 1/8 by 3/8 inch in size, into rings of the proper diameter. Second, with a suitable holder on the lathe faceplate, finish these rings to the correct diameter and form. Third, cut the rings into the required number of pieces (see Figs. 7 and 8); they are then ready for inserting in the spindle and gland cases. For this purpose two tools are made, one machined as shown in Fig. 5 for the spindle rings, and the other machined to fit the gland rings for the cases. Experience has proved that these tools stand up best when made from a soft steel of suitable carbon that will toughen under oil tempering; and with careful manipulation of the tools, a very satisfactory job may be done by this method without sending parts to the shop.

* * *

It has frequently been claimed that the great number of young men graduated yearly from the higher technical institutions in Germany tends to create an over-supply of highly educated men in the industries, and to lower the rate of compensation of the whole engineering profession in that country. During the past year the number of students at the eleven higher German technical institutions was still on the increase. At the institution in Berlin there were close to three thousand students on the lists. At Munich there was about the same number, and at several others about fifteen hundred students. In all, there were about seventeen thousand students at these eleven institutions, an increase of 3.4 per cent over the attendance during the previous year.

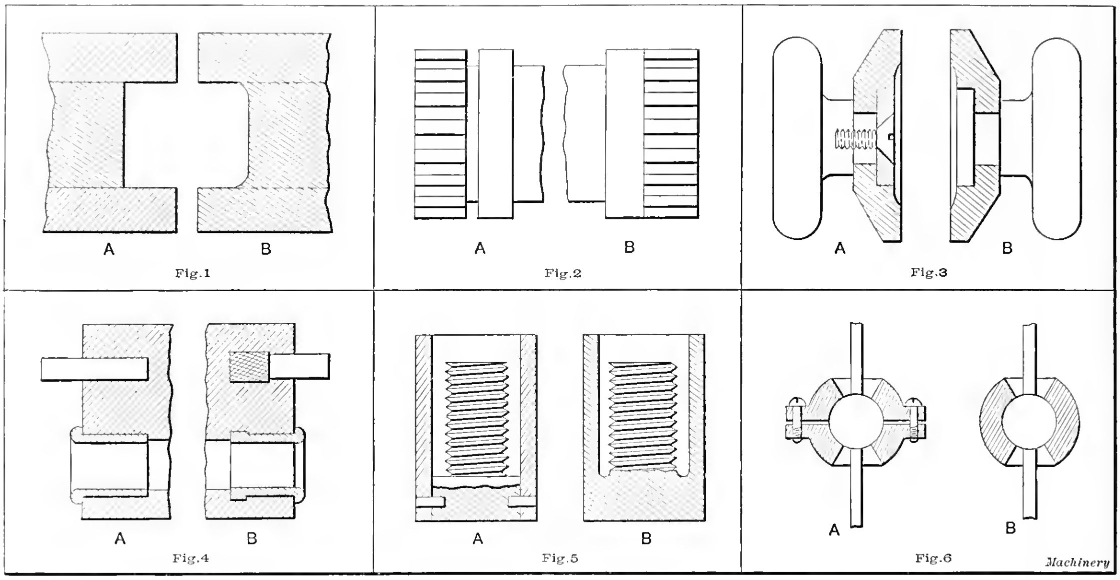
DEVICES MADE POSSIBLE BY DIE-CASTING*

ADVANTAGES OF THE DIE-CASTING PROCESS TO THE DESIGNER

BY CHESTER L. LUCAS†

DIE-CASTING has done a great deal for the designer and manufacturer of small metal articles. By a proper knowledge of what may be accomplished by this process, the work of the designer is greatly facilitated, and by taking advantage of the different points in his favor, he may produce a superior product. Some of the advantages of die-casting are diagrammatically shown in Figs. 1 to 6. These views illustrate the results that can be obtained by this process. In these illustrations the ordinary method of securing a desired result is given at the left, while at the right is shown how much better a result is secured by die-casting. Take, for instance, Fig. 1: at *A* is shown a very ordinary construction, in which two plates are laid over a central block in cases where, because of the difficulty in machining between the plates it is not possible to make the entire piece solid. By die-casting, this piece can be made solid, as shown at *B*, with fillets in the corners which greatly strengthen and finish it. In Fig. 2 is shown the usual method of cutting gear teeth up to a shoulder. This is invariably provided for by cutting a recess into which the gear-cutter may "run out." At *B* is shown the possibility of die-casting for work of this kind. The dies may be constructed so that the gear teeth run up close to the shoulder, strengthening the teeth and simplifying the construction. In Fig. 3 is shown a knob construction, in which the knob must turn within the plate. This is usually done by making the knob itself of two pieces, as at *A*, with a flange that is screwed into place after assembling. By die-casting the flange, as at *B*, and coating the contact surfaces with a graphite paste, the knob may be cast in place and still be freely turned when finished. This is an advantage of die-casting that is being made use of to a very great extent.

In Fig. 4 at *A* is shown a method of inserting steel pins or bronze bushings in another base metal, the whole dependence for strength being placed on driving fits. At *B* is shown the method employed for inserting steel pins or bronze bushings in die-castings. As the metal is cast around the insert, the ends of the rods may be knurled and the bushings may be turned with projecting flanges so that the die-casting metal will embed itself thoroughly around the inserts and effectively prevent pulling out. Of course the shrinkage of the die-cast metal helps to hold these inserted parts even more firmly in place. Fig. 5 shows a case in which die-casting can be used to great advantage. The construction shown at *A* cannot be secured with ordinary machining methods on an integral piece. With one-piece construction it would be impossible to cut the thread on the central stud, as the space between it and the walls would be insufficient to use a die. The only solution would be to make the central threaded section on a separate piece and pin the outer casing over it. At *B* is shown the result that may be readily obtained by die-casting. It is only necessary to put a core in the die, and after the die-casting has been finished the core may be unscrewed from the casting. Turning now to Fig. 6 we see at *A* the familiar ball and socket construction in which the halves of the sprocket are necessarily made separate and screwed together about the ball. At *B* is shown the die-casting method of securing this result by first making the ball and casting the socket around it. By using the proper alloys for the die-casting metal any desired degree of friction can be secured.



Figs. 1 to 6. Design Advantages to be gained by Die-casting

Aside from the construction advantages that die-casting gives, there are often cases where a designed article could not be manufactured at all, except at a prohibitive cost, were it not for die-casting. Two excellent illustrations of this point are in evidence in the two types of "Stoco" instruments shown in Figs. 7 and 11. These are made by the Standard Optical Co. of Geneva, N. Y., and are two of their line of high-grade opticians' instruments. After this company had designed these instruments, it found that it had manufacturing problems that could only be solved by die-casting of the highest order. The H. H. Franklin Mfg. Co. of Syracuse, N. Y., was given the proposition and is now making practically all of the parts for these instruments. When the die-castings reach the Standard Optical Co.'s factory they must be ready for assembling, and as no machining operations are performed save tapping and plating, the work must come from the dies finished in every sense of the word. One of these instruments is shown in Fig. 7. This device is a tilting lens chuck, and is used when boring the holes in spectacle lenses of any curve or thickness. The lens may be tilted in any position or held horizontal without the necessity of a special adjustment for each position.

* For additional information on die-casting practice see "Van Wagner Mfg. Co.'s Die-casting Practice" 1 and 2, published in the January and February, 1913, numbers of MACHINERY and articles there referred to. See also MACHINERY'S Reference Books No. 108 "Die-casting Machines" and No. 109 "Die-casting Dies and Methods."

† Associate Editor of MACHINERY.

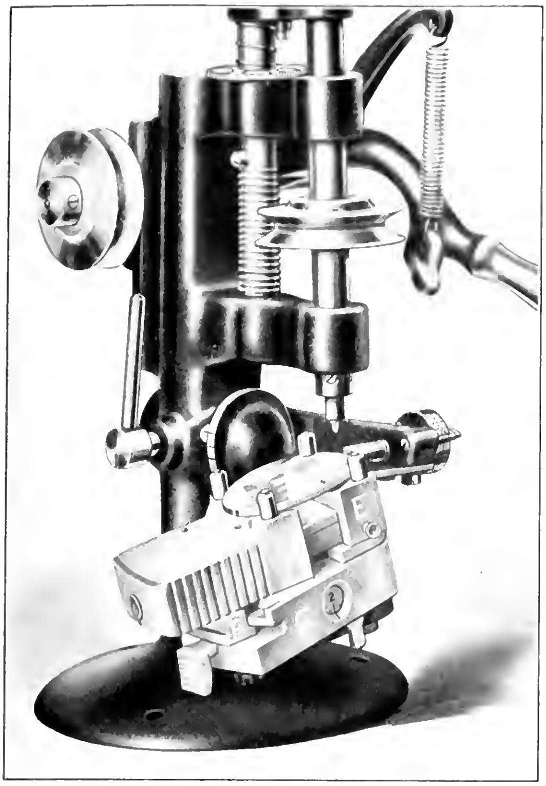


Fig. 7. "Stoco" Lens Chuck in Use

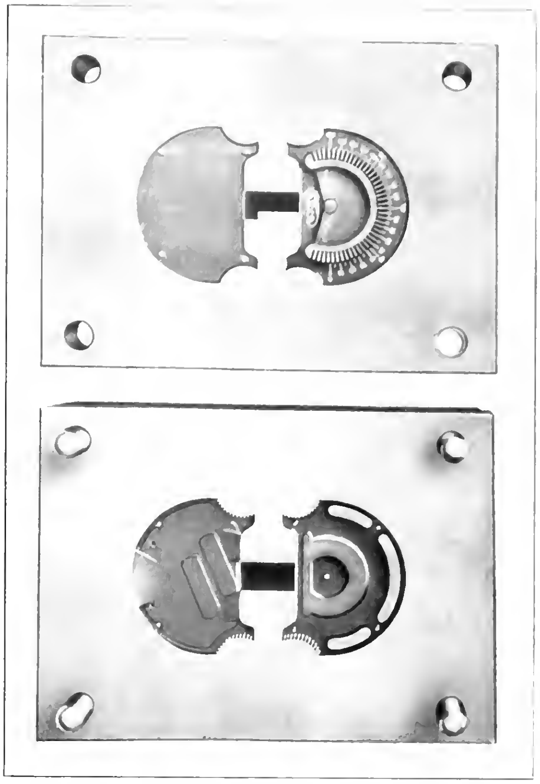

Fig. 8. Die-casting Mold-halves for "Stoco" Inclinometer

As many lenses require boring at a certain distance, in millimeters, one side or the other from the actual center, this lens chuck may be adjusted by the small lever, using the graduated scale so that the entire chuck may be swung sideways to accomplish this. Lenses are drilled half way from each side, and with this chuck the lens is quickly relocated after the first half of the hole is bored. The chuck may be taken apart for cleaning without any tools whatever.

The lens chuck is also shown assembled at *A* in Fig. 9, and the succeeding six views show the parts of the device separately. By referring back to Fig. 7, it will be seen how this instrument is used for drilling. To give an idea of the complicated mechanism, it should be noted that jaws *D* and *E* may be moved independently of each other for locating the lens longitudinally on the device. The jaws slide on a swiveling sub-base *B* and these three parts may be swiveled about a central axis by depressing locking bolt *F*, which, as shown in Fig. 9, has teeth that engage those in sub-base *B*. There is also a limit stop *G* for locating the fixture any desired amount off center. These parts, of themselves, comprise good examples of die-casting, because there are under sections, gear teeth and other difficult points of construction to be taken care of. When it is considered that, in addition to their individual difficulties, these pieces must be die-cast so that they will slide together perfectly and work freely without excessive play, it will be realized what possibilities die-casting has.

A description of one of the die-casting molds used on this job should be of interest, and we have selected the mold or die used for casting the base of this device. This base is shown at *C*, Fig. 9, and the working drawing of the mold is shown in Fig. 10; its construction is as follows: The face-plate *A* is a plain flat plate that is clamped to the working face of the die-casting machine; upon this plate the mold is built. Resting on the upper side of plate *A* is plate *B*. Plate *B* is an important part of the mold, as it contains the outline of the piece and through it work the three cores *C*, *D* and *E* that form the under cut sections of the piece, and the round beveled edge hole at the front. These may all be observed at *C* in Fig. 9. Upon plate *B* is imposed upper die-plate *F*, in the face of which are the projections necessary to form the recesses and slots in the top of the die-casting. As with other types of die-casting molds, the metal enters the mold cavity through gate *G*. The supply is cut off and the sprue is severed by sprue-cutter *H* that works within the gate *G*. The end slides *C* and *D*, as well as the core-pin *E*, are operated by toggles *I*, *J* and *K*, respectively. The slides and core must, of course, be removed from the casting after each piece has been made. This allows the casting to

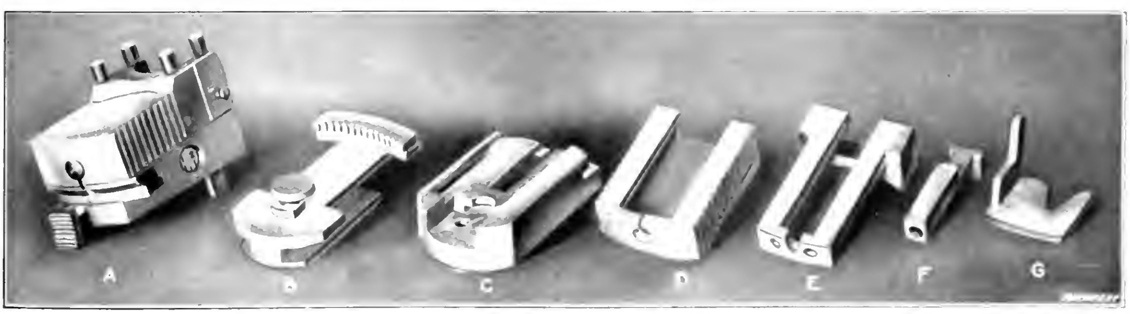

Fig. 9. The Lens Chuck and its Principal Parts

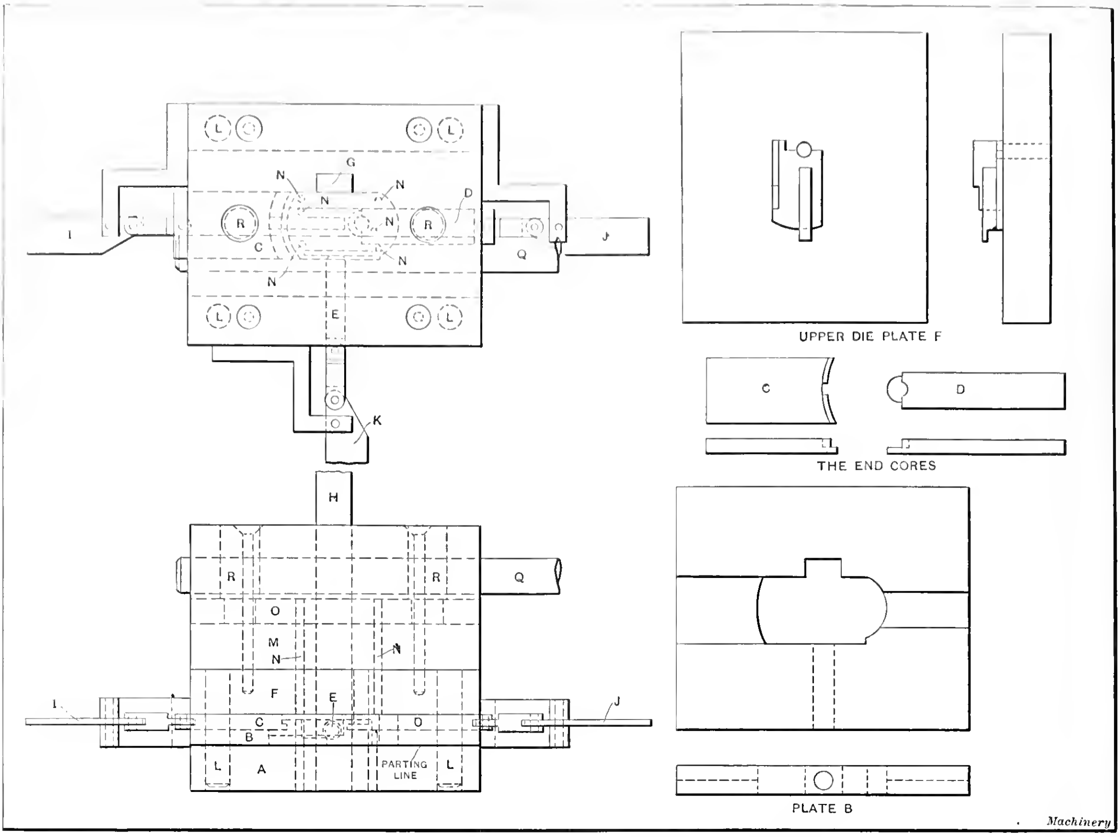

Fig. 10. Die-casting Mold for the Lens Chuck Base shown at C, Fig. 9

be taken from the mold, after which the slides are put back into position for the casting of the next piece. It should be explained that the mold parts between the plates *A* and *B* as indicated. Driven through plates *A*, *F* and *B* are the four dowel-pins *L* that work through holes in plates *B* and *A*, insuring perfect alignment of the parts. Plate *B* is permanently attached to plate *F*. At the right-hand side of Fig. 10 the principal parts of the mold are shown separately.

The above description refers to the die-casting mold proper, but the mechanism for ejecting the casting from the mold is also interesting. It consists of the ejector box *M* and ejector pins *N*, held at their upper ends in ejector plate *O*. After the casting has chilled, and the mold has been opened at the parting line, the toggles *I*, *J* and *K* are operated and the cores and slides pulled back. Then crank *Q* is turned, which advances the ejector plate *O* by means of racks *R*, meshing with teeth on the crank, and therefore causes the ejector pins to push the casting from the die cavity.

Another Die-cast Instrument

Fig. 11 shows another of the "Stoco" instruments for opticians' use. This is an inclinometer, used for determining the axes of lenses. In use the instrument is held between thumb and finger, and the lens jaws, nominally closed by spring pressure, are opened by pressing the finger lever at the bottom and the lens inserted. By tilting the instrument and lens until the marked axis of the lens coincides with the vertical line, the inclination is readily found. The pendulum is free to find its own location by gravity while the instrument is being inclined, and when the lines coincide the instrument is tilted backward, thus causing the pendulum to find its bearing in the serrated portion of the instrument. By noting a center line on the pendulum in connection with

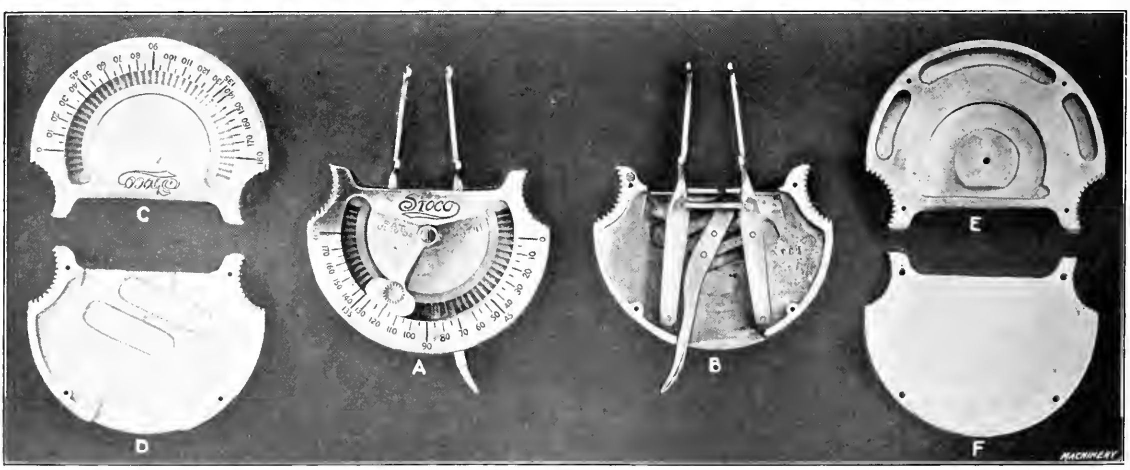

Fig. 11. "Stoco" Inclinometer with Face and Back Views of its Parts

the graduated arc on the body of the instrument, the angle of the lens axis may be observed. Fig. 11 shows at *A* the assembled instrument; at *B* the instrument with the cover removed; at *C* and *D* the outsides of the two main castings; and at *E* and *F* the inner sides of the same pieces. The levers that work inside the instrument, as well as the pendulum, are die-cast, using an alloy that is stiff enough so that in case of injury the levers will break before bending. Should they bend, the accuracy of the instrument would be impaired, while in case of breakage they could be replaced at slight cost.

The illustration Fig. 8 shows the working faces of the die-casting mold used for producing the two halves of the body of the instrument. As will be seen, these two castings are cast in the same die. In one mold-half is the impression of the rear side of each piece, while in the opposite mold-half the front sides are reproduced. The metal enters the mold cavities through the square opening or gate at the center, and after the die cavity has been filled the sprue cutter working in the same opening severs the sprue from the casting and pushes it out of the gate. At each operation of the die two complete pieces are made. The fact that the lettering and figures must be depressed in the finished casting means that they must be raised in the mold cavity. This impression is much more difficult to produce than it would be if the figures and letters were to be made raised on the casting.

These "Stoco" instruments of the H. H. Franklin Mfg. Co. are excellent examples of the possibilities of die-casting, and they should serve as reminders to the designer that die-casting is one of the modern processes at his command, and if properly made use of may prove the solution of some of his manufacturing problems.

* * *

Diesel engines are broadly divided into two classes, namely, the two-stroke and the four-stroke cycle. In both types a cylinder full of air at atmospheric pressure is compressed by the piston at the top center till its pressure becomes about 500 pounds per square inch. The compression raises its temperature to about 1000 degrees F. At this instant a small quantity of oil fuel is blown into the very hot high-pressure air by means of a blast of air at still higher pressure. The oil is broken into a fine spray and its admission lasts only for one-tenth of the downward stroke. During this short time much of the oil is burned in the hot air. The aim is that the compression shall proceed at the critical rate which shall permit the increase of volume occupied due to the motion of the piston and the increase of temperature to be so balanced that the pressure will remain constant until all of the oil has been burned. After this the expansion of the hot gas will still further push the piston down and the pressure will rapidly decrease. The maximum temperatures actually obtained in the cylinders are very high, approximating in some cases nearly 3000 degrees F. It is these exceedingly high temperatures which occasion much of the special difficulties of Diesel engines, and it is necessary to keep the rubbing surface of the metal exposed to the hot gases sufficiently cool to permit of their retaining their lubrication; it is also necessary to prevent all the metal with which the heat comes in contact from becoming so overheated as to impair its strain-resisting properties.—*J. T. Milton, in paper "The Marine Diesel Engine," read before the Institution of Naval Architects, April 2, 1914.*

THE DESIGN OF BRONZE BUSHINGS

BY B. D. PINKNEY*

A branch of machine design that I have not seen treated is the proportioning of bronze bushings for shaft bearings. For several years I was engaged in the design of machinery on which large numbers of bronze and phosphor-bronze bushings were used. It was important to get the bushings just thin enough so that their stiffness was not impaired while being forced in place, owing to the high cost of bronze and phosphor-bronze. A bronze bushing of 5 7/16 inches bore by 8½ inches long by ¼ inch thick was distorted in being forced into a box with sufficient pressure to warrant its being secure. This bushing had the appearance of having been bruised with a hammer, an exaggerated idea of its condition being shown in Fig. 1. The high ridges appeared very soon after the shaft was rotated in the bushed box. A bushing of the same bore and length but ⅜ inch thick was forced in with the same pressure and showed no sign of distortion.

The following rules for forcing bushings into place were formulated from the results of a series of experiments on bushings from 1 to 6 inches bore and of lengths varying from one to six diameters:

First: The thickness of the bushing varies approximately as the square root of the product of the bore and the length.

Second: The amount that the bushing should be oversize to obtain a substantial force fit varies as the square root of the bore.

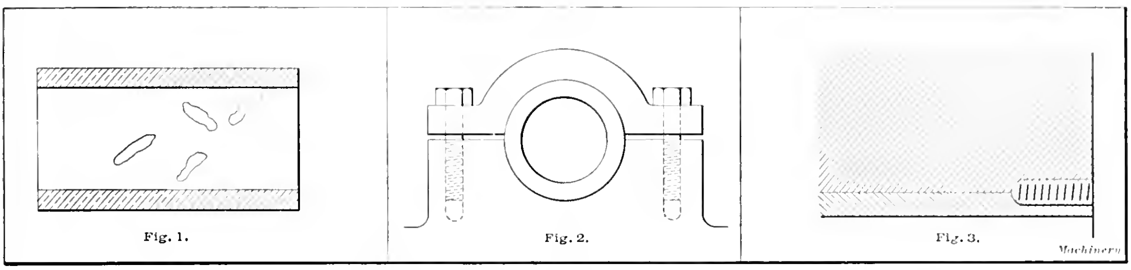

Fig. 1. Fig. 2. Fig. 3.

Figs. 1 to 3. Bushing damaged while being forced into Place and Two Methods of securing Bushings

$$T = 0.05\sqrt{BL} + 0.05 \text{ inch} \qquad (1)$$

$$O = 0.0008\sqrt{B} \qquad (2)$$

where T = thickness of bushing in inches;
B = bore of bushing in inches;
L = length of bushing in inches;
O = amount bushing is oversize in inches.

For bushings that are not forced into place, but are held in position by friction clamps in order to facilitate removal, as shown in Fig. 2, or for bushings which are placed in a pocket in a frame and held in place by babbitt, the thickness is obtained from Formula (3), where it will be seen that the length is not a factor:

$$T = 0.125\sqrt{B} \qquad (3)$$

It is well to provide means for fastening a bushing in the box to guard against the possibility of rotation—particularly in the case of those of 1 15/16 inch bore and over. The writer uses one or more screws, depending upon the size of the bushing, fastened "half and half" in one end as shown in Fig. 3. The number of screws that are required may be found by means of Formula (4), using the next larger whole number. Thus, if the required number of screws N = 1.35, use two screws.

$$N = \sqrt{B} \qquad (4)$$

I have used these formulas for several years with the best of results and, no doubt, many of MACHINERY'S readers will be pleased to get some information along this line.

THE USE OF GAGES

BY F. W. GATES*

A few months ago a body of automobile manufacturers from abroad visited this country to inspect our American manufacturing methods in their industry. While visiting one of our large plants they were given a list of finished parts that make up a complete car, and in passing through the plant they marked, with a specially colored chalk, one piece taken at random from each pile of completed parts. Workmen, following the party, took the marked parts to the assembling department and when the visitors had completed their round, they were escorted to the street in front of the office building and there stood the pieces which they had selected, assembled, mounted, motor running—everything ready to take them for a spin. Any American who is not proud of an achievement like that is a fit subject for—well, some other country.

Anything approaching a feat of this kind would be impossible without the use of gages. Every single part from the tiniest screw to the motor casting had to pass through its particular gage, so when parts reached the assembling floor they "went together" without any filing, grinding, fitting or grumbling. It was so often the case that all the profits made by the rest of the factory lost themselves in the assembling department, that careful gaging is now a practical necessity in almost every factory producing tools or machinery. It is absolute folly to expect interchangeability of parts if different workmen measure different parts in different ways, using different tools made by different manufacturers. A measuring tool may be ever so fine and accurate, it is still a tool and not a gage. The difference is that a tool is an adjustable device for taking the dimension of various articles; while a gage is a standard to which one article must be fitted. A tool will measure a whole range of sizes, having adjustable points of contact. A gage measures its one size or shape only and has fixed points of contact.

But there are occasions when the use of standard gages may, instead of bringing about economy, so add to the production expense as to make them positively objectionable. This is the case where close accuracy is not needed to produce interchangeability. For instance, I once inquired of the superintendent of a small machine shop working on a very ordinary class of work what limits he allowed. "Limits!" he exclaimed in indignant surprise, "we don't use any limits—every piece is brought to dead accuracy." Apparently he had not yet learned that "accuracy" is a variable term. Go into one shop and they figure and think in sixty-fourths of an inch and believe that that is close. Go into another shop and they speak of one-thousandth of an inch as if it were half a mile. Now the superintendent mentioned was trying to make all of that common work absolutely exact. He spent a great deal of time in doing it and thought he was succeeding, but I could find a difference of 0.002 inch on one cylindrical projection. The fact is, anywhere within 0.005 inch would have answered the purpose fully as well, and had he been willing to admit the point and put limit gages on the job instead of standard gages, he would have saved at least 25 per cent of his labor cost.

There is no question but that limit gages enable any shop to produce uniform work that will interchange with perfect satisfaction; but it often requires not only careful planning, but also a thorough practical knowledge of the cutting action of certain tools to lay out a system of limits that will bring the parts together without a "hitch." Take the very excellent A. S. M. E. screw thread system. Opposite No. 24 they give the maximum pitch diameter for a screw as 0.3314 inch and the minimum tap corresponding to this size as 0.3334 inch, allowing a difference for a working fit of 0.002 inch. On paper this looks fairly close, but when you are using commercial taps, as most shops do, you will never find a tap that cuts down to its measured pitch diameter. The sharpening always throws up a fine wire edge along the cutting faces and the tap will cut (on a No. 24 size or thereabouts) from 0.001 inch to 0.003 inch over its size as ascertained with a thread micrometer or pitch diameter gage. Hence, if you should follow the standard literally, you would find a difference between maximum screw and minimum tap hole of from 0.003 inch to 0.005 inch. Even this would not be so bad in the majority of cases, but the standard further provides a tolerance of 0.002 inch on taps and 0.003 inch on screws. So if you should bring together a *minimum* size screw and a *maximum* tapped hole, the difference between them would be from 0.008 inch to 0.010 inch—too loose for anything but very coarse work. We are very apt to forget that tables of limits, such as that referred to, are generally given to show the widest possible range of tolerance and cannot take account of the cutting action of the tools used, even though they may give dimensions for the tools, as in the A. S. M. E. thread standard. The figures are limits, not ideals.

As to the types of gages in general use, too little attention appears to be given to the question, "Is this type adapted to my uses?" Generally speaking a gage should not be of such a design as to necessitate taking it in the hand. It is far better to have gages which can be placed on a standard or base, or fastened to the bench or machine. If this is not practicable, by all means let there be a projecting handle (perhaps screwed into the body part) and cover the handle with a non-conducting fiber. Then the question of "touch" is an important item. Some men think it is incumbent upon them to force the part between the contact surfaces if it is a physical possibility to do so. Others, with a less vicious disposition, touch very lightly. Both extremes can be avoided if it is made a rule that the weight of the part being gaged determines the "touch." That is to say, with the gage opened upward, lay the piece upon it. If its weight carries it down between the contacts, well and good; if it will not go through, consider the part too large. By carrying out this idea, both cylindrical and screw thread work will improve in uniformity greatly.

The ordinary questions of size and touch, which are comparatively simple in cylindrical work, become complicated when screw threads are reached. Here we have both diameter and lead to contend with, and a changing angle of helix adds to the difficulties. I recently saw a machine operator testing ½ inch U. S. S. screws as they came from the screw machine with a female thread gage. The screws fitted with a good "gage fit." I tried one with a thread micrometer and it measured 0.444 inch, or 0.006 inch too small. The operator explained that he thought the "mike" was out of whack. Taking the screw to a "lead tester," it developed that the die was cutting a long lead—about 0.005 inch over size. Now perhaps an experienced inspector would know that a variation in lead on an undersize screw would compensate for the undersize in diameter and (apparently) equalize the fit; but hardly any machine operator realizes it, or ever stops to puzzle out the reason why. Hence, there are places and conditions where a female thread gage is apt to contribute to defective work rather than to avoid it.

In perhaps the majority of cases where constant testing of a machine product is needed, gages of the fork or crescent type for screw threads are far better than female thread gages. But it must be borne in mind that such gages only test the pitch diameter of the thread. They do not take account of variations in lead any more than a thread micrometer does. But, given a die that cuts close to the normal lead, the fork or crescent gage enables an inexperienced "hand" to test the threads (every one) in a mere fraction of the time required for testing in a female thread gage. The care of gages and frequent comparison with standards (which are used for no other purpose) is given scant attention and yet both are of vital importance. Where a working gage is in more or less constant use every day, better results will ensue if at least two are provided, giving out to the workman a new gage each morning, and keeping the one used the day before in the inspection department for comparison with the standard and adjustment if any is needed, having it ready for use again the next day. The chief inspector should also be provided with setting plugs for every size and gage in use. It would be advisable to have these setting plugs certified by the Bureau of Standards at Washington.

It is really astonishing to find how little attention is paid, in this country, to our fundamental unit of length. A factory

* Advertising Manager, Wells Bros. Co., Greenfield, Mass.

wants some gages; they are bought from some gage manufacturer and purport to be a certain fraction or decimal of an inch. The factory accepts the gages, takes it for granted that the gage maker is working to the right standard (or else they give it no thought whatever) and proceeds to work up their material to fit those gages. But the whole scheme depends upon how long an inch is. The inch is a legal dimension in the United States, legally established and legally maintained with extreme care, and at great expense, by the Bureau of Standards. I care not how painstakingly a manufacturer preserves his primary standard (so-called), if it does not agree with the Bureau of Standards, he's wrong—just as wrong as the farmer who measures with a bushel basket containing only 2135 cubic inches. And yet, in the face of this undeniable fact, it is unusual to find even a gage manufacturer equipped with certified standards. The day is coming when it will be expected and required of gage manufacturers to supply comparison standards bearing the certification of the Bureau of Standards to their accuracy. The gage maker who realizes this and equips for it now will be strictly in line and find a widening demand for his product. The gage maker who sneers at the legal standard and prides himself on his own carefully maintained dimensions will find himself left alone with them. The inch is $\frac{1}{39.37}$ of the international meter, and that meter is officially maintained at Washington, where, for moderate fees, gages of almost every type can be sent and compared, receiving in return a certificate as to just how much variation there is—carried down to 0.00001 inch if desired. Equipped with certified standards, any chief inspector is in position to adjust the working gages of the shop and keep them in good condition. Without those certified standards, he is at the mercy of every toolsmith and gage maker and will find himself in doubt and perplexity all the time.

The first cost of equipment often deters a manufacturing executive from ordering gages, even after he is convinced that he would get more uniform results by adopting the use of such gages. He has lived along, permitting and expecting his workmen to measure his product with their own tools, and he hates to spend the money. The answer to this attitude comes almost automatically: his competitors will produce so much more uniform work at a lower price that he will soon have no work to measure, and so will have need for neither gages nor workmen. I can point to one shop that used to test their screw machine products by micrometers, both cylindrical and thread work. It was one never-ending squabble between the inspection department and the operators. The lost time and defective work sometimes swallowed all the profit on a job. Limit gages of the fork type were installed. The limits were all carefully worked out in advance, allowance being made for the cutting action of taps, hobs, etc.; as many working gages were ordered as needed and enough more to provide one working set in reserve for unusual cases or accidents. No gage was allowed to remain out of the inspecting department over night. Setting plugs were supplied to the chief inspector, and every gage was tested for wear once a day (if used). The general reputation of that shop for precision work has improved wonderfully in two years. Over 90 per cent of former defective work has been made impossible now, and annoying disputes have ended—a most important factor in the smooth operation of the plant. The inspection cost is less than 25 per cent of its former cost and the whole outfit of gages, standards, etc., has been paid for many times by increased profits. Their precision product today costs less than their mediocre stuff of two years ago. It is all due to gages, planned right, made right, used right, and maintained right.

* * *

As another step in the development of wireless telephony should be noted the fact that messages have been transmitted by wireless telephone between the Nauen wireless station at Berlin, Germany, and Vienna, Austria, a distance of over three hundred miles. Special apparatus of new design was employed and it was possible to hear in Vienna a newspaper article read at Nauen.

TYPES OF ROTARY MAGNETIC CHUCKS*

BY O. S. WALKER†

During an experience in the manufacture of magnetic chucks, extending over a dozen or more years, our firm has constructed a wide variety of styles of chucks, especially of the rotary type where much variation in the contour of the magnetic face has been in demand. The object of this article is to illustrate and describe some of the more common forms that we have constructed to meet different conditions. The detachable magnetic face feature, which is a well-known characteristic of the Walker magnetic chucks, has enabled us to easily meet these conditions. The electrical features of these chucks are now so well known that it is only necessary for the purposes of this article to discuss the magnetic faces of the chucks and the arrangement of the magnetizing coils. In all the illustrations referred to, the positive and negative poles are indicated by the letters *P* and *N*, these poles always being separated by a narrow ribbon-like space called the magnetic gap, which is filled with non-magnetic metal.

Referring to Fig. 1, it will be seen that a circular path has been provided for the magnetic gap. This form is not only the simplest, but also the strongest possible to construct, inasmuch as the magnetic gap is the shortest length obtainable, thus concentrating the energy produced by the magnet. This style of chuck face, however, is suited for but an extremely small range of work, and while it may be extended by the construction of additional circular poles separated by similar magnetic gaps, it is impossible to locate the poles close enough together to avoid wide dead spaces for work such as rings, which would not cross over the gap from a positive to a negative pole; hence the chuck would have no holding power whatever. The evolution from the circular style of magnetic gap, therefore, has been in the direction of extending the gap radially in order that it might cover an increased range of diameters and have no circular dead spaces.

To this end the style of chuck shown in Fig. 2 was introduced, in which the magnetic gap takes a zigzag course. The fault of this construction lies in the fact that the outer points of the poles are too widely separated, forming wide areas of dead space between them. To remedy this objection, the style of chuck shown in Fig. 3, which is called the radial pole type, was introduced, this style having the sides of the polar branches approximately radial and dividing the circumferential dead spaces evenly. This style of chuck is found to be well suited for holding disks or rings of a considerable thickness, though it is somewhat unsuited for very thin work or for packing on a load of small parts on account of the outer ends of the poles being still considerably separated. To overcome this objection a six-branch radial pole type, shown in Fig. 4, was introduced, this bringing the outer ends of the poles closer together. The style of chuck face shown in Fig. 5 is a further elaboration of the radial pole type, in this case carried to an extreme in order to hold a multiplicity of small parts (especially small washers) in a circular row. Bringing the pole branches so closely together, however, has reduced the range of the chuck for holding single pieces of small diameter concentrically.

The chuck faces described in the preceding paragraphs all pertain to single coil chucks and in the following are described chuck faces which we have constructed suitable for both single and multiple coil chucks, the latter being generally used for chucks of larger diameters where it is desirable to sub-divide the magnetizing power to more thoroughly distribute it over the chuck face. It will be well at this point to call attention to the fact that excessive multiplication of the magnetizing coils in the chuck is detrimental to the action of the chuck in holding a multiplicity of small pieces, inasmuch as the intensity of the holding force of one of the small magnets of the combination is less than that of a like portion of the magnetic circuit of a large magnet of the single coil chuck. The advantage of the multiple coil

* For additional information on this subject see "The [illegible] of the Magnetic Chuck," by H. L. Thompson, published in the April and May, 1914, numbers of MACHINERY.

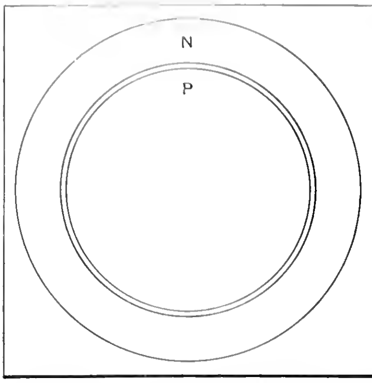

Fig. 1. Chuck with Circular Magnetic Gap

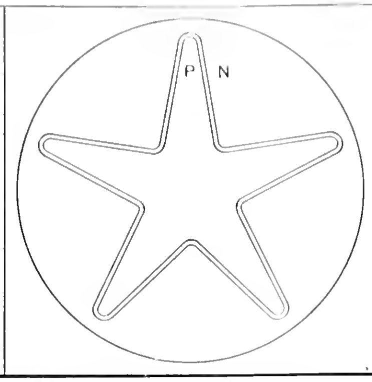

Fig. 2. Chuck with Zig-Zag Magnetic Gap

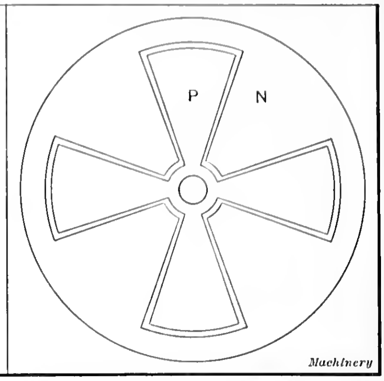

Fig. 3. Radial Pole Type of Magnetic Chuck

chuck lies in the aggregate power of the whole combination and in the somewhat shortened magnetic circuit.

Users of magnetic chucks, as a rule, desire them for a special purpose, and hence the demand for a wide diversity of styles, each of which has its particular merit. In Fig. 6 is shown a separate segment four-pole magnetic face which can be used either with single or with multiple coils, as previously mentioned. Fig. 7 shows a further elaboration of the separate segment type shown in Fig. 6. In this chuck face, the central portion, as well as the separate segments, is of positive polarity. In Fig. 8 is shown a multi-pole type of magnetic face, in which each of the positive pole segments is bifurcated at its outer and wider ends and into these separations are inserted interlocking radial teeth from the outer part of the chuck face, the magnetic gap, of course, separating the two. This construction is valuable for holding a multiplicity of small parts, as many sub-divisions are formed, with close spacing, so that the whole outer face can be utilized. This chuck face is made in the single or multiple coil styles, depending on the diameter of the chuck.

Another style of chuck face is shown in Fig. 9, this being similar to the one shown in Fig. 7, except that the central positive pole has been eliminated and in this case the inner ends of the separate positive polar segments have been brought quite near to the center of the chuck to assist in holding single pieces of small diameters. It will be seen from the preceding that still further changes in the style of magnetic faces can be made, but those shown are the ones we have found to be practicable. A very important feature in connection with the design of magnetic chucks should not be lost sight of and that is the feature of concentration of the lines of force to obtain the maximum power. The above holds true for work of considerable thickness, but for thin work the rule is often reversed as, on account of the slight cross-sectional area, only a certain amount of magnetization of the work can be effected, and it is better in such cases to extend the poles and to provide a more diffused magnetic power under the work, even though it be of less intensity.

Whatever may be the shape or extent of the magnetic gap of a chuck, its power as a unit can only be determined by mounting on it a piece of work that completely covers all parts of the magnetic gap.

TABLES OF SPIRAL GEARS HAVING A RATIO OF TWO TO ONE

BY E. S. WIKOFF*

The accompanying table gives the pitch diameter, outside diameter and center distance for spiral gears having a ratio of 2 to 1, with shafts at an angle of 90 degrees; the angle of the driving gear is 47 degrees 34½ minutes and the angle of the driven gear is 42 degrees 25½ minutes. These tables will be found convenient by those who have to do with the computing of spiral gears of this class. A great many gas and gasoline engine timing gears are of this special form, and several automobile builders are contemplating using this system. The writer has computed these tables for this special purpose and knows from his own experience with spiral and helical gear-

Machinery

ing, as employed in engine and motor timing gears, that they will prove of real value to the designer. Should a greater number of teeth or a larger pitch be required than given in the tables, multiples may be used.

Example: It is required to find the dimensions for two spiral gears having a ratio of 2 to 1, and provided with 26 and 52 teeth, 6 diametral pitch. Take the pitch diameters for 13 and 26 teeth, as given in the table, and multiply by 2, thus obtaining the pitch diameters for 26 and 52 teeth. Thus:

$$3.2116 \times 2 = 6.4232, \text{ and } 5.8704 \times 2 = 11.7408.$$

To find the outside diameter for 26 and 52 teeth, add twice the addendum to the pitch diameters just found.

Dimensions for diametral pitches not given in the table may likewise be found by proportion. For example, the dimensions for 3 diametral pitch may be found by multiplying the pitch diameters found in the 6-diametral pitch column by 2.

TWO INTERESTING PAINTS

BY J. P. S.

As the result of work accomplished by members of the chemical profession, two interesting paints have recently been placed upon the market. The first of these, known as "efkalin," is a light red paint which is applied to any machine members which are likely to run hot and result in damage to the machine. This paint shows immediately if the part is beginning to heat, by a change of color. As previously mentioned, the normal color of the paint is light red, but at a temperature of 50 degrees C. (122 degrees F.) it will become a dark red, and at 70 degrees C. (158 degrees F.) the color changes to a brown-red, while at temperatures exceeding 85 degrees C. (185 degrees F.) the color becomes nearly black. Through the use of this paint, the engineer or foreman is able to tell immediately if any of the bearings are becoming heated, without having to feel them with his hands. An important feature of the paint is that it returns to its normal light red color when the temperature of the part has dropped back to the normal point. Thus the paint will last practically indefinitely, which is an important item because the cost is rather high owing to the expensive ingredients from which it is compounded. "Efkalin" is manufactured by Franz Korn, Halle a/d S., Germany.

"Acalorin" is another interesting paint which has recently been developed by a German chemist. This paint is also used to afford protection against heat but in an entirely different way. Its purpose is to intercept heat rays given off by the sun, thus rendering rooms of a building protected by this paint from 15 to 35 degrees F. cooler than they would otherwise be. It will be obvious that this paint is especially suitable for use on roofs, windows and walls which are exposed to the sun. The paint is a light blue in color and does not have any appreciable effect on the amount of light which enters a room through windows covered with it. This paint is especially suitable for application on glass, slate, corrugated iron and other roofing materials, and also for use on large factory windows. The reduction of temperature in hot weather is the means of increasing the efficiency of employes. The workmen will be more comfortable if the rooms in which they work are not too hot, and as a result their daily output will be more nearly normal than would otherwise be the case in extremely hot weather. The paint may either be applied with a calcimine brush or sprayed onto the roof, walls or windows. The use of this paint may possibly permit the establishment of industries in semi-tropical or tropical countries where it has formerly been out of the question to employ white labor. "Acalorin" is manufactured by Koch & Gruen, Offenbach, A. M., Germany.

BENCH LEG PATENTED

The bench leg illustrated with the article "Modern Equipment for Industrial Plants" in the May number of MACHINERY, page 731, engineering edition, is covered in several important features by Patent No. 803,873, owned by the New Britain Machine Co., New Britain, Conn. This notice is published for the benefit of those readers who might infer from reading the article that the design is open to the public.

TAP FLUTES—FORGED VS. MILLED

BY HARRY E. HARRIS*

Should tap flutes be forged or milled? That is a question often asked but I do not recall having seen any answer to it in print. In a paragraph in MACHINERY for March, 1914, it was remarked that a maker of taps having forged flutes imitated the shape of milled flutes in order that the purchaser should not be adversely influenced by the fact that the flutes were forged and that, as a matter of fact, forged flute taps should be better than when the flutes are cut from the solid. The time was when high carbon steel ("cast steel") was supplied by the steel mills in such condition that hammer forging and its attendant heats and workings was practically necessary to make the steel uniform, increase its elasticity and refine it generally. This was properly done by several heats of moderate temperature and light blows well distributed and balanced. Whether done by hand or power hammer, it required a conscientious and skillful man. High heats being positively detrimental to high carbon steel, and heavy squashing blows or cold hammering being equally, if not more detrimental, the results of forging were widely divergent and varied directly with the care and skill of the operator, how long he had been standing on his feet, how late he went to bed the night before and various other things.

With the present high state of development of steel manufacture and specialization in different products for different purposes, the high-grade steel company specializing in steel for taps can today produce a material which has passed through heats, forgings, rollings, annealings and drawings that leave little, if any, room for improvement which might be secured by further forging by the tap maker. In fact, the higher the grade and carbon content of the steel, the greater would be the risk to the quality of the tap produced by any such process. The object, then, in forging flutes would be to decrease the cost of manufacturing by getting away from the high cost of milling the material away and the waste of the expensive material itself. To do this the forging must be done quickly with heavy blows and as few heats as possible (this would be a drop-forging operation in one heat) which necessitates a high temperature. High-grade steel with a carbon content great enough to produce taps of proper temper and enduring qualities is very susceptible to overheating and would cause many failures under such treatment. The alternative would be to use a lower grade steel, and in either case the gain to the user would be doubtful when compared with milled taps made from steel of proper analysis and mill treatment. In other words, the ultimate result is better and more uniform if the tap maker selects the best special steel for the purpose (testing it for vital qualities, examining its structure microscopically, and cooperating with the steel mill for improvement wherever possible) and then conserves and enhances its value by careful machining, annealing and scientific heat-treatments, than if he, in order to improve a poorer steel or cheapen his manufacturing costs, changes its form by forging.

The other half of the question is, why should the milled shape of flute be imitated if the flutes are forged? Obviously the milled form should be "imitated," no matter how they are shaped, if a milled flute of proper form is taken as an example. A large proportion of commercial taps have improperly shaped flutes, but more of that later. Forging does not produce the same accuracy as milling. More or less scale and decarbonized surface is present and a keen cutting edge is practically impossible. We forge a lathe or planer tool, but grind both the top rake and the clearance to get a tool having the proper angles to cut efficiently. We would get poor work, if any, and the tool would not last long, if we tried to use it *as forged* or if we ground but one of the two surfaces that meet at its cutting edge. But we might file or machine the tool to the proper shape, and harden it, and we would then get a tool that would work well and stand up. Then why isn't it much more important to machine the front face of the cutting edges of a tap, where each tooth has so much harder service, than to leave them rough-forged? It is. A test with a tap wrench of a tap of each kind in a

* Superintendent, Wells Bros. Co., Greenfield, Mass.

piece of cast or wrought iron will convince anyone. Try it; or if you can, put the two kinds of taps into service in a tapping machine of some sort, get production speeded up to where it ought to be and see which will give the better threads and last longer. Or you probably know without trying it.

In regard to what milled tap to imitate, one should be taken that has the combination of the greatest strength compatible with the necessary chip room, a shape or profile that in the hardening process will not tend to raise the "heel" higher than the cutting edge (thus causing "back clearance" and making the tap bind) and one which has that part of the flute forming the "rake" of the cutting edge so formed as to easily separate the chip from the metal and break it up into sections small enough to readily work out through the flute and not cause the tap to clog. I have never yet seen a truly correct form of flute described or illustrated in technical journals or books. I have tested many different kinds that have come under my observation, both in laboratory on testing machines and in commercial work under practical conditions, and while they varied greatly in efficiency, the best gave results considerably below those obtained with the ideal form. A tap having a "hooked" or curved front face on the cutting teeth such as that produced by a radius mill, or modifications of the same, produces curling chips which roll up within themselves, forming tight spirals that tend to tear the thread and jam or wedge the tap fast; the deeper the hole and the more tenacious the material the worse this action becomes. On the other hand, a tap with a straight front face to the teeth and with a small corner or radius at the bottom of the flute, will turn off a straight chip which will slide down this front face to the corner at the bottom of the flute. When the end of the chip strikes this obstruction the tendency is to resist further action, compelling metal subsequently removed to wedge into it and over it, and the metal removed will become a compressed lump, clogging and tearing the threads, and generally breaking the tap at an early stage in its use.

The proper form of flute has a front face (or "rake") to the teeth which is flat or straight for a short distance, joining a curve in the bottom of the flute which has sufficient magnitude to bend the straight chip and break it into such lengths as will prevent wedging and allow the pieces to be readily washed out with the lubricant. Greatest effective strength is not indicated by large dimensions from bottom to bottom of the flutes; that is, by shallowest milling. Too shallow milling of the flutes is cheap, making less metal for the tap maker to remove, and thus allowing him to do it at higher speed; but that is the only advantage. It has been found by numerous tests that these heavy taps, while having approximately 1½ times the torsional strength of properly milled taps, have a varying factor of safety from 0 to 2, while the properly milled tap averages over 9 as a factor of safety. To be plain, and taking ½-inch taps to illustrate: In tests on a Riehle testing machine, the heavy taps showed a maximum torsional strength of 1500 inch-pounds, and in threading a test piece they either broke under the strain or else took power of from 750 inch-pounds upward to thread the test piece; the deeper milled taps showing a minimum torsional strength of 1000 inch-pounds (due to their lighter section) averaged but 110 inch-pounds to thread the test piece.

The angle that the front face of the cutting teeth forms with a tangent drawn to the outside diameter circle of the tap is a feature of vital importance in its cutting action and should vary somewhat for different metals. These points are apparently not considered by tap makers generally, commercial taps being largely the same. However, at least one of the more progressive makers has experimented largely on different materials and has produced a standard form that will give excellent results on the most common machine shop materials. This firm also holds itself in readiness to make special taps suited to any peculiar materials or uses, and to give expert, practical advice on the subject. The angle of the back face of the land is also important, in that it is a factor in controlling any distortion of the tap in hardening and also in cleaning out chips in "backing out," although the latter function is not so important where chips are broken up instead of curled or wedged.

The writer has not attempted in this article to give rules, formulas or diagrams for producing properly shaped flutes in taps, as the matter is an exhaustive one and would require a treatise by itself, which would embrace all kinds, diameters and pitches of taps, including special gages, cutters, cutter grinders, flute grinders, etc., that are necessary. In fact, this matter of flutes parallels in importance any other step in the process of tap making, including the selection of steel and heat-treatment. It might even be said to exceed them, as a properly constructed tap of inferior steel might produce good results for a time, but a badly fluted tap of most excellent steel and temper would never be a success. A word about finish. The only excuses for fine polish on the shank of taps, aside from the fact that customers prefer it, is that it rusts less easily; the maker's trademark is stamped on the shank, the quality of the tap can be more readily seen, and the final inspector can see and throw out taps showing any defects such as slight checks or cracks. In regard to the finish of flutes: the flutes, particularly on the smaller taps, should be ground as smooth as possible, as the rougher the surface the coarser the cutting edge, and also the more surface friction resulting from the action of the chips.

PRESENTATION OF THE SEAMAN MEDAL TO GENERAL GORGAS

The Louis Livingston Seaman medal was presented to Surgeon General William C. Gorgas, U. S. A., under the auspices of the American Museum of Safety, Tuesday evening, April 28. The medal was presented to General Gorgas for his work in making the Panama Canal Zone habitable and sanitary for the workers on the canal. The presentation was made in the rooms of the American Society of Mechanical Engineers, New York City, and President Arthur Williams, of the American Museum of Safety, presided. Prof. F. R. Hutton made the presentation speech, and Dr. Norman E. Ditman and Dr. Louis Livingston Seaman recounted the work of General Gorgas as a great sanitarian. In accepting the honor conferred upon him, General Gorgas expressed the thought that the great value of the sanitary work done on the Panama Canal Zone was in showing that the tropics are inhabitable by white men. He predicted that these regions would eventually be great centers of population. Food is produced there with a minimum of effort and the labor of man is rewarded as nowhere else. With the banishment of disease these regions, which are largely uninhabitable now, would become the most important, fruitful and productive sections of the globe. General Gorgas modestly disclaimed credit for the discoveries in sanitation attributed to him. He spoke of his work as that of application of discoveries made by other eminent sanitarians and asked recognition for the four or five hundred young Americans who were his able assistants in the Panama Canal sanitation work and who in the beginning risked their lives and health in promoting the sanitary work.

NEW LIFE-SAVING RAFT

A novel life-saving raft is described in the *Scientific American*. A material known as Java kapok, a fibrous, silky material, the product of a tropical tree found in the East Indies and Java, is said to be very suitable as a filling for mattresses, cushions, etc. The best quality of kapok has wonderfully buoyant properties. The fiber is very fine and will support twenty times its own weight in water, and if enclosed in a leather or artificial leather casing, it will continuously support this weight for two months, before the water finally penetrates the mass sufficiently to make it sink. Ocean liners equipped with mattresses of this kind would be provided with what would virtually be a great number of small sized rafts. An ordinary mattress filled with kapok will easily support a man lying on it. In tests made, it has been found that a mattress covered with ordinary ticking would support a load of two hundred pounds for eight hours. It is stated that the Navy is beginning to use this material for mattress filling, but the merchant marine will not be interested until cushions and mattresses filled with kapok are acceptable instead of cork life-preservers to steamboat inspectors.

WATCH PENDANT DRILLING AND BOW-BENDING MACHINES*

AUTOMATIC MACHINES FOR DRILLING, COUNTERBORING AND TAPPING PENDANTS AND FORMING BOWS

BY CHESTER L. LUCAS†

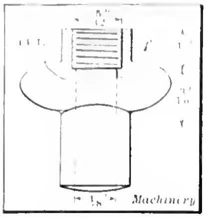

Fig. 1. Operations performed on the Watch Pendant

THE designing and building of automatic machines for making watch parts presents difficulties not found in other lines of automatic machinery construction. In addition to the automatic features to be provided for, the fact that the work is very small and must be handled carefully to avoid abrasion or distortion greatly adds to the designer's problems. In this article will be described two machines which were designed and manufactured by the Sloan & Chace Mfg. Co. of Newark, N. J. The first of these machines is for drilling, counterboring and tapping watch pendants. One of these pendants is shown in section on an enlarged scale in Fig. 1. In Fig. 2 samples of the pendants are shown before machining at *A* and after machining at *B;* at *C* is shown a different style of pendant handled on the same machine. The machine itself is shown in Fig. 4. One of the watch bows is shown before bending at *D* in Fig. 2 and after bending at *E*. The machine for bending these bows is shown in Fig. 5 and the details of the machine appear in Fig. 7. Both of these machines are extremely small, being less than two feet long in their greatest dimensions, and either one of them may be picked up bodily without much exertion.

Taking, first, the watch pendant machine and referring to Fig. 1, it will be seen that the work to be accomplished is the drilling of a hole 5/16 inch deep, the counterboring of the outside and the tapping of the larger portion of the hole as marked in the illustration. The blank watch pendants are made by hydraulically pressing a rolled-gold covered composition piece of metal. While the machine is shown as a whole in Fig. 4, it will be best to refer to Fig. 6 in order to understand its design and operation. Referring to the latter illustration, then, it will be seen that the machine is of the multiple spindle type, having three spindles for drilling, counterboring and tapping. The work is held in a turret and revolves to the different spindles. In this illustration, the turret is shown between indexings in order that none of the important parts may be hidden. Power is received at the driving wheel, a part of which is shown at *A*. At the end of this driving shaft is the miter gear *B*, that, in connection with the mating gear *C* carries rotation to the second or counterboring spindle *D*. Rotation is carried from the counterboring spindle *D* to the tapping spindle *E* through pinion *F* on the counterboring spindle that meshes with an idler *G*, and thence to the gear *H* on the tapping spindle. The reversing gear for the tapping spindle is also carried from the counterboring spindle by means of pinion *I* meshing with gear *J*. Rotation is carried to the drilling spindle *K* by means of a belt *L* directly on the tapping spindle.

The watch pendants are held in the four stations in the turret and the turret is rotated by the indexing shaft *M*. Midway between driving wheel *A* and miter gear *B* on the driving shaft is a worm that meshes with a worm-wheel *N* on the indexing shaft *M*. At the lower end of the indexing shaft is the segment gear *O*. The teeth on segment *O* mesh with those in the turret gear *P*. By means of the worm and worm-wheel, indexing shaft *M* is slowly and continuously rotated. As, however, the movement of the turret can only take place when the teeth in the segment are in mesh with gear *P*, the indexing takes place but once during each revolution of the indexing shaft. During the time that the segment is running idle, the turret is locked in position by a locking bolt that engages one of the four tapered slots cut in the disk *Q* that is integral with the turret gear *P*. The locking mechanism

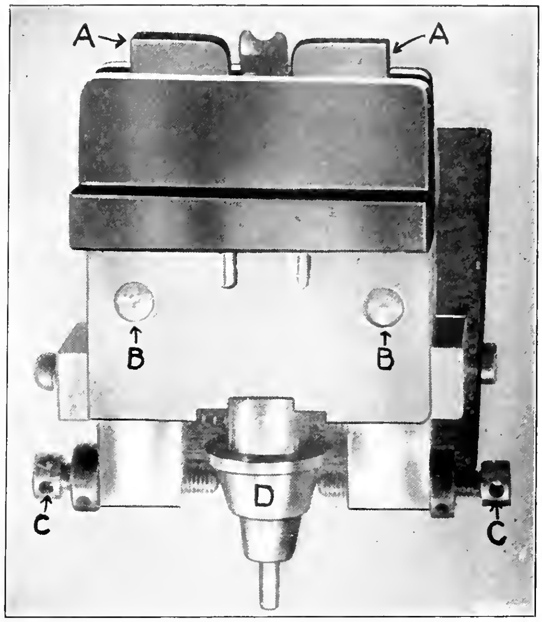

Fig. 3. One of the Turret Chucks

is concealed beneath the indexing segment but its manipulation is very simple, being operated from a cam on the lower part of the indexing shaft.

The turret rotates upon a stud mounted on the base of the machine. Each of the four stations on the turret is provided with a chucking fixture *R* in which the pendant is held and a chute *S* that serves to conduct the finished piece away when at the ejection point. One of the chucking fixtures is shown separately on a larger scale in Fig. 3. This type of fixture provides for an automatic chucking of the pendant as well as for the automatic loosening of the jaws from the work and the ejection of the piece. These movements are accomplished by having the two gripping jaws *A* of the fixture, as shown in Fig. 3, pivoted upon studs *B* that pass through the body of the fixture. The bottom ends of the jaw levers are fitted with adjustable screws *C*. The points of these screws project inward and are acted upon by the tapered plunger *D*. Any upward movement of the taper plunger allows the jaws to open and continued upward movement causes a rod to rise and eject the piece from the jaws. Referring again to Fig. 6, the method of operating the chuck will be seen. The fourth

† Associate Editor of MACHINERY.

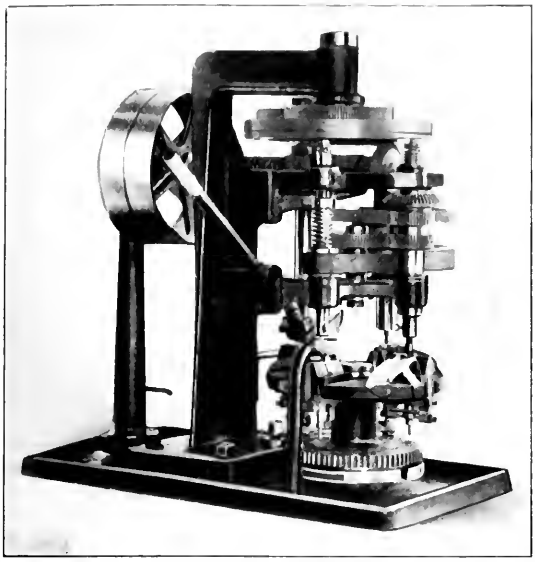

Fig. 4. The Pendant Drilling, Counterboring and Tapping Machine

station of the turret, at the rear, is for the purpose of ejecting the machined pendant and taking on the new blank pendant. At the time of indexing, when the turret is turning and the completed piece is approaching the fourth station, the lower end of the chuck plunger comes into contact with a gradually ascending grooved track *T*. As the piece approaches the ejecting point, the plunger is, of course, rising and allowing the jaws to open; at the same time the plunger raises the pendant in the chuck so that all that is necessary is for it to be swept out of the way. Ejecting lever *U* is operated upon by cam *V*. When the pendant has been raised in the chuck and is ready for ejecting, a sharp drop in cam *V* allows the ejecting lever to be pulled against the pendant by spring pressure, thus knocking it out of the chuck and down chute *S* into a receptacle placed there for the purpose of catching the finished work. The gradual ascent in cam *V* brings the lever back into position for ejecting the next piece that will be finished. The pendants are fed to the machine through a tube *W* which is of the right section to admit the pendant blanks but will not allow them to turn in the tube. At the bottom of tube *W* is the latch *X*. This latch is for the purpose of allowing but one of the pendants to drop from the tube and into the chuck at each loading time. This latch is operated by a cam lever *Y* that is located on the indexing shaft.

The method of feeding the spindles downward for the cutting action is interesting and the three spindles are all operated from the cam plate *Z*. The cam plate is turned by means of spur gearing from the top of the indexing shaft. The ends of the three operating spindles are rounded over and bear against separate cam sections upon the under side of this cam plate. By means of spring pressure the ends of the spindles are kept normally in contact with the cam surfaces. As cam *Z* turns, the inclined faces of the cam paths cause the spindles to descend in their brackets, thus advancing the tools in the work. At the end of each cut an abrupt drop in the cam paths allows the tools to jump back out of the work and leave the field clear for indexing. The changing of the tapping spindle direction from forward to reverse is accomplished by means of a friction within the spindle. This friction is operated from the cam plate and when the spindle has reached the limit of the tapping operation, the engagement of the friction clutch causes the reversing gears to act on the spindle and back the tap out of the work.

The operation of the machine is as follows: Loading cam *Y* operates the latch on the feed tube and allows one pendant to drop into the open chuck. Indexing now takes place, the chuck jaws grip the work and it is carried to the drilling station. The drilling takes place while the counterboring and tapping operations are proceeding on other pieces and then the turret indexes, bringing the drilled pendant to the counterboring position. At this point the outside of the pendant is counterbored as shown in Fig. 1 and a subsequent indexing brings it into the tapping position while another pendant blank is chucked and goes to the drilling position. Here a 5/32-inch tap, 64 threads to the inch, taps out the upper

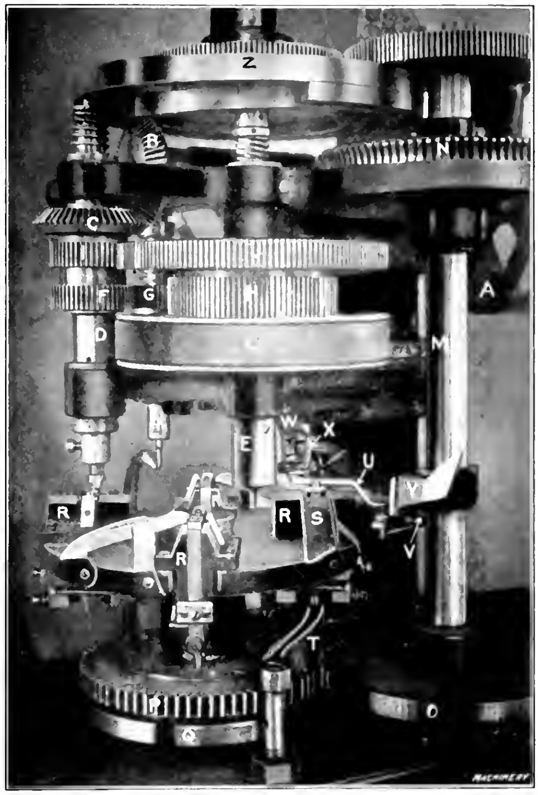

Fig. 6. Details of the Pendant Machine

section of the hole, after which the last indexing brings it into the ejecting position. At this point the ejecting lever comes into action and sweeps the piece from the chuck into the chute and out of the machine. Just after the ejecting operation takes place, the loading cam operates the latch on the tube and allows a new piece to drop into the chuck. Thus one piece is finished at each indexing.

The operation of the machine is entirely automatic after the pendants have been placed in the feed tube. The machine can be used for different types of pendants and, in fact, by proper tooling, for any work requiring similar drilling and tapping operations.

A Machine for Bending Watch Bows

In the lower part of Fig. 2 at *D* is shown the blank for a watch bow. This, it will be noticed, is thinned down at the

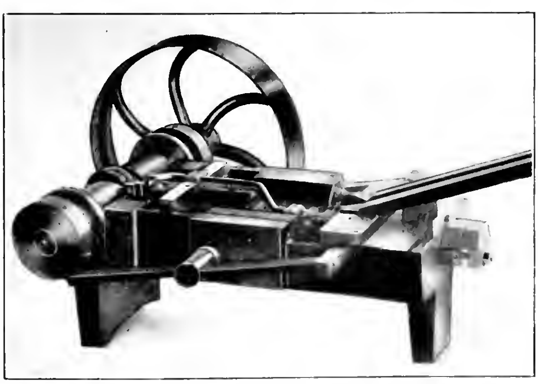

Fig. 5. The Watch Bow Forming Machine

ends so as to leave the central portion of the link of the correct thickness. The wire stock used is rolled gold and the ends are thinned down by swaging. At E in the same illustration is the bent watch bow, and it is for the purpose of performing this bending operation that the machine illustrated in Fig. 5 was designed and built.

The details of this machine may best be seen by referring to the enlarged illustration, Fig. 7. This shows the machine as viewed from above, and those familiar with wire working machinery will recognize that it works on the same principle as the four-slide wire forming machine. The straight blanks for the bows are fed down the inclined chute A. Directly under this chute is a semicircular stationary forming tool. This is not shown in the photograph. The principal forming tool or arbor B is located on the ram C of the machine. This ram has, at its extreme rear end, a roll D that is acted upon by contact from a cam E on the crankshaft of the machine. The function of this cam is to advance the ram and the forming tool on it. The ram is re-

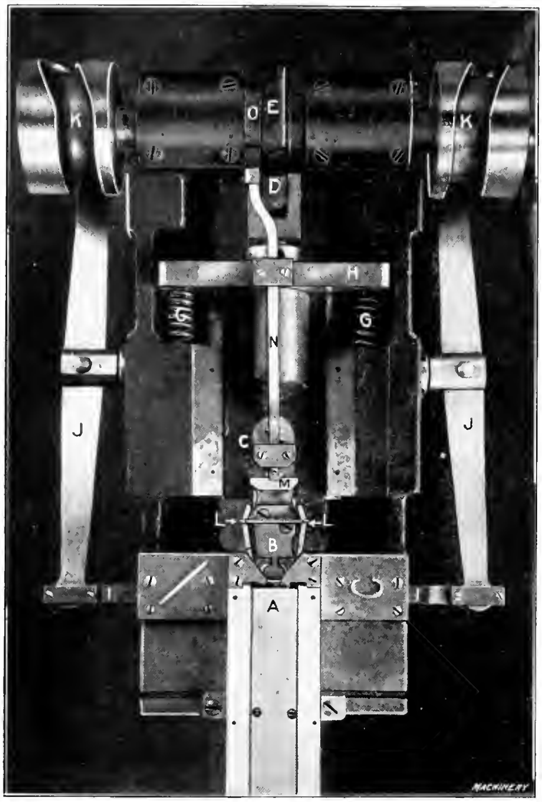

Fig. 7. Plan View of the Watch Bow Machine

turned by springs G that bear against a plate H, keeping roll D always in contact with the cam on the driving shaft. There is a dwell on cam E that serves to keep the forming tool B and the bow that it has pushed into the semicircular stationary forming tool in its innermost position, while the side arms I, actuated by the long operating levers J, come in from the sides and force the ends of the wire around forming tool B. These levers are operated from cams K on the driving shaft. As soon as tool B is withdrawn by the spring action of the ram, the formed bow drops from the forming tool B to a box beneath the machine. The slight spring of the wire is sufficient to loosen it from the arbor, and as the entire lower half of this arbor tapers sharply, the bow drops off by gravity.

An interesting feature of this machine is the method by means of which the blank is centered in relation to the forming tools. As soon as the blank drops down into the bending position its ends are caught between spring fingers L. These spring fingers are evenly brought together when the ram advances, just before the bending takes place, by means of a wedge shaped block M. This wedge shaped block is, in turn, pushed forward by lever N that is operated by a cam O on the crankshaft. This centering action takes place just before the bending tools start to act upon the wire and insure that the ends of the link are bent, leaving them the same length. Like the watch pendant turning drilling machine, this machine is entirely automatic after the blanks have been placed in the chute.

APPROXIMATE RULES FOR STEEL BEAMS

Some useful approximate formulas are to be found in a paper on "Calculations and Details for Steel-frame Buildings from the Draftsman's Standpoint," recently read before the Concrete Institute (Great Britain) by W. C. Cocking. The author states that the section modulus of an I-beam is given approximately by the expression:

$$M = \frac{W_s\, d}{10}$$

where W_s denotes the weight of the section in pounds per foot run, and d its depth over flanges in inches. The safe load on a 1-foot span for I-sections is approximately

$$\frac{W_s\, d}{2},$$

the corresponding stress being 7½ to 8 tons per square inch.

For I-beams used as pillars, the safe load is approximately equal to the safe load per foot run on a span, which measured in feet is equal to twice the width of the flange in inches, the load being taken as applied laterally, and the column considered as fixed at both ends. For a stress of 7½ tons per square inch the section modulus required is $M = 0.2\, w L^2$, where w denotes the load in tons per foot run, and L the span of the beam in feet. The approximate weight of a beam to carry a given load is:

$$W_b = \frac{W L^2}{1000\, d},$$

where W_b denotes the weight of the beam in tons, W the total equivalent uniform load in tons per foot run, L the span in feet, and d the depth of the beam in inches. The weight of a column is approximately:

$$W_p = \frac{W L}{C},$$

where C is 2500 for both ends fixed, and 2000 for one hinged and the other fixed. In this case W denotes the total central load on the column, and L its laterally unsupported length in feet. The weight of a beam-casing is approximately:

$$W_c = 0.00035\, b\, d\, L,$$

where W_c = total weight of the casing in tons, b the breadth, and d the depth, both in inches, while L is the length in feet. The same formula applies to columns. For calculating the effect of eccentric loads on columns, Mr. Cocking recommends the following factors: For I-sections the equivalent central load

= 1½ times eccentric load if latter is connected to the web of the I-beam,

= 2½ times eccentric load if the connection is to a flange.

The corresponding factors for an I-beam column with plates over each flange are 1¼ and 2½, respectively. For a double I-section, with plates riveted to each flange, the factor is greatest when the connection is made to the web of one of the I's and may be taken as 2¾ times the eccentric load.

The Detroit Executives Club was recently organized in Detroit for the purpose of determining how the efficiency of local organizations can be increased. E. St. Elmo Lewis of the Burroughs Adding Machine Co., Detroit, is the chief promoter of the idea. The club is at present in a formative stage. Primarily it will be composed of fifty members of as many different organizations in Detroit, and only those who are invited to join will be made members. The object of the club is to study efficiency, scientific management, welfare work, methods of employment, etc. One subject will be taken at a time, and exhaustive researches will be made in factories all over the country.

A GAGE LIMIT SYSTEM FOR GENERAL WORK

BY FRED W. MC ARDLE*

The system of gage limits here described was devised for use in an engineering office which specializes on general machine design. The various machines designed are built in different factories, depending on the client for whom the work is done, and often without supervision by the engineer; so it is evident that any system of limits used must be simple and readily understood. When a new machine is designed it is almost impossible to make a set of drawings so complete in detail as not to require more or less explanation, and one of the most important items is that of fits. It is not sufficient to give nominal sizes on a detail, as it then leaves the matter to the judgment of the individual machinist as to whether a stud, shaft or other part shall be up to size, over or under. If the man is a careful workman, he either refers it to his foreman, who as likely as not knows little more than

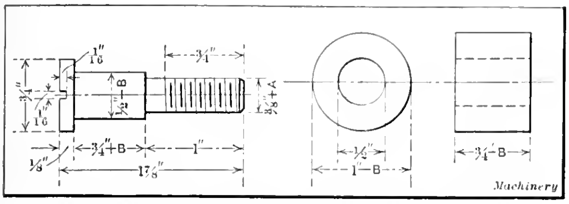

Fig. 1. Examples of Details showing Use of Gage Limit System

GAGE LIMITS.

All holes are standard reamer size unless noted.

Machinery

Fig. 2. Form of Gage Limit System for General Work

he does about the matter, or he makes it "full" to allow for final fitting.

In either case there is a loss of time and added expense. This is equally true if parts are designated as "running" or "driving" fits, for still the machinist must use his judgment, which is apt to be such as to leave him on the safe side. If instead of following this practice, the sizes are given in thousandths, with or without limits of variation, it often occurs that the work will be built in a small factory unaccustomed to such specifications, and the cost will be increased by the extra care that is taken with parts that do not require particularly close work, solely because the job bears the hall mark of accuracy on some of the parts. The latter method has the additional disadvantage of causing extra work in placing the limit sizes on the drawing. This, of itself, is something of an item on any design requiring a considerable number of details.

Experience with these and kindred difficulties led to a tentative method that has been developed into a system, in no sense perfect, but one which can be readily used in general work, and which insures good work without fitting or questions as to fits; these are decided by the designer and indicated in a way that is easily understood by the workman. This result is accomplished by affixing to all dimensions which require limiting, a plus or minus sign and a letter, *A*, *B*, or *C*, which indicates the amount of variation; plus indicating over nominal size and minus indicating under size. A rubber stamp giving the data presented in Fig. 2 is used on each detail sheet and the various details are marked accordingly, with the result that the machinist makes a part regardless of fits, and each individual part is made without the disturbing element of thousandths on some other part.

The gist of the method is this: If a dimension has a plus letter after it, it must be up to size or over, within the limits called for by the letter. Similarly, if a dimension is followed by a minus sign, it cannot be over size and may be under, according to the letter. A finish dimension without plus or minus letter indicates that the size is nominal, and ordinarily careful work is all that is required. Slots and depressions that would be measured by a plug gage may be considered as holes, and come under the heading "all holes are standard reamer size unless noted." Working on this basis, studs, shafts, slides, etc., are marked minus if a running fit, plus if a driving or press fit, and the limiting letter according to the judgment of the designer. Both the plus *A* and the minus *A* dimension may ordinarily be considered as plug size, with this difference that the plus sign would be used where it was essential that the part be absolutely rigid, as in the neck of a stud where it fastens or is screwed in to another part, making it integral; the minus sign would be used where a part is subject to frequent removal, as in a stop plug or other part where ease in removing is essential. If preferred, however, plug sizes may be specified in thousandths, which of course would admit of no variation. Drilled holes are so marked, and cored holes should be specified. Fig. 1 will illustrate the application of this method to detail work. The roll shown is a running fit on the stud, and it is evident that the two details may be made independently and yet work together without subsequent fitting. It will be noticed that limits are given, both on the length of the shoulder on the stud, and on the width of the roll, and this apparently departs from the general method described. It seems advisable, however, to allow variation when possible, rather than absolute sizes, and in such cases as this, side clearance may be split up between the two details with satisfactory results.

Since the adoption of this method, two machines radically different in class have been designed, and the form shown in Fig. 2 could not be used without modification. One of these machines was of a character that forbade a maximum variation of more than 0.002 inch; the other was of an exactly opposite character, being used on heavy work, subjected to the action of water, and lubricated with heavy grease. In the latter machine a maximum variation of 0.015 inch or even more was allowable, without affecting the action. To meet these conditions, the same rubber stamp was used and the values of the limiting letters changed, as shown in Fig. 3.

After a year or more, it has been found that little or no explanation is required when a drawing marked as described

GAGE LIMITS.

All holes are standard reamer size unless noted.

Machinery

Fig. 3. Special Forms of Gage Limit System for Fine and Rough Work

is put into the shop; moreover, the men seem to take kindly to it. In estimating costs, it is found valuable as an aid to the contractor in getting a closer figure than would be obtainable where nicety of finish would be a matter of guess work. Finally, one additional safeguard is given both to the designer and to the machinist. Errors are almost certain to occur either in the shop or drafting-room, or in both. The writer has a case in mind where cumulative errors in finish, any one or two of which would have had no effect, resulted in apparent discrepancy which affected to a considerable extent the working of the parts. In going over the work it was found that fits were made according to the judgment of

* Address: 704 Paddock Bldg., Boston, Mass.

the man making the piece; in making fits he kept on the side of safety, and no blame could be attached to him for his work. In several parts all fitting on the safe side the net result was over size. Apparently it was a mistake of the draftsman, until the drawings were shown to check up correctly. The only thing that could be done was to alter the parts affected in order to make the machine operative, and there remained a lurking impression in the minds of both the builder and the man who paid the bills that somehow it was the fault of the draftsman, but that he had got out of it on a Scotch verdict, "not proven." The method described may be improved and amplified, but the results obtained from the present form are such that it has been thought inadvisable to introduce additional complication.

PROFIT-SHARING AND CO-PARTNERSHIP

An interesting report on profit-sharing and labor co-partnerships has been issued by the British Labor Department of the Board of Trade and is reviewed in a recent number of the *Mechanical Engineer*. This report indicates that under present industrial conditions, co-partnerships and profit-sharing are successful only in exceptional instances. It shows that, as far as the engineering and allied industries are concerned, the present outlook is discouraging. Out of six mining and quarrying companies that started on a profit-sharing basis, the co-partnership scheme has been abandoned. In the metal trades, out of nine firms that started profit-sharing arrangements only one still employs the method, and out of twenty-one engineering and shipbuilding firms, only four still maintain the system. The only trade or industries in which schemes of this kind seem to be successful are those in which the company has more or less of a monopoly and in which the profits are almost assured from the beginning. As an example of this may be mentioned gas works, where out of thirty-four cases reported, in only one instance has the profit-sharing been abandoned. France is the country in which methods of this kind have been longest in existence; in fact, its oldest profit-sharing undertaking dates from 1820. In Germany, profit-sharing has made little progress and many of the arrangements introduced have been comparatively short-lived. Thus, out of fifty-four profit-sharing instances recorded in 1878, only nine were in existence in 1901. At the present time, there are only thirty profit-sharing institutions known to be in existence in that country; twenty-one of these undertakings for which particulars are available employ about 15,000 people. In the United States there are about twenty-five or thirty firms that have introduced profit-sharing schemes, and some of those that have done so are very large. A general survey would therefore indicate that at the present time there is little hope of relieving industries from labor difficulties by arrangements of this kind. A much better method would seem to be the Canadian provision for public investigation and publication of all the facts when differences arise between employers and employes.

* * *

Every new movement is attended by quackery, and no matter how meritorious it may be, the effect of the fakers engaged in promoting it for large personal gains is to discourage and retard its legitimate development. Scientific management of manufacturing plants is no exception. In fact, it has suffered severely from the absurd methods and claims made by "efficiency engineers" who have exploited it to their own profit and the loss of concerns who have engaged their services. The possibilities of scientific management properly worked out are almost unlimited, but they will be realized in the greatest measure when it is developed by practical men who are able personally to do the work they aim to direct. The result of malpractice in efficiency betterment is reflected in the fact that some concerns actively engaged in the study of production methods will not admit that such work is being done for fear of being discredited in the eyes of their workmen. The study is carried on unobtrusively by men who do not pose as "efficiency experts." No radical changes are made, but when the weak places are found changes of method are made gradually.

REDUCING LABOR COSTS BY BROACHING*

BY A. B. CORMIER†

The rough forging for a bearing ring and one of the finished rings are illustrated in Fig. 1. In machining these forgings, a prominent automobile parts manufacturer has reduced the labor cost materially by the application of broaching in machining the inside surfaces and the four holes through the ring. In this article a description will first be given of the methods now employed in machining these forgings, after which a comparison will be drawn between the present method and that formerly employed, with the object of showing how the saving of time was made possible by the change.

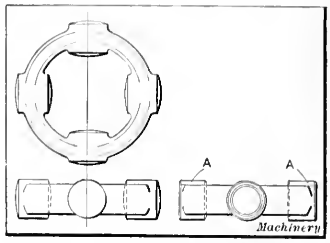

Fig. 1. One of the Rough Forgings and a Finished Ring

The rough forgings are made from 0.25 to 0.30 per cent carbon open-hearth steel. The first operation consists of machining the surfaces *A* which come in contact with the fixture used in broaching the inside of the ring in the second operation. The broaching fixture consists of a faceplate which holds the hardened steel block *B*. This block guides the broach, and the finished surfaces *A* on the forging are also held in contact with the block to locate the work properly. A set of three broaches is used; the first broach takes a coarse chip because the cut is relatively narrow; the second broach takes a finer chip; and the third broach, which has the maximum width of cut to deal with, removes but 0.001 inch of metal. The last seven teeth of this broach are straight while only the last three teeth of the first two broaches are straight. Accuracy in this operation is particularly important because it is not only employed to finish the forging, but the four surfaces finished by broaching are used in locating the work for all subsequent operations.

The duplex milling fixture on which the third operation is performed is illustrated in Fig. 3. The forgings are

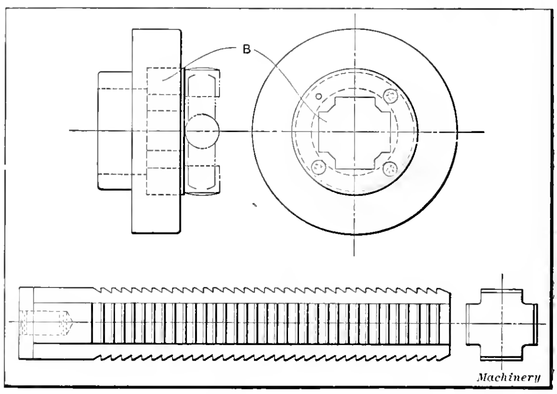

Fig. 2. Broaching Fixture and One of the Broaches used for finishing the Inside of the Forgings

located on hardened plugs *C* and clamped down against the surfaces *A* which were machined in the first operation. The two work-holding plugs of this fixture are indexed simultaneously by means of spur gears *D*, and the blocks are located in position by means of tapered plungers *E* controlled by operating screws. The milling cutters are employed to finish the outside faces of the forging corresponding to the

* For additional information on broaching previously published in MACHINERY, see "Broaching a Dovetail Key-seat in a Taper Hole," February, 1909; "Broaching Automobile Parts," April, 1909; "Broaching a Connecting-rod End," June, 1912; "Broaching the Square Holes in Vise Bodies," February, 1913; "Broaching Automobile Parts," June, 1913; "Broaching Vs. Reaming," by F. J. Lapointe, February, 1914; "Broaching vs. Reaming," February, 1914; and "Broaching Round Holes," March, 1914.

† Address: 124 Bushnell St., Hartford, Conn.

four inside faces which were finished by broaching in the second operation.

After completing the milling operation, the forgings are taken to a four-spindle semi-automatic horizontal drilling machine of special design where four 31/32-inch holes are drilled in each piece. The work is held on a hardened plug *F* of the fixture shown in Fig. 4. The plug has holes in it to admit the drills when they pass through the work. After the holes have been drilled on this machine, the forgings are transferred to another broaching machine where the four holes are broached to 0.999 inch in diameter. In performing this operation, the work is held on a hardened plug *G* of the fixture shown in Fig. 5. This plug also has holes in it to allow the broach to pass through in finishing the holes on opposite sides of the forging. Nothing in the way of an indexing mechanism is attempted on this fixture, the work being lifted off the plug and replaced in position for broaching the other two holes.

After the broaching has been completed, the forgings are burred by the tool shown in Fig. 6. The lower burring cutter is made with a square hole in it. This cutter is placed in position and the arbor with the fixed cutter mounted on it is entered through the upper hole in the work and moved down until it enters the hole in the lower cutter. After the operation has been performed in this position, the work is moved three times in order to burr the other three holes. One operator is employed for each of the operations except those of milling the outside of the forgings and drilling the holes, these two operations being performed by one man.

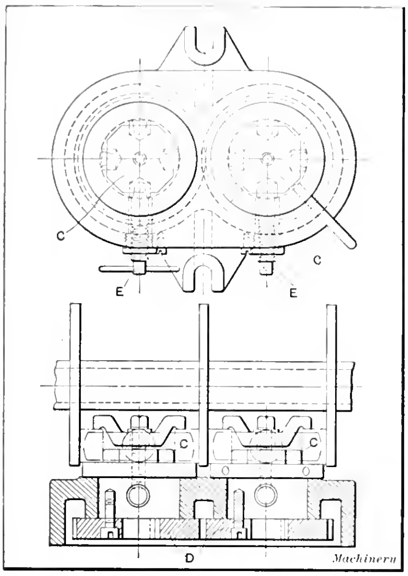

Fig. 3. Duplex Fixture for use in milling the Outside Faces of the Forgings

The original method of machining these pieces was to first drill and ream the holes on a four-spindle drill press provided with two drills and two reamers. Four box jigs were used in a row on this machine. The second operation consisted of profiling the inside of the forging, a fixture being used for this purpose which had four locating pins. In the third operation, the square hole was broached to the required size, the work being located by a fixture with four pins as in the preceding case. The fourth operation consisted of rough- and finish-milling the outside faces of the forgings on a hand miller, which milled one face at a time.

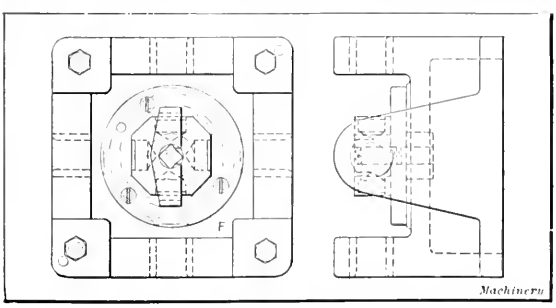

Fig. 4. Jig used for drilling the Four Holes in the Forgings

In the fifth operation the holes were broached to the required diameter of 0.999 inch, and after this had been done the final operation was performed, which consisted of burring the holes by hand.

A great saving of time has been effected by adopting the new method. Through the use of special four-spindle semi-automatic drilling machines, one man is able to finish eight holes in the time formerly required to drill and ream two holes. The substitution of broaching for profiling in finishing the inside of the forgings has not only effected a saving of time, but it requires less manual labor and produces more satisfactory work. There was a tendency to chatter in finishing the inside of the forgings on the profiler. The new milling operation has also been the means of effecting a great saving of time. We were at first under the impression that the length of cut was too short to allow the work to be handled efficiently with power feed, but it was found that when hand feed was used the operator pushed the work across the cutter at a greater speed than was necessary, the result being poorly finished work. As previously mentioned, only one roughing cut is now taken which gives a very nice finish.

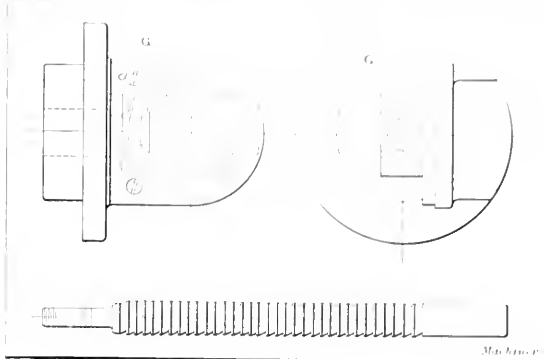

Fig. 5. Broach and Fixture used for broaching the Four Holes in the Forgings

In order to obtain the most efficient results, particular attention has been paid to the grouping of the machines in order to allow the work to be transferred from one machine to the other as rapidly as possible. The arrangement is such that when the work is finished on one machine it is laid down within easy reach of the operator of the next machine and so on until the last operation has been performed. This method of grouping is, of course, only possible in factories which specialize on standard products.

* * *

It is interesting to note that in the battleship machinery of today there is not found the great amount of copper, brass and gun-metal that was common in ships built twenty years ago. In the propelling machinery of the modern battleship, the weight of non-ferrous metals today equals about 17 per cent of the steel and iron, whereas twenty years ago the non-ferrous metals in the propelling machinery amounted to about 34 per cent of the weight of the steel and iron parts. Except for the very smallest pipes, for example, copper steam pipes are not used in the most modern types of battleships. Gun-metal ends for condensers have also disappeared and the condenser shell is made from sheet steel, which is lighter, although not so durable as gun-metal. It has, however, sufficient life as compared with the probable life of the battleship. In the whole structure of the vessel, however, the proportionate amount of the non-ferrous metals has not been reduced as compared with twenty years ago, on account of the increase in gun turrets, fire control appliances, electric lighting, telephones, etc., where non-ferrous metals are advantageous or necessary.

ON INDUCING OURSELVES AND OUR MEN TO EARN MORE MONEY*

SOME POINTS ON SECURING EFFICIENCY THROUGH COOPERATION OF EMPLOYER AND EMPLOYE

BY J. C. SPENCE†

THE record of the recent past and the evidence as to the immediate future point to the fact that if the American machine tool industry is to compete for the best workmen, there must be a change in our methods. Competition with Europe and within the trade precludes the possibility of any great increase in the selling prices of our products. The changes, then, must take place within our organization; we must get more salable goods per dollar of investment, and this result must be attained, not by a decrease in the earnings of all concerned, but by an increase, else we will gradually lose the best of our men to such other industries as have, at present, a larger margin of profit. This movement has already made inroads into the field of good machinists, and everyone is familiar with the statement that "we can't get the kind of man that we could some years ago." This lack of good men is, of course, not due entirely to the fact that other industries are offering better opportunities, but is more or less influenced by the growth of industry in general being faster than the supply of trained men can keep pace with. Nevertheless, one industry in particular is taking from us many of our brightest young men, and is taking them almost entirely because of wages. Granting, then, that conditions will remain practically as they are, the only method by which we will keep the personnel of our particular industry in the highest class is by the offering of greater wages. The mere act of holding a job has ceased to be the all-important inducement.

Inefficiency of Workmen

Whenever the word "efficient" or "inefficient" has been used as applying to our line of work, the natural tendency has been for all minds to turn to the shop end of the business, especially to the man who runs a machine. Practically all of the illustrations by means of which our eminent experts have arrested the attention and gained a permanent lease of the ears of managers and board of directors have had to do with such perfectly awful incidents as a shaper tool taking a 5-inch stroke when a 3⅝-inch stroke would have been sufficient. I hold no brief for the man who cuts air when he should cut metal, but to my mind it is no more than right that we should first look to ourselves to see wherein we fall short of the mark of 100 per cent. If the workman is not efficient, just what is our share of the cause of his inefficiency?

First, let me say, that it is my firm belief that the large majority (if I were to state a percentage I would say 90 per cent) of all machinists employed by the National Machine Tool Builders' Association, are endeavoring to give an honest day's work. That they do not produce more work than at present is largely the employer's fault—so much so that it is going to take the whole of his attention to certain details before he can induce his men, and hence himself, to earn more money. I am saying this from a mind that only a comparatively few years ago looked at the workman's side only of this question. I am not so far away from the operation of a machine that my memory has become dulled to what went on when I was trying to produce against obstructions allowed to stand in my way by my foreman and his superiors.

The metal cutters, or chip makers, on the simpler class of work, may be assumed to be fairly efficient in most of our shops. It has been a comparatively easy matter to set standard times or prices on these operations. There is still a good field for improvement in the making of drawings, especially for the workman's use. I'll venture to say that in every one of our shops today there are blueprints that the "old man" himself would not recognize as showing a part of his own inventions, if someone should cut the title corner off, and as for settling where the machining should begin he would have to lose a good many minutes in study. Even the simpler drawings are a puzzle to the beginner and the foreman cannot be in all places at once. We should point out, on our drawings, by the copious use of English and by means of routing sheets, just what the workman is expected to do. Most of the shops that I have seen are open to this criticism: We are all drifting along, to some extent at least, in the old way of leaving a workman to his own initiative to find ways and means of doing a great share of the operations. The draftsman who learns to make drawings with the idea of saving time in the shop gradually makes of himself an engineer in the true sense of the word, because in order to tell how a piece should be made, he first has to learn by consulting with those who do know. He is inducing himself to earn more money. The foreman who is fortunate enough to have his blueprints come to him in such form that the more intelligent of his men need little personal instruction and supervision has more time to devote to the weaker members of his gang and his department output is higher—consequently, his own value increases.

Putting the Workman in Business for Himself

Right in line with this plan I recently tried an experiment that is interesting because it is illustrative of exactly what is going on in many shops, and is causing the loss of a lot of money. A quantity of a certain small piece was sent to us by another firm to be ground. We had quoted on the work and there was a price we had to meet. As usual, in such cases, before letting the work start in the shop we sent along with the pieces a routing sheet, which told how many pieces per hour we had estimated to be a fair production. The pieces were produced inside of the time limit and the net cost per piece was 1½ cent. Several months later a lot of the same pieces came in, and these were put into the shop and ground by the same man, but without anything to tell him what was expected of him. The second lot cost 2 cents each. Now the operator was not dishonest. I do not believe that he intentionally held back. He simply wasn't in business for himself. He would have produced those pieces for 1½ cent if there had been any means supplied for concentrating his mind on the job. Even if he had run into an obstacle that he couldn't overcome, he would have called for help quickly, in order to protect his own record. As it was, the time drifted by without his having a very clear idea of anything in particular. You have to get the man interested, and there's only one way—put him into business for himself. How this is to be done, whether by premium or by piece-work, matters little, provided you see to it that more product means more wages. There is just this much about it—those who stick to a straight-day work system, unless ways are devised for periodically rewarding increased efficiency, will lose their men to the shops that succeed in putting every man into business for himself.

I know of a shop that has reduced the cost of erecting its machines as shown by the following table, by doing two things: first, by giving up the old, slipshod method of starting to erect before everything was ready, and second by putting the assemblers into business by giving them a generous bonus for speed.

Machine	Old Cost, Average	New Cost, Average	Machine	Old Cost, Average	New Cost, Average
No. 1	$43.73	$22.62	No. 4	$36.78	$18.25
No. 2	45.01	19.78	No. 5	41.26	18.84
No. 3	45.21	18.26	No. 6	32.35	18.97

The bulk of this reduction was due to the fact that all the parts were ready before the erecting was started, but a lot of the saving came from putting the men into business. Where they were formerly paid $3 a day, at day rates, they now earn about $4.50 per day, and it would be a difficult task to try to hire one of those men to go back to the old $3 job, even if he were guaranteed less exertion per ten hours.

An incident reported to me by the foreman of that job shows how it works out. He overheard one of the assemblers

* Paper read before the National Machine Tool Builders' Association convention, Worcester, Mass., April 23, 1914.
† Superintendent, Norton Grinding Co., Worcester, Mass.

using rather forceful language to a truckman. It seems that the truckman had been sent to the stores to get a certain mechanism that was to be the next one to go onto the machine. He arrived there at about six o'clock, and, as the mechanism was covered with an anti-rest compound, the stores boy, not wishing to have to wash his hands again, put him off with some excuse. The truckman went back with an empty truck and the conversation overheard by the foreman was the result. I cannot, for obvious reasons, quote verbatim what he told the truckman, but the gist of it was to get back to the stores with word that the mechanism had to be at the machine ready to be used at seven o'clock the next day or something unpleasant would happen. That assembler was in business for himself.

Another incident: A lot of gears were being machined at the turret lathe. The operator could, ordinarily, make good pay at ten cents each. The foundry had evidently made the gears of iron that was intended for larger work. They were hard. Under the old methods it would be only by accident that this fact would be discovered before the job was completed. In this particular case the workman appealed to his foreman who took the matter up with the superintendent. The result was that the foundry acknowledged its error, paid for the amount the operator ran behind, and the expense was put where it belonged.

An operator noticed that some bars in a lot of tool steel machined much more rapidly than others. His insistence on having all the bars good ones led to a thorough investigation and the formulation of specifications for tool steel that now enable that firm to form three-inch diameter tool steel bars with tools three inches wide at a surface speed of over 100 feet per minute.

The firm from whose experience these incidents have been cited believes that the best way to put a man into business so that he can share profits on each job he does is to have a rate setting department that is made up of good operators, under the leadership of a man who is himself capable of taking hold of any productive job in the works. It is almost always found to be a fact that a careful study of a job, not by the stop watch, but by actually doing it, leads to improvement. Sometimes there is only a slight gain. In other cases the time has been reduced to one-third of what it formerly was. The rates are set on the principle that since it has been found possible to reduce the cost and the concern was satisfied with that cost, before this discovery, then the new rate can be placed well above what it actually can be done for. This is contrary to the old spirit of management, but is right in line with what most machine tool men at least believe, and is the only way you can get your men into business for themselves.

Efficiency Movement on a Common Sense Basis

In this connection I do not wish to be understood when I mention the stop watch as not agreeing that oftentimes facts can be learned and gains made through the medium of so-called "efficiency" workers, who are themselves perhaps incapable of performing the operations, but who are intelligent observers. What I do mean is that I personally believe that greater savings are to be made by having a skilled man study the job from an inventor's standpoint rather than from that of a recorder or historian. All interferences with production are not evident to a mere observer. Most of them hark back to the design or to conditions imposed by the relations of a given piece to others in the same machine. The "efficiency" movement, like many other great movements, has its quacks who seize the time of unrest to play upon the credulous ignorant. But every one of us should be thankful for the impetus given to our minds by the crusade definitely started by F. W. Taylor. The obtaining of the benefits of this common sense scheme need not cost anything. In fact, it can be made to pay almost from the beginning. One good man can do enough for a group of men in so short a time that the extra production of the group will pay not only for the money spent on them, but also for further work with other groups. The scheme, properly conducted on a common sense basis, without frills, soon is compounding its gains. Such a movement, to be successful, requires the hearty backing of the management, for there will always be men in every organization, perfectly honest in their view, who are unable to see beyond the tips of their own noses when it comes to making a change from the established order of things. A management that will accept, without considering it a personal affront, the statement that it is not as efficient as it could easily be made, and at the same time is so constituted mentally that it is eager to share with the producer in any saving that may be made, will easily find ways to reduce cost, and need have no fear of being unable to get good men or to keep them loyal.

Educating Men in the Value of Materials

Men are more often careless through ignorance than by nature or intent. The man who spoils a piece of work knows that he has destroyed value, but to him the time lost is usually the item that appears to be the most important. Men should be educated in the total value of the goods they handle. They should know the cost of materials and approximately the shop burden. I know one superintendent who has adopted the system of having all spoiled work reported to him on a card that states the fault and the number of pieces spoiled. Whenever the case is of enough importance to attract his attention, he makes it the excuse for a friendly talk with the man who did the job. He talks the affair over in a way that brings out both sides of the case. Before he lets go of that incident he has taught that man a whole lot about what it costs to carry the burden of a business. He has done more good than any "call down" would do, and he has strengthened the workman's loyalty to the firm, and this, without saying, includes a determination to spoil no more if he can help it.

Discharge should be the last resort, and a frequent use, under ordinary conditions, of the power of discharge, for any reason other than the lack of work, is the sign of poor shop management. Under the management that finds its main corrective in discharge, the new man will be at a still further disadvantage because he will not have had the experience that caused the downfall of his predecessor.

The Foreman as an Executive

Now and then you will find a foreman who is a natural born business man, but this kind is rare, as foremen are usually promoted to their positions because they are good workmen, and not because of the other qualities that a foreman should have. There is a lot of difference between being a good workman and being a good executive. Most foremen have no definite idea of the cost of anything, except net labor, and it is not their fault either. Management rarely interests itself in a foreman to the extent of trying to make a real business man out of him. Yet the returns are well worth the effort. Just start a scheme whereby your foreman really runs his own department, and knows exactly where every cent was spent for which he was responsible, and you will find a most interested and watchful lot of men. You will find that having the entire list of officers on the alert for economy is way ahead of trying to do all the worrying yourself, about the time the cost department reports the facts, which is several weeks after the damage is done.

At the Norton Grinding Co. we keep an account against each foreman and gang boss, of all of the expenses for which he is directly responsible, that is, repairs and replacements, supplies, non-productive labor, spoiled work, etc. Such items as taxes, rent, power, etc., are, of course, not considered, as he has no direct control over them. The total of his expenses divided by the total of his productive labor gives what we, for the sake of comparison, call the overhead of his department. At the end of the month he is given by the cost department all of his supply requisitions with the costs marked in, and all through the month, if another foreman does for him any non-productive job, such as repairing a machine or grinding a cutter, a duplicate of the time card is sent to him with the total money cost showing. This system has aroused more interest among the foremen than any scheme we have yet found.

One foreman found that he was being charged \$10 per week for trucking, the truckmen, up to that time, being responsible

to the head inspector, and responding to calls much the same as the bell boy plan in a hotel. The foreman kept careful record for a few weeks, and then made the announcement to me that his trucking was worth only $6 per week, and that he didn't want to pay $10 for it. The result was that we took one truckman away from the inspector and put him at productive work in the casting department, and the foreman hired a cheaper man to do simple productive work some of the time and trucking when it was needed.

Another foreman came to me with a milling cutter and said, "We make cutter grinders for sale. How much time would you tell a customer that it would take to grind this?" I knew something was up, so I was conservative. My estimate was that it ought not to take over two hours. He thereupon produced a charge by another foreman of sixteen hours for the job. We both made a trip to see the other foreman with the result that the charge was reduced to two hours, which all agreed was ample. The foreman who had done the job was charged with fourteen hours of spoiled work, and the grinder operator was given his notice because his foreman said this was simply the climax of several such incidents, and he had failed to show any interest.

Even second-hand belting suddenly assumed great importance. I did not, at first, foresee that hairs would be split so fine, but it did not take long before a foreman wanted to know what became of a certain belt that was taken out of his department and replaced by a new one. I told him the good part of it would be spliced to another piece and used again. He wanted to know if I didn't think he ought to have credit. So now, when we take an old belt out, if the man in charge of belting says the bulk of it can be used again, after cleaning and repairing, we credit the department with one-half the price of a new belt. When we use that belt again, we charge the department getting it with one half the price of a new belt. Cotton waste is down to one-quarter pound per week per man using waste, and belting is down to $18 per month, average, for the whole shop, where there are 1160 belts in almost constant use every working day.

The foremen are enthusiastic over the scheme. One foreman said, "Sure, I like it. It teaches me so much about my job that if you don't treat me right I can go to someone else and tell him just how much I can run a department for, including my own wages." That is just the position we want him to be in, because we, being on the inside, know all about him, and ought to be able to keep him, if we consider him worth keeping. If, by poor judgment, on our part, he leaves and is really worth more, then we can rejoice with him.

Duties of the Superintendent

The superintendent should never be too busy to take care of any matter that the foremen or workmen think is important, whether or not it is firm's business or personal, and he should be a man in whose word the men have confidence. His training and his actions should be such that the men will know that he is not asking anything unreasonable or that he would not do himself. He must be an enthusiast in his business. He must be a boy with the boys, in fact, he must never forget to be a boy at heart. All first-class enthusiasts are. He must always be on the lookout for good qualities in men. He must campaign for loyalty, a shop's best asset, just as the nation, through the public schools, campaigns for patriotism, for both are the result of plan and not of accident. Loyalty, like patriotism, is spontaneous only in times of intense emotion. It has to be created and fostered by well laid plans that have for their fundamental principle the giving of value for value received.

The superintendent must have the cooperation of the management in teaching the so-called "non-producer" that the business of capital is to make dividends, and that the only excuse for his particular "non-productive" existence is to help "productive" labor to make more chips or to get something assembled faster or better, and that the closing of his day's duties at a certain hour is merely an unimportant incident instead of being the great event that tradition has made it.

Misunderstanding between Employer and Employes

Before we leave this subject of loyalty, it seems necessary to me that I should broach a topic that is usually tabooed in open meeting, but it is one which, to my mind, should be discussed openly, as it has to do directly with the earning power of all workmen who become infected. I refer to unionism as it is now conducted. What are we doing to combat or counteract it? Practically nothing that will have a permanent effect. The opposing of strikes by means of strike breakers and by any other combative means within our power is simply the expedient of necessity and is costly to both sides. We must get at the question through the education of the individual. Practically nothing is being done in this line. The machinist who knows absolutely that there is nothing for him in unionism, as it is today conducted, learned it only by costly experience. It is going to take too long for all men to be educated by that method.

The manufacturer has thus far stood between the union and the public, and has been discredited by the public because the public has been left practically ignorant of the employer's side of the question. The other side of the question sells more newspapers, the people hear all about that side and many untruths about the other.

If all workmen could know, today, the burden that shop owners have been carrying and are carrying in the problem of how to keep their men at work during this period of depressed business, there would be a great many men who would not stop to listen to the agitator when he starts in again. That these men do not know such facts as this is our misfortune, and it is my belief that we have every right to uncover such facts and especially to educate our men to such an understanding of business conditions that they will cease to listen seriously to many of the wild statements made on the street. For instance, in Fitchburg, during the machinists' strike, the daily papers quoted a union leader as saying something like this: "You fellows average to get $2.50 a day. You average to produce $10.00 a day. The man in the automobile gets $7.50 a day out of each of you." Now that statement was allowed to stand, and I believe that many of that man's hearers accepted it as being practically true.

Those who can remember back, if they were so fortunate as to have the privilege of learning a trade, can also recall a time when that man would have arrested their attention, and if they had not followed him, it would simply have been because they had other ideas about what they were after, and not because his statement appeared to be so very far wrong.

The employer has not taken the trouble, through well planned intelligent means to teach the workman that net labor is not the great item in an industry. He thinks it is a serious sin to mention the word "overhead" outside of the office. He has not actually proved to anybody, but himself, that if a machinist gets $2.50 a day and only produces $10 worth of salable goods in the heavy lines of machinery, such as are made in Fitchburg, the "man in the automobile," in a good many cases, would lose money. This kind of education should be spread broadcast. It is not a dream to think that it would be good for a high school boy to know something of the "overhead" of education and of business, just as the engineering schools, notably the Worcester Polytechnic Institute, are teaching it. Trained men should address workmen, in front of the shops, if you like, and the public at every possible opportunity, in an endeavor to clear the workman's mind of the ignorance that continually works against his own advancement. Employers already issue several very good papers for this purpose, but those papers are confined, in their circulation, almost entirely to men who already believe in that side of the question. These papers should be put into the hands of every man in the shops, and would do a whole lot of good in the hands of men outside of the machine tool trade. The printed matter should be followed up by intelligent, enthusiastic effort to convert men to the right way of thinking. Men must be taught that although they have rights every right entails a duty to the community, and the service must be rendered before the right can be justly claimed. It is about time that the sane men of this country who hire labor take hold of this question in an honest endeavor to get together with the sane men of this country who have labor for sale, instead of leaving this important duty to labor leaders who would lose their jobs if they ever really did succeed in doing what they claim to be trying to do—that is, get us together.

NORTON SAFETY FIRST ASSOCIATION

In view of the fact that the question of safety is becoming more vital and more widely recognized the world over, it may be of interest to note the steps that have been taken by the Norton Co. and the Norton Grinding Co. to further this movement in their plants.

A "Safety First" association was formally organized among the officials and workmen of the Norton Co. and the Norton Grinding Co., March 20. At the organization meeting there were present all the foremen and assistant foremen of both companies, as well as one workman from each department. The first safety work in the factory of the Norton Co. began in March, 1909, when a safety committee was organized. This committee was composed of five members, four being heads of departments, and one a member of the engineering department, who made monthly inspections of the plant and subsequent recommendations. The result of their work has been that practically all dangerous places in the plant have been guarded and a great many accidents have been prevented. That the work of the safety committee has been thorough is proved by the fact that on investigation of the causes of all accidents reported to the Norton hospital it has been found that very few can be attributed to the lack of mechanical safeguards. The safety committees of the Norton Co. and the Norton Grinding Co. will continue this work as they have in the years past, and will enter into the "Safety First" association, being designated by the constitution as the permanent executive committee.

A study of the accidents that happened in the plants of both companies showed that they were almost always due either to inevitable risks or to carelessness. Further study showed that if the accidents caused by carelessness could be eliminated those remaining would be almost insignificant in number. With this in mind the safety committees of the Norton Co. and the Norton Grinding Co. were called together for the purpose of organizing a safety educational campaign. After several meetings the following plan of procedure was recommended and has been carried out.

First, to establish a standard for all mechanical safeguards, a book of standard safety specifications was given to all foremen, draftsmen, inspectors and others who have occasion to order machinery of any kind. Second, a book of safety rules for workmen was drawn up, and each man who learns the rules to the satisfaction of the committee is made a member of the Norton "Safety First" association, and is given a button. This society holds social meetings at which discussion of safety topics forms part of the program. Only members wearing buttons are admitted. Third, a set of safety rules for foremen was adopted, which was issued to each foreman and assistants. Fourth, to assist the foremen in enforcing the safety rules, a safety inspector was appointed in each department, whose duty it is to report any one whom he sees violating the safety rules or any dangerous conditions which he observes in his department. These inspectors wear a special button as a badge of authority and an official notice of their appointment is posted in each department. To introduce the subject to the men, the words, "Safety First" were printed in large letters on the pay envelopes. This prompted the men to ask what these words meant. After two issues of such pay envelopes, large placards printed in English, Swedish and Italian, as shown in the accompanying illustration, were posted in various parts of the works, which gave a short explanation of "Safety First." An announcement of the proposed organization was also published in the monthly *Health and Safety* bulletin, issued by the health and sanitation department. No attempt has been made to coerce the men into joining, but the response of the workmen to the invitation has been prompt and many from all departments have already qualified as members. Following are the safety rules issued for the foremen:

Safety Rules for Foremen

Learn all safety rules for workmen. You will be held responsible for the enforcement of all these rules in your department.

When you hire a new man, you must explain to him all safety rules in connection with his work.

When you put a man onto a new class of work, explain to him all safety rules in connection with his new work.

Watch all new men carefully and see that they take no unnecessary risks.

You are responsible for keeping in place all safeguards in your department.

If a new machine is set up in your department, do not allow same to be started until you make sure that all gears and other dangerous parts are protected.

If a machine has been repaired, do not allow same to be started until guards have been replaced.

If a guard or safety device is out of order, do not use machine until it has been repaired.

Keep all passages in your department clear at all times.

Examine frequently all belts in your department and see to it that they are under the proper tension, also that lacings are in good condition.

See to it that all overhead work, shaft-hangers, etc., in your department are kept rigidly secured.

* * *

The complexity of modern manufacturing conditions has led to the use of a variety of methods of transmitting power, each of which has its advantages for different installations. One advantage of rope drives is that this transmission is practically independent of the relative positions of the driving and driven shafts. Where shafts are at an angle to each other, the application of a rope drive does away with the necessity of using a quarter turn belt which is regarded as a troublesome problem in mill-wrighting. Regardless of the type of drive that is used, it is essential for the design to be worked out by an experienced engineer who is able to advise the most suitable method for the case in hand.

SAFETY FIRST

What does this mean?

It means that SAFETY should be your FIRST thought always.

Never take any chances with your own or others' safety, for the sake of getting a little more work done, or saving a little time.

It NEVER pays in the end to TAKE CHANCES; You and your family are the ones who suffer.

It is ALWAYS best to think of SAFETY FIRST.

Försiktighet Först

Hvad betyder detta?

Det betyder att FÖRSIKTIGHET bör alltid vara Eder FÖRSTA tanke och sträfvan.

Gör ingenting, som kan sätta Eder egen eller andras säkerhet på spel, i afsikt att få litet mera arbete gjordt eller vinna litet tid.

VÅGSAMHET i detta afseende BETALAR SIG ICKE, ty Ni sjelf och Eder familj äro de som bli lidande.

Det är därför alltid bäst att tänka: FÖRSIKTIGHET FÖRST!

La Salvezza Prima

Che cosa significa cio?

Significa che la salvezza deve essere sempre il vostro primo pensiero. Non cercate mai di azzardare la vostra o l'altrui salvezza, con la speranza di fare un poco di lavoro di piu, o per risparmiare un poco di tempo.

Infine non paga azzardare, giacche voi e la vostra famiglia siete i soli a soffrire.

E'sempre buono pensare prima alla salvezza.

Norton Company

MAKING WING NUTS IN A PUNCH PRESS

DIES, TOOLS AND METHODS USED IN MAKING A PATENTED TYPE OF WING NUT IN THE PUNCH PRESS

BY DOUGLAS T. HAMILTON*

The utilization of a punch press for producing wing nuts may seem to be rather unusual—as it is—but as the following description shows, the operations are handled in a perfectly practical manner. The wing nut to be described is used largely on knock-down furniture and articles of a similar kind. The methods of manufacture are patented, the patent being held by R. Smith, general superintendent of the National Screw & Tack Co., Cleveland, Ohio, at whose plant this information was obtained. The wing nut is made from a cold-rolled coil of wire 0.248 inch in diameter, and is completed in seven operations, the first two being accomplished by one blow in a cold heading machine.

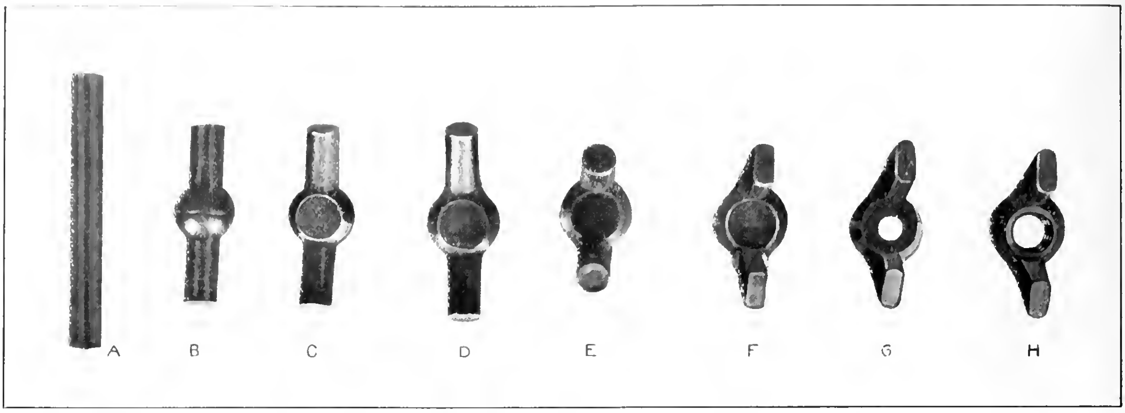

Fig. 1. Development of a Wing Nut in a Punch Press

Cutting Off and Upsetting the Stock for the Wing Nut

The first operation on the wing nut is to cut off a piece of wire 2 3/32 inches long. This is accomplished in the Waterbury Farrel cold header illustrated in Fig. 2. The wire *A* is held on a reel and is drawn in to the cutting-off tool by means of rolls, cut off and then gripped and upset in the center, as indicated at *B* in Fig. 1. The method of operating a machine of this type was described in the article entitled "Cold Heading—2" which appeared in the July, 1913, number of MACHINERY. This upsetting operation reduces the length of the cut-off stock from 2 3/32 to 1 3/8 inch, and at the same time increases the central portion or bulge on the stock to 0.460 inch diameter.

Fig. 2. Cutting and upsetting the Blank—First Operation on the Wing Nut

Shaping the Body and Bending the Ends to Form the Wings

The next three operations on the wing nut, illustrated from *C* to *E* in Fig. 1, are accomplished in the punch press shown in Fig. 3. This machine has been arranged with a special dial and work-carrying mechanism similar in operation to the multiple plunger press described in the August, 1911, number of MACHINERY. The dial *A* located to the right of the machine has sixteen elongated slots which conform in shape to the upset stock. This dial is filled by the operator, and as it is indexed, one blank at a time drops out and is located in fingers in the carrier *B*. The carrier moves the blank to a position over the first die and as the punch *C* descends, the blank is flattened in the center and slightly bent at the ends as shown at *C* in Fig. 1. The carrier *B* then picks up the blank and carries it to the next position. Here the blank is located over another flattening die and the punch *D* performs the final flattening operation on the center of the blank and at the same time bends up the ends a little further. This punch is provided with a conical impression in its lower face, which forms the sides or beveled portion on the center of the nut; it also has semicircular grooves in its sides corresponding to the shape of the wire so that the wings can pass up by the punch. The result of this operation is shown at *D* in Fig. 1. The slide *B* which carries the blanks from one position to the next is operated by a crank motion that transmits a movement to the slide through arm *F*. The sequence of operations is progressive until the blank reaches the last position where it is forced through the die and drops into a box under the machine. Seventeen thousand of these wing nuts are turned out from this machine in ten hours.

Flattening the Wings

Following the flattening of the body and the bending up of the wings, comes the flattening of the wings. This is accomplished in the punch press shown in Fig. 4. The operator lays the blank in a slide, operated by means of a crank motion, that carries the work to the flattening die. The work is carried forward with the two prongs or wings facing in toward the machine. This slide places the wings over the die and holds the blank in position until the punch descends and flattens the wings. Upon the return stroke, the flattened wing nut is ejected from the carrier and dropped into a box. Seventeen thousand blanks are turned out from this machine in ten hours.

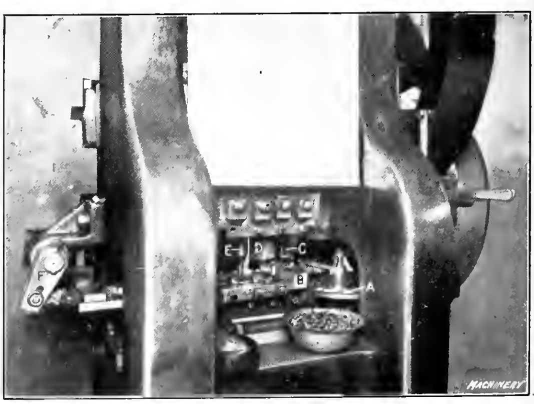

Fig. 3. A Progressive Punch Press Operation—Flattening and Bending the Wing Nut

* Associate Editor of MACHINERY.

Punching the Hole and Tapping

The hole is punched in the wing nut in the machine shown in Fig. 5; this is provided with a special work-holding device consisting of a stationary and a movable slide. The movable slide *A* is controlled by the lever *B*, and to insert the work this slide is drawn back, the nut placed in the cage and the slide returned to its clamped position. The press is then operated, and as the punch *C* descends it punches the hole in the nut. When the ram of the punch ascends, the operator again moves lever *B* outward, pulling back the slide, removes the punched wing nut and inserts an unpunched one in its place. The rated capacity of this machine is from 16,000 to 18,000 in ten hours.

The tapping of the wing nut is accomplished in the tapping machine shown in Fig. 6. This machine is provided with four spindles and carries long shank taps held in quick-

Fig. 4. Flattening the Wings of the Nuts

removing sockets. The operator places the wing nuts in cages and as the taps descend, they pass through the nuts, the latter traveling up on the shanks of the taps. When the shanks of the taps are filled they are removed, inverted so that the nuts drop out into a box, and then replaced in the collet.

* * *

A public hearing was held by the United States Commission on Industrial Relations, in Washington, during the three days beginning April 13, for the consideration of efficiency systems and their effect on industrial relations. Witnesses were called by the commission to testify with special regard to the status of workmen under scientific management. Consulting engineers and employers who have led in the introduction of efficiency systems alternated with trade union officials in giving testimony. Among others who were re-

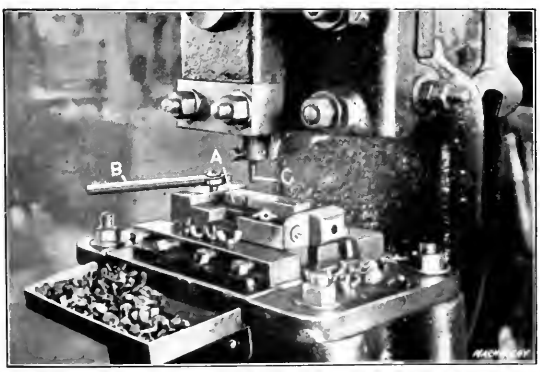

Fig. 5. Punching the Hole in the Wing Nut

quested to give their opinions were F. W. Taylor, who originated and developed the Taylor system of scientific management; James Duncan, first vice-president of the American Federation of Labor; Louis D. Brandeis, H. L. Gantt, Harrington Emerson and Carl G. Barth, consulting engineers; J. M. Dodge, president of the Link-Belt Co.; William H. Johnston, president of the International Association of Machinists; and A. L. Berres, secretary of the Metal Trades Department of the American Federation of Labor.

APPLICATION OF A PROTECTIVE METAL SURFACE BY SPRAYING

BY J. OSBORNE*

In many industries it is necessary to coat one metal with another. Hitherto such a coating has been applied by electrical deposition, but a process is now available by which one metal can be deposited upon another by mechanical means. It is claimed that the new method offers many advantages. The invention has been worked out by a Japanese metallurgist, and is especially designed for the coating of iron or steel with aluminum to prevent rusting. The process is a simple one. The metal surface to be protected is, in the first instance, galvanized or tinned; it is then immersed in molten aluminum under the surface of which it is scrubbed with steel wire brushes to remove the zinc or tin coating, which is replaced by the aluminum. The metal with its new coating is then ready for any processes through which it may have to pass, such as rolling, pressing, polishing.

Large castings or built-up iron or steel members cannot be subjected to the process just described. As it is often desirable to render structural steel work rustproof by means of a coating that is not easily corrodible, an alternative system has been worked out for this class of work, which may be briefly described as follows: The protective metal is, in the first instance, pulverized and is then forced by mechanical means into intimate contact with the surfaces which it is desired to protect. Molten lead can be readily pulverized by methods which have been known for three decades and have been very extensively used in the manufacture of electrical apparatus; the finely divided metal is applied in the form of a paste and pressed into grids to form the active material in accumulators. The stream of pulverized metal could also be directed onto plates made of some such material as asbestos,

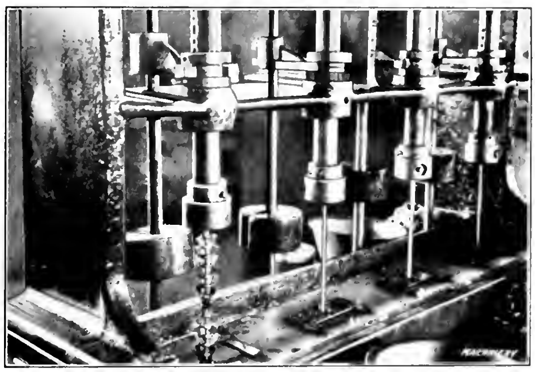

Fig. 6. Tapping the Hole in the Wing Nut

which is not sensitive to the action of sulphuric acid, so that these plates with their porous film of lead could be used without further preparation as accumulator plates.

This was the first step in the development of a process for the pulverization and spraying of metals. A steam boiler was first used for pulverizing and spraying the lead, high-pressure steam being delivered through a conveniently situated pipe and caused to impinge on the surface to be protected. Melted lead was injected into the path of this jet of steam from a suitable container, with the result that the lead became completely pulverized and was carried forward in that form by the steam and thrown against the surface to be coated with sufficient force to make it adhere. The process was then carried a step further. An apparatus was designed to enable jets of oxygen and hydrogen to be obtained at a high speed and ignited at the point of emergence, in that way forming practically an oxy-hydrogen blowpipe, capable of melting a portion of the metal held in the flame and at the same time pulverizing it and throwing forward the pulverized particles under pressure. The pulverized metal was directed against the surface to be coated. Now if means can be provided by which the pulverized metal will be fed at the desired rate, a spraying apparatus will be ob-

* Address: 18 Atlanta Chambers, Manchester, England.

tained by means of which even substances fusible with difficulty can be worked easily and continuously.

There is the alternative of using an electric arc, should the heat of the oxy-hydrogen blowpipe be insufficient. The electrodes are made in the form of hollow carbon rods; they melt off the metal used for the protective coating and this melted metal is carried forward by a highly heated or burning stream of gas passing through the hollow electrodes. In practice, the idea just outlined is carried out by means of an extremely compact little apparatus in which the compressed gas, before it is used for pulverizing the metal, first operates a miniature air turbine, the rotation of which determines the rate of feed of the metal in exact accordance with its consumption. The thickness of the deposit may be anywhere from a few thousandths inch up to half an inch or more, according to the duration of the period of treatment, while the density of the deposit can be varied. Thus a lead covering which was sprayed with superheated steam had a specific gravity of 9.5, while another lead coating sprayed under similar conditions by means of hydrogen had a specific gravity of 11 to 11.3.

It has been ascertained that, for a given pressure, hydrogen possesses a much higher velocity of flow than superheated steam, and so the pulverized metal is projected by it with proportionately greater energy. This increase of energy is proportional to the square of the velocity and, knowing this, it is possible to vary the velocity to obtain a density of the coating suitable for any particular purpose. The hardness of the sprayed coating is usually considerably more than that of the cast metal and, indeed, in many cases which have come under observation, it is even equal to that of a rolled sheet. The manufacture of metal coatings by this process should be found useful in the electrical industry. To give an instance, very thin sprayed strips should come into use as electrical resistances for all classes of electrical heating apparatus, and, as a matter of fact, the heating element in such apparatus has already been made in extremely thin layers of the more costly metals, which are painted on in the form of salts that are subsequently reduced to metals. Such strips offer a very high resistance to the passage of the current and therefore become incandescent very rapidly.

The process described is available for coppering carbon brushes and the ends of electrodes, and for the production of contacts. The spraying of two adjacent surfaces at the interstice formed at the point of contact causes this to be entirely filled up, thus providing a perfect union of the two bodies. It also facilitates mending a cracked or broken surface, so that a simple substitute for soldering and welding processes is provided. Another important application is that of galvanizing iron of irregular section used for structural work. Aluminum—the single metal that so far has not been available for treatment by electric deposition—can now be utilized by means of the spraying process. It has been suggested that sprayed aluminum could be used for coating aeronautical fabrics to render them air-tight, also for the coating of the wooden frames and fabrics of aeroplanes for the purpose of protecting them against the weather; it would, in addition, increase their stability. The coating of wood with metal is a novel idea and its application has many possibilities. Wooden parts protected in this way would be insured against dampness and rotting, or in the tropics, against damage done by insects. Packing cases could easily be strengthened by spraying the edges, or the boxes could be sprayed all over to exclude dampness.

* * *

An electrical instrument has been developed that promises to be of considerable value to electric light and power companies, inasmuch as it will enable them to sell current at two rates and to measure it at the rush and slack hours with the same meter. The device responds to a momentary slightly higher current wave than normal and it shifts the meter from one rate of register to the other. Thus, when the lighting load is heaviest in the early evening, the meter is set to register at the high rate but when the demand falls off after midnight, the wave impressed on the circuit shifts the meter to register at the lower rate.

IMPORTANCE OF PURITY OF OXYGEN USED IN CUTTING STEEL

BY J. F. SPRINGER*

The cutting of steel by means of the torches employed in autogeneous welding may be divided into two rival procedures. These differ principally in respect to the generation of the heating flame, one employing the oxy-hydrogen and the other the oxy-acetylene flame. In some respects, cutting with the hydrogen flame is to be preferred. In most cases, however, either will accomplish the desired result with economy and despatch.

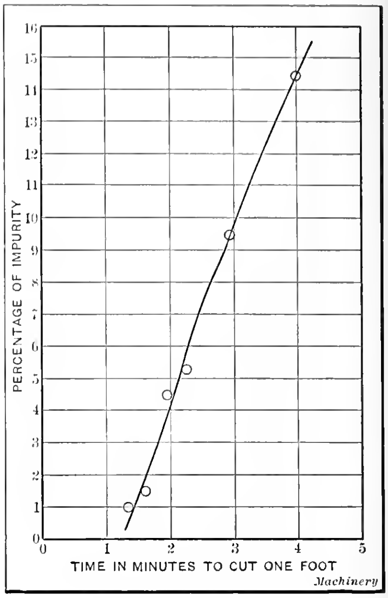

Fig. 1. Showing the Effect of Impure Oxygen on Oxy-Hydrogen Cutting

Impurity of Oxygen

It is of considerable importance to understand the effect of impure oxygen. The impurities which have any especial claim to attention are those which arise through the presence of nitrogen or hydrogen. If the oxygen is prepared by the liquefaction of air, some percentage of nitrogen will be very sure to be present. Nitrogen itself seems to be harmless, in so far as any ill effect on the metal is concerned. It is, however, practically unburnable, and so clogs the action of the oxygen. It probably also tends to cool the heating flame and thus retard the work. In the manufacture of oxygen by the electrolytic process, the principal impurity will probably be hydrogen. As hydrogen is a gas that is readily combustible it has but little effect on the heating flame, but in the cutting stream of oxygen its presence doubtless gives rise to a clogging effect similar to that of nitrogen. At all events, whether we account for the result in one way or another, the presence of nitrogen or other impurities in the oxygen supply has the effect of retarding the cutting operation. This retardation means a labor loss in addition to a gas loss, besides hindering output. Certain experiments carried out abroad will assist us in seeing just how serious the retardation is. Table I gives the results of twenty-six experiments, all tried on sheets of the same kind, of the same thickness, and with the same style of torch.

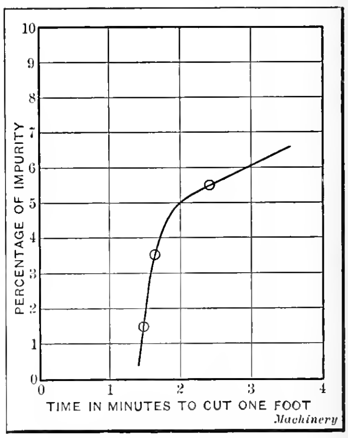

Fig. 2. Showing the Effect of Impure Oxygen on Oxy-acetylene Cutting

It will be seen at once that the purity of the oxygen plays a most important part in the efficiency with which cutting

85.50	21.7	420	3.87	3.99
85.50	23.6	480	4.07	

Machinery

may be accomplished. With oxygen 85.5 per cent pure, it requires three times as long to cut the 1.18-inch plate as with oxygen 99 per cent pure. This means that the cost is three times as much. Even the one-half of one per cent drop from the 99.0 per cent oxygen to the 98.5 per cent quality means an increase in the expense amounting to 16 per cent. So even if the better grade of oxygen should cost more, we see from the foregoing that it would have to cost a great deal more to make it a matter of no importance which grade of oxygen were used.

In Table II the same kind of steel and the same thickness of sheets are to be understood as in Table I. The pressure of the oxygen is increased, however. Note especially that here we have the alternative procedure with acetylene gas.

It will be noted that we do not have any experiments here

TABLE II. TIME REQUIRED FOR OXY-ACETYLENE CUTTING OF METALS

Machinery

with 99 per cent oxygen. Comparing the 98.5 per cent purities in Tables I and II, we see that the acetylene cutting has the advantage. The result with 94.75 per cent oxygen, hydrogen cutting, when compared with the work done with 94.50 per cent, acetylene cutting, indicates that the efficiencies at this degree of impurity are about the same. This would become clearer by drawing curves illustrative of the last columns in Tables I and II. It must be borne in mind, however, that the oxygen pressure is distinctly higher with the acetylene experiments.

* * *

HIGH PRESSURES

Cold iron can be made to flow like molasses, providing the pressure on it be great enough. Many may not have seen it do so, but it is stated in the *English Mechanic and World of Science* that the late Sir William Roberts Austen, who was then Master of the Mint in London, once made a public exhibition of this phenomenon before an audience at the Royal Institution. He subjected iron to great hydraulic pressure and by an optical device he threw the image of the iron, at the point where the pressure was applied, on the screen, and the solid iron was seen to flow slowly, it being extruded through a small aperture. Investigations with very high pressures have lately been made by Dr. Bridgeman of the physical laboratory at Harvard University, and he has probably been experimenting with higher pressures than have ever before been reached. In some of his experiments he obtained a pressure of something like 300,000 pounds per square inch, and succeeded in measuring the pressure with reasonable accuracy up to 175,000 pounds per square inch. What these pressures mean will be understood when we consider that the highest pressures commonly produced are those exerted by the explosions in modern arms with smokeless powder, where a pressure up to 30,000 pounds or more per square inch is developed when the gun is fired. Pressures of 200,000 pounds per square inch have been produced by exploding nitro-glycerine in a closed vessel.

* * *

Not all improvements in working conditions are appreciated by men who have become accustomed to those that appear to others as being intolerable. An example showing the effect of imagination is of interest in this connection. A basement lighted artificially had been used as a casting cleaning and snagging room. The working conditions were abnormally bad. The floor was damp, no windows permitted daylight to enter and dust removal apparatus had not been provided. Consequently, the air was filled with dust and grit but the workmen could not *see* the dust. The superintendent fitted up a floor in a new building above ground with exhausters and removed part of the cleaning force to it, but the men soon became dissatisfied and clamored to go back to the basement. They said that the dust in the new place would soon kill them. The fact, of course, was that the dust was much worse in the basement but being more visible in the new place because of being lighted by the sun, they imagined that they were being choked and injured by it. The superintendent was able to make use of the new department only by placing men in it hired to take the places of the old ones as they left. These, being unaccustomed to the former conditions, had no fault to find.

* * *

No other feat in the history of the oil industry has equalled the killing of the wild gas well near Oil City, La., that has been wasting from 10,000,000 to 20,000,000 cubic feet of gas a day for the last six years. This great loss was stopped by the boring of a relief well close to the old one. When this well reached the same depth, water and then mud was forced into the relief well under heavy air pressure. This soon choked the gas stratum and shut off the flow. The work was done under the direction of the Louisiana State Conservation Commission which furnished a portion of the funds for the work. The remainder was furnished by gas and oil companies operating in the district. As soon as the flow of gas had been stopped, the well was cemented. The well had made a crater 225 feet in diameter and 50 feet deep. *Compressed Air*

WHY CENTER THE HOB?*

CAUSES OF THE PRODUCTION OF FLATS AND METHODS OF PREVENTION

BY JOHN EDGAR†

Whether or not it is necessary to center the hob in order to get satisfactory results, is a question that is not so readily answered as it might appear. For the sake of making the matter clear to those who have not the time to make a study of the subject, the results of an investigation conducted by the writer will no doubt be of interest. Theoretically speaking, these results should show no difference whether the hob is centered or not. However, practical modifications enter into the actual conditions and

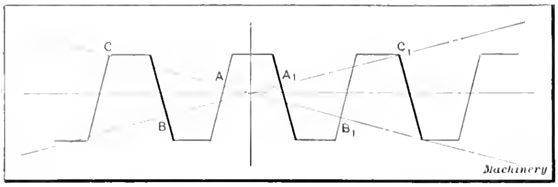

Fig. 1. Diagram showing Points of Intersection of the Pressure Lines with the Hob Teeth equally spaced at each Side of the Pitch Point

exert peculiar effects upon results produced. To briefly explain the action of the hob, we may say that the generating operation consists of a successive trimming of the teeth of the gear by those cutting edges of the hob located in the generating path. The portion of the cutting edge that forms the tooth of the gear lies on the pressure line of the hob, intersecting the pitch point, and the maximum length of the hob in this generating space is $2s \div \tan \phi$, where $s =$ addendum or reciprocal of diametral pitch and $\phi =$ pressure angle; in the cases of the small pinions this length may be as short as the circular pitch of the teeth.

The point where the two opposite pressure lines cross the pitch line is the center of the hob, and the object of centering is to get corresponding portions of the generating edges at equal distances on each side of the center, so that the sides of the teeth generated will be symmetrical. Thus in Fig. 1, the points where the pressure lines intersect the teeth of the hob at A, A_1, B, B_1, and C, C_1, are at an equal distance on each side of the center or pitch point, and at a like distance from the axis of the hob when the pitch point lies in the center of a tooth or space as shown. If the pitch point is shifted out of the center of the tooth or space, the radial distances of the respective points of intersection are not equal, the points A, B and C being a greater or less distance from the axis than the points A_1, B_1 and C_1.

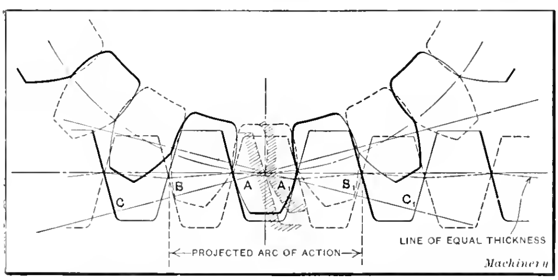

Fig. 2. Case I. Hob with Low Tooth and High Space centered. Full Lines show High Side and Dotted Lines show Low Side

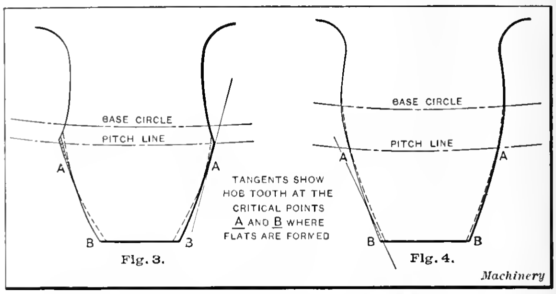
There are defects in the hob that no amount of centering will compensate for and insure symmetrical teeth being generated. Among these we may cite the defects due to distortion in hardening, unequal tooth thickness due to springing of the tool in forming, and errors in size resulting from careless workmanship. The defect that can be favored in the setting of the hob is that in which the eccentricity of the form and axis causes the teeth to run out. This eccentricity may be caused by the use of an inaccurate mandrel in the backing-off operation or in not truing up the hob properly in grinding the hole; and may also be caused by an untrue hob arbor on the hobbing machine itself. These defects can be determined and proper allowance made to counteract the natural results by a careful setting of the hob. By knowing what result will be obtained with these eccentric hob conditions the defect can be diagnosed and a remedy applied or the setting can be made to favor the defective conditions.

Let us take the most common condition—the case where the axis of the form and that of rotation are eccentric and parallel—and treat it as follows: Case I. Hob with low tooth and high space centered. Case II. Hob with high tooth or low space centered. Case III. Hob not centered, but half way between the conditions of the two preceding cases.

Case I for Fourteen and One-half Degree Teeth

The method of treatment is to take a normal gear and show it in mesh with the eccentric hob in the desired position: in this case, with the "high" space centered. This setting brings the tooth on the opposite side of the hob in the center if the number of gashes are even, and this opposite side is the "low" side of the hob. This is shown in Fig. 2. In each case, the high side is shown in full lines and the low or opposite side in dotted lines. The intermediate teeth which range from high to low are not shown except in the central



Figs. 3 and 4. Tooth Outlines showing how Flats are formed at the Pitch Line and at the Point in Case I

position in Figs. 2 and 5, and in the extreme positions in Fig. 8. An inspection of Fig. 2 will show that the pitch line of the hob, considered in its relation to the tooth itself, does not lie along a straight line parallel to the axis of the hob, but on a zigzag line that is shown broken. This line represents the pitch location of the right side of the hob tooth, and may be termed the "line of equal tooth thickness." It will have a drop for each pitch length of the hob for every convolution of the thread. In reality, the line instead of being zigzag should be a reverse curve.

In the central position indicated by the full lines, the contact between the teeth of the hob and gear is normal and correct. If the hob be given one-half revolution, the position taken is indicated by the dotted lines and it will be noticed that the gear and hob do not come into contact as they should at the points B and B_1, the space widening from the points of contact A and A_1 to the points B and B_1. From this we may rightly assume that the hob would form the teeth of the gear with a fullness at the point, as indicated by the full line from A to B in Fig. 3. The dotted line shows the normal curve of the tooth. If the hob is given a quarter turn from the full line position, the relative position of the teeth of both the gear and hob is at the dotted line position shown in the center of Fig. 2, midway between the teeth instead of giving the normal contact at the pitch point on the pitch line of both gear and hob. This should develop a fullness of the gear tooth at the pitch line diminishing again to normal at the point A. But the normal position of the hob tooth at the point A brings the edge of the hob tooth inside of this bulge, so that it would remove the greater

* For other articles on the subject of hobs and hobbing which have appeared in MACHINERY see "Special Hob Tooth Shapes," by John Edgar, published in May, 1914, and other articles there referred to.

† Address: 61 Bruce Ave., Windsor, Ontario, Canada.

portion of it shown in cross-section in Fig. 3, leaving a flat from the point A extending to the pitch line. In exaggerated cases, in cutting large numbers of teeth, the flat will extend past the pitch line to the base of the involute.

When the projected arc of action shown in Fig. 2 is greater than twice the pitch of the teeth, which is the case when cutting gears with a greater number of teeth than 36, the trimming of the involute portion of the teeth takes place through two or more turns of the hob instead of one. This brings the tooth of the hob more nearly into the normal position at the end of the gear tooth, tending to make the point of the tooth nearer to the proper thickness; but the correct thickness is never reached as it would be necessary for the contact to continue to the position C, which is the case of a gear of infinite diameter. This develops a flat at the point of the tooth for the same reason as that given for the flat produced at the pitch line. The result of this action on gears with teeth greater in number than 36 is illustrated in Fig. 4, where the cross-sectioning shows the excess metal removed, resulting in the production of the flat. The effect on the flank of the tooth need not be taken into consideration; as the hob leaves it, there is ample clearance for the gear tooth of the mating gear, it being only in the case of a gear meshing with a rack that the flank would be apt to give trouble.

Case II for Fourteen and One-half Degree Teeth

The high tooth centered, as illustrated in Fig. 5, shows the normal contact between the teeth at the points B and B_1. With the hob revolved one-half turn, the low space comes into the central position, but there is no contact between the teeth at the points A and A_1. In the central position where the pitch lines of the gear and hob are tangent, instead of the normal contact we have a space between the teeth. A

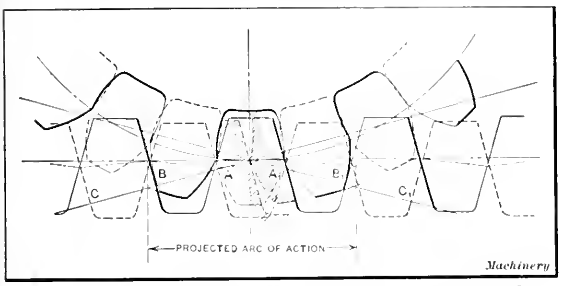


Fig. 5. Case II. Hob with High Tooth and Low Space centered. Full Lines show High Side and Dotted Lines show Low Side

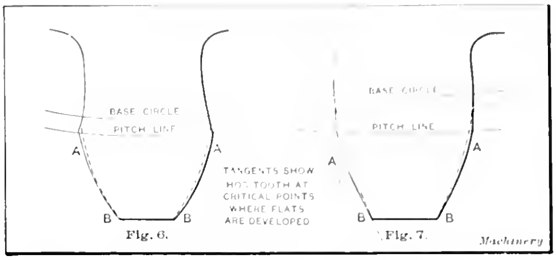
gear generated with the hob set in this position would have teeth of the form illustrated in Fig. 6, with fullness at the points A and a perceptible flat below the pitch line, which extends to the base circle in gears with a large number of teeth. In the case of gears with more than 36 teeth, the normal contact at the points B and B_1 develops into a space and results in a flat at the point of the teeth, as shown in Fig. 7.

The two preceding cases give the two extremes in setting the hob central and show the results of eccentricity of the axis of form and the axis of rotation. Of the two methods, the latter is the more practical. By centering the high tooth the depth is easily obtained, whereas in the first case with the high space centered, the depth is not so easily obtained because the centered tooth is the low tooth and if the hob is fed to depth after bringing it so as to mark the blank, the depth will be deeper than that shown in Fig. 2 and the tooth thickness will be under size. The reverse is the case with the second method of setting, but to obtain the proper tooth thickness the hob will have to be fed in deeper than the standard amount. The pointing of the tooth at B in Case II will give better running gears than the fullness at the point as in Case I.

Case III for a Fourteen and One-half Degree Tooth

By moving the hob along so that the pitch point lies on the edge of the high tooth, as in Fig. 8, we have a case which gives results similar to those obtained by setting the hob at random, and we will get results more or less unsymmetrical. The full lines in Fig. 8 show the high side of the hob in normal contact with the gear teeth, with contacts at the pitch point and at the point A_1. On bringing the hob into the opposite position with the low side, or to the location shown by dotted lines, we find no contact at the pitch point nor at point A. Rolling the gear until the teeth come to the end of the normal point of contact on the pressure line at B and B_1 on each side of the pitch point, we will find a space at B_1 instead of the contact as at A_1, and a lessened space at B. Had this rolling brought the gear tooth to the low hob tooth position, as at C_1, the space at B_1 would have been maximum and the position at B would come into con-



Figs. 6 and 7. Tooth Outlines showing Points at which Flats are produced in Case II

tact with the high tooth at C. Further rolling of the gear away from these positions would tend to reduce the space to the right and to develop a space to the left.

A hob in this condition and so set would generate a tooth with the left side normal at the pitch line, with a bulging face; and with the right side full at the pitch line and nearly normal at the point of the tooth, with a flat near the point when the hob is cutting to depth. The case of a twelve-tooth pinion is shown in Fig. 9; and the case of a larger gear in which the contact between the teeth of gear and hob continues to the point C of Fig. 8 is illustrated in Fig. 10. In both cases, the last "swipe" of the hob tooth will cover a broader length of the tooth than it ought to, and will leave a flat at the point on the left side of the tooth. Similarly, in the case of both Figs. 9 and 10, the hob tooth in the position A_1 of Fig. 8 will leave a flat at this point covering considerable of the right side of the tooth face. The cross-sectioned areas show portions of the bulges cut away, leaving flats.

The method outlined in Case III has the same effect as centering any of the teeth of the hob except the high or low tooth, so that the usual procedure of shifting the hob to bring new cutting points into position will result in unsymmetrical teeth being developed in the gear if the hob runs out of true with the axis of rotation. The actual amount of the distortion in the teeth generated will depend upon the amount of eccentricity of the hob form and is approximately one-fourth of the eccentricity on each side of the

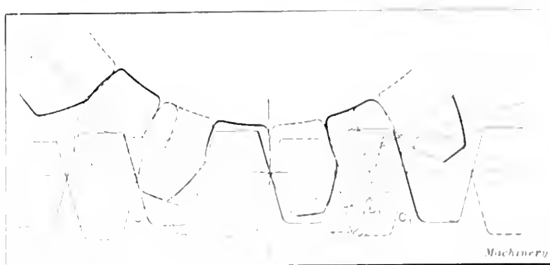


Fig. 8. Case III. Hob centered midway between Positions in Case I and Case II

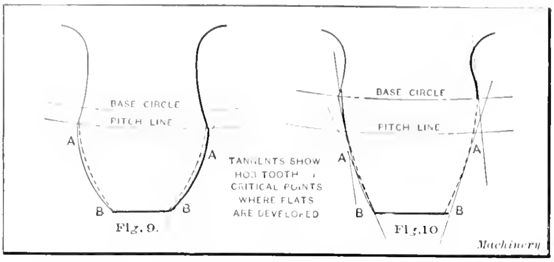
tooth. In Fig. 3, for example, the amount that the tooth is thick at the point B, for a hob 0.002 inch eccentric, will be 0.0005 inch on each side or 0.001 inch altogether. The amount of the space at the pitch line would be the result of only one-half the eccentricity, as the tooth is in the mean position at this point.

Several cases could be treated in this way, as for instance, the case where the axis of form is not parallel with the axis of rotation but where these axes intersect. The only remedy that would make it possible to obtain symmetrical teeth

would be to find the point of intersection of the axes and set the hob central with that point. But instead of setting the high tooth central, as in Fig. 5, the hob should be set in such a position that the axis of the form lies in the same plane as the spindle on which the gear is placed, and the hob should be set central irrespective of the location of the teeth of the hob. That is, the hob should be set so that the point of intersection of the two axes will lie directly in line with the axis of the work spindle of the machine, whether or



Figs. 9 and 10. Tooth Outlines showing Flats produced by Hob set according to Conditions of Case III

not the tooth of the hob comes central. Of course if a tooth comes into this position, so much the better for the symmetry of the teeth of the gear. This setting is illustrated in Fig 11. The unsymmetrical results sure to be developed by any other setting are quite obvious without further exposition.

The preceding treatment of three typical cases gives some light on the cause of the poor shape of the teeth so often complained of in the results obtained from the hobbing machine, and while this discussion does not include all of the defects that will produce similar results, it does emphasize the fact that more care will be necessary in the preparation of the hobs than has formerly been the practice. Eventually we shall have the ground hob, with the defects of hardening and careless forming eliminated by grinding the hardened hobs on precision machines in which the human element will be reduced to a minimum, so far as its effect on the accuracy of the hob is concerned. When such hobs are available, the hobbing process will meet with little or no opposition based on the unreliable results obtained by it. However, until the ground hob is perfected, flats and unsymmetrical tooth outlines will be a source of worry to the user of the hobbing machine and he will meet the results already pointed out in my article "Hobs for Spur and Spiral Gears," published in the July, 1912, number of MACHINERY. In that article, a remedy was given to reduce the effects of the careless workmanship, and a further means of correcting such defects and distortions of the hob teeth is outlined in the following paragraph.

This consists of the more direct process of grinding out the distortion of the teeth from the narrow helical path, and of bringing their cutting edges back into the proper helical relation with each other. All that is necessary for the operation is a toolpost grinder—preferably an electric machine. Of course it goes without saying that the more carefully the performance is carried on, the more satisfactory will be the results obtained.

The procedure is simply this: Set the lathe to the proper lead of the hob, with the toolpost grinder on the slide-rest, and with a clean cutting wheel grind the edge of the side of the teeth into the proper helical relation. It is necessary to be careful not to grind too much from the side of the teeth; just let the wheel touch the teeth all the way around, and if the mandrel on which the hob is held is running true, the hob thread will be straightened up. It will be noticed that the land left by the wheel is not uniform and the amount that the teeth are out of true is directly proportional to the width of this land. It will also be noticed that some rows of teeth will have wide lands while those of the opposite side of the hob will have narrow lands; this is the result of the eccentricity of the axis of form with the axis of rotation and should be corrected by grinding the teeth back until the lands are of uniform width. This is the same treatment that was given for the correction of careless spacing and improper sharpening in the previous article referred to. Besides this regular variation in the width of the ground lands, other irregular lands will be noticed which are the result of singly distorted teeth, due to careless forming or to distortion in hardening. If the land left by the wheel is not so wide as to cause the teeth to drag on account of the relief being ground away, they may be allowed to remain in the condition as left by the wheel, or they may be treated singly by grinding back as in sharpening.

The results obtained by this treatment more than pay for the time and expense, and where a hob is giving trouble this remedy is recommended. A hob thus treated need not be centered, as the teeth generated by it will be symmetrical by the most rigid test usually applied to commercial work. The treatment will have to be repeated at each sharpening, however, to insure the continuance of the good results. In choosing the change gears for the lathe, the axial lead corresponding to the normal pitch of the teeth must be used; and as a difference of 0.0005 inch is noticeable in the angle of the teeth, the lead must be closely followed. Some such treatment as this is necessary with the irregular hobs now obtainable.

In conclusion, it may be well to apologize for the title. The answer is that with the unground hob in which the eccentricity is an unknown quantity, but may be taken as sure to be existent, it is well to center the high tooth as in Case II; and with the accurate hob, that will be available when the methods of grinding the teeth are perfected, it will be unnecessary to center the hob *if* the hob has been carefully sharpened and the hob arbor runs true on its axis. While the results revealed by the treatment of the three cases seem to be unfavorable to the hobbing process, it is such studies as these that bring the truth to light and lead the way to the remedy which, when applied, brings to the hobbing process the share of consideration it deserves as one of the simplest and most efficient methods for the production of the teeth of gears.

Engineers, designers and others who have studied foundry practice, know that it is bad practice to make patterns with sharp corners. The sharp corner in a casting is the seat of weakness and possible failure. But notwithstanding this common knowledge, we go on committing the error every day. Prof. John E. Sweet has preached the gospel of liberal fillets

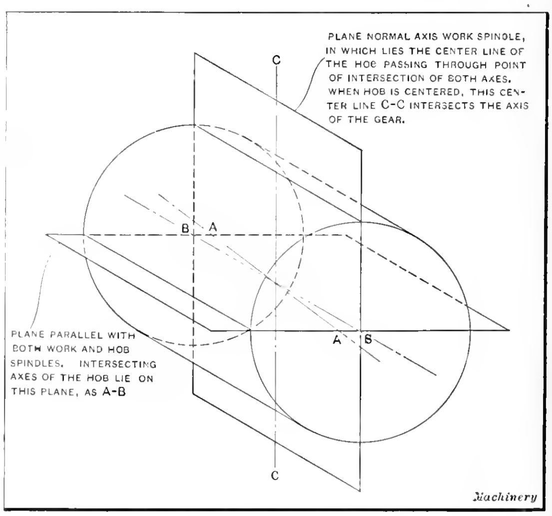

Fig. 11. Method of setting Hob when Axes of Form and Rotation intersect

and points out that in many places their use means an appreciable saving of iron. In the case of large cast-iron pipe tees, a fillet with a radius of three inches at the junction of the tee saves ten pounds of iron as compared with the not uncommon pattern having a very small fillet radius, and a better and lighter casting is the result.

REPLACING PINS IN THE WILLIAMSBURG BRIDGE

AN EXCEPTIONAL BORING OPERATION PERFORMED UNDER UNUSUAL DIFFICULTIES

THE structure of the Williamsburg Bridge, New York City, is at present being strengthened to sustain the increased load to which it is being subjected by additional traffic. This is done by building four additional towers under the approach spans between the main towers and the anchorages, and by strengthening the trusses. In connection with this work it became necessary to replace four hinge pins which connect the approach span trusses with those of the main span just outside of the main towers on the land sides. The original hinge pins had a diameter of ten inches, whereas the new pins are thirteen inches in diameter. One of these pins is located at the point indicated by the arrow in Fig. 1, and the other pin for this tower occupies a corresponding position on the opposite side of the tower. There are also corresponding pins for connecting the approach span to the tower on the other side of the river. These pins are about two feet below the level of the roadway and twenty inches from the tower leg. Fig. 2 shows the opening made through the floor of the south roadway preparatory to removing and replacing the pin on this side.

Heretofore, each of these pins was subjected to a load of 800,000 pounds from the approach span. In order to replace the ten-inch pin with the thirteen-inch size, this load was transferred to a new girder erected transversely above the ends of the main span trusses close to the tower. From this girder the approach spans were suspended, the load being transferred to them by means of wedges to relieve the pins. In order to rebore the pin holes from ten to thirteen inches in diameter, the truss members surrounding the hole had to be held perfectly rigid during the boring operation. This rigidity could not be obtained while the traffic on the bridge was in operation and even without the traffic the wind pressure and temperature stresses were likely to interfere with the boring; moreover, as the bridge is a main artery of traffic, only one night could be spared for the operations of removing one of the old ten-inch pins, enlarging the pin hole to thirteen inches in diameter, placing the new pin in the hole and erecting the new wind member on this pin.

Fig. 1. Williamsburg Suspension Bridge across East River, New York City—Arrow indicates One Point where 10-inch Pin was replaced by a 13-inch Size, necessitating an Unusual Boring Operation

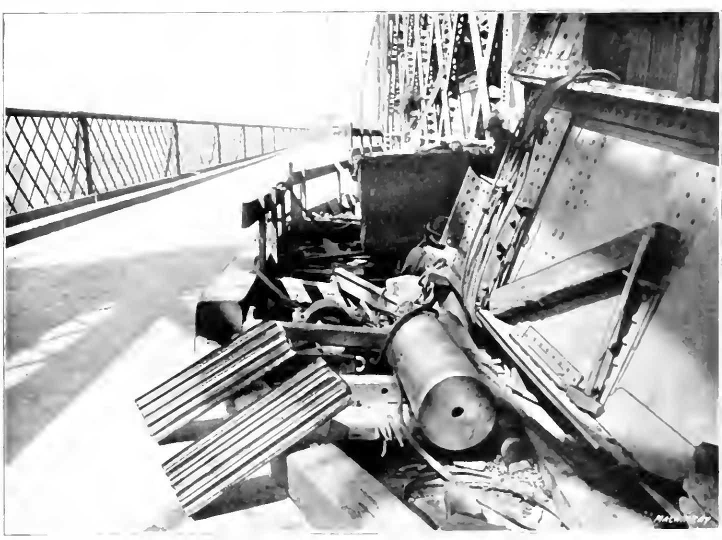

Fig. 2. Hole made in Roadway to make Room for Boring Machine—Collapsed 10-inch Pin and New 13-inch Pin in Foreground

To obtain the necessary rigidity between the different members while boring, steel plates, tie rods and special castings were fastened to the truss members and joined by bolts and wedges just before the boring operation was started. All traffic on the bridge but that of pedestrians, was stopped at 1 A. M., and the task of removing one of the pins, rebor-

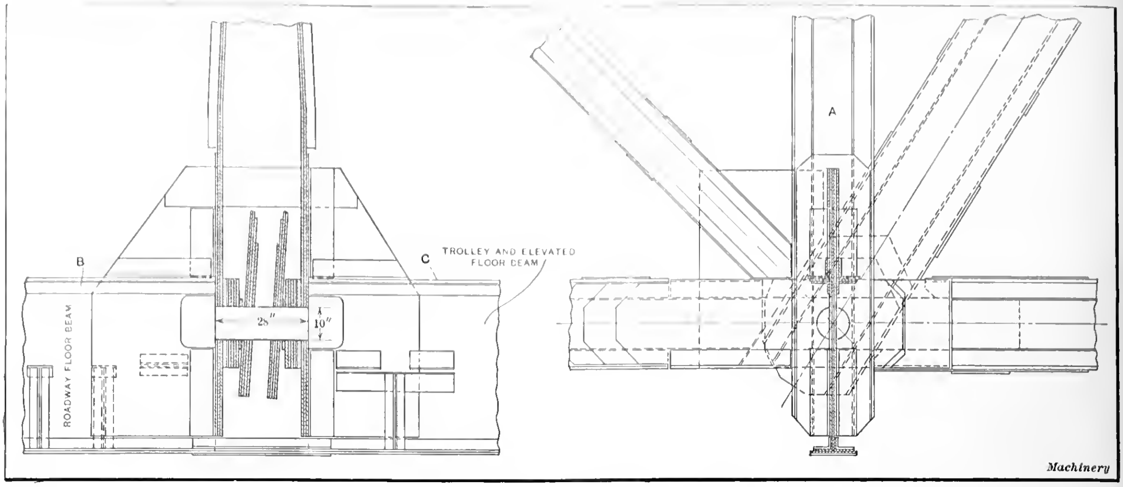

Fig. 3. Section and Elevation showing Pin Connection between Approach and Main Span Trusses

ing the hole and inserting the larger pin was begun. At 5:50 A. M. of the same day the new pin had been put into place and the bridge was open to traffic. It is evident that every step connected with this work had to be carefully planned beforehand. First, it was necessary to design and build a special machine for reboring the pin holes. The total length of the hole is twenty-eight inches, twenty-four inches of which is formed in solid steel plates. Some of these plates occupy oblique positions, as shown by the sectional view to

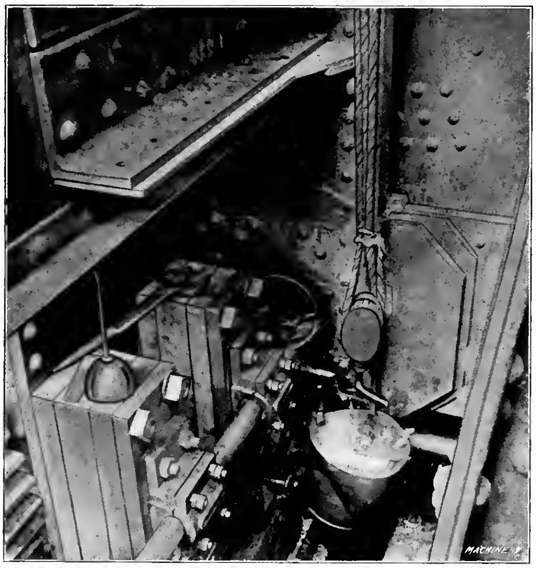

Fig. 4. Drilling Series of Axial Holes through Old 10-inch Pin to collapse it

the left, in Fig. 3, which further complicated the boring operation. The total amount of steel which had to be removed was 1300 cubic inches. The time limit for the boring operation was two hours.

The design of the boring machine was limited in several ways, but principally by the small space available between the axis of the pin hole and the leg of the main tower of the bridge, this distance being only about twenty inches in a horizontal direction. The problem was made more complex by the fact that the truss and roadway of the bridge connected thereto, are constantly moving either toward or away from the tower, which prohibited the use of the latter as a support for the boring machine. To the post *A* of the bridge (Fig. 3) which holds the pin, floor beams *B* and *C* are fastened on both sides at the vertical center line so that their webs cover the pin hole, as shown by the elevation at the right. While it was possible to remove a part of the floor beam on the roadway side of the post, the beam on the rear side, which supports the trolley car tracks, had to remain in place. After considering various ways of doing this work, a design of boring machine was finally adopted by the Department of Bridges; F. J. H. Kracke, commissioner; Alexander Johnson, chief engineer; Austin Lord Bowman, consulting engineer; and Leon S. Moisseiff, engineer of design. The structural design was in charge of Isidor Delson, assistant engineer; and J. R. Geogham, assistant engineer, was in charge of construction. The design of the machine and the boring operations were in charge of Martin Joachimson, assistant engineer.

It was found impossible to remove the old ten-inch pin, which was tightly stuck into its hole, even after the load had been transferred to the overhead transverse girder previously referred to. All attempts to remove this pin failed. An idea as to how tightly it was held in place may be obtained from the following: The pin had a 1½-inch hole extending through its center and this was enlarged at the outside end to 2½ inches and tapped. A bolt was then entered into this hole and by tightening a nut against a resistance, with large wrenches, an attempt was made to pull the pin out. The result was that the bolt snapped across the body but the pin did not move. It was then decided to collapse the pin in the following manner: On a horizontal line each side of the 1½-inch central hole, two 1 15/16-inch holes were drilled through the pin from end to end, which left six walls about ⅛ inch thick across the mid-section of the pin. As soon as a hole was drilled, tapered plugs were driven into both ends to prevent any distortion of the pin that might result from the stresses to which it was still subjected. After all the holes were drilled, the walls were removed one at a time, and, finally, after removing all of the plugs, the pin was collapsed and the two halves were pulled out easily.

In the operation of boring the 1 15/16-inch holes, the frame of the boring machine was used as a support for the smaller boring-bar. This bar, which is 2½ inches in diameter, was carried in two ordinary boxes or bearings as shown in Fig. 4, and was provided with an internal Morse taper at the end toward the pin. At the outer end there was an external

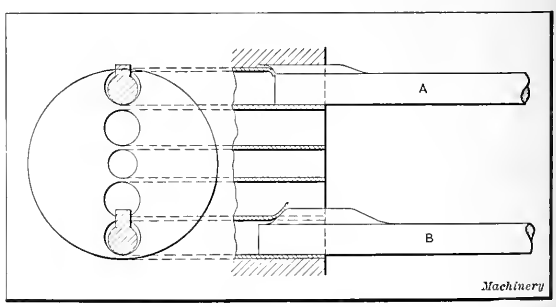

Fig. 5. Tools used to cut away Walls between Axial Holes drilled through Pin as illustrated in Fig. 4

taper where connection was made with a pneumatic drilling machine. After one hole had been bored, the bar was aligned for boring the next hole by placing packing blocks under the journals. The length of these holes was 29 inches and the drilling of each hole required three drills of different lengths, because of the limited space which made it impossible to use a longer boring-bar. These drills were of high-speed steel and had lengths of twelve inches, twenty inches, and thirty inches, respectively.

The walls between the holes were removed for collapsing the pin by means of special tools, as indicated by the diagram Fig. 5. Two types of tools were used, as indicated at

Fig. 6. Pin Hole after Removal of Pin and before reboring

A and *B*, and these were driven through the holes by means of a sledge-hammer. The slanted nose of tool *B* was used to cut away the walls between adjacent holes, whereas the walls at the outside of the pin were removed by the tool shown at *A*, which was provided with a cutting edge at the front, as the illustration shows. It required only about fifteen minutes to drive out one of these walls, where the minimum thickness was 1/8 inch, but a considerably longer time was necessary where the wall was thicker. The drilling of one of these 1 15/16-inch holes through twenty-nine inches of steel required about five hours, but the holes were drilled so accurately that not one of the walls was pierced when drilling the adjacent hole.

The two halves of the severed ten-inch pin are shown in Fig. 2, and also the new thirteen-inch pin at the right. The

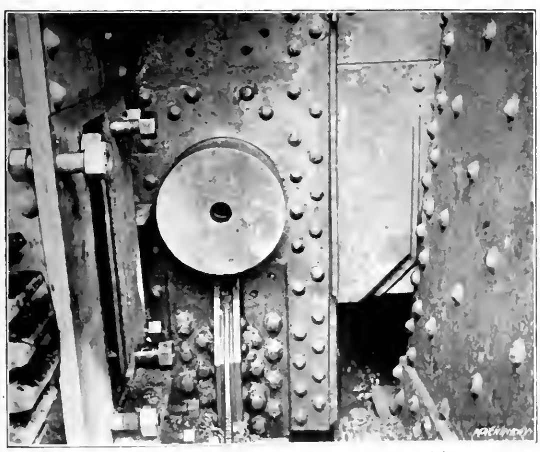

Fig. 7. View showing New 13-inch Pin in Position

ten-inch hole, after the pin was removed, is shown in Fig. 6; whereas, Fig. 7 is a view taken after the hole was bored and the new thirteen-inch pin was inserted. The special boring machine and tools used will be described in a later article.

The British Navy Department has announced that it has abandoned its own fine screw thread system in favor of the British standard fine screw threads.

ELECTRIC MOTOR STANDARDIZATION*

WHAT FEATURES OF ELECTRIC MOTORS CAN BE STANDARDIZED FOR MACHINE TOOLS

BY CHARLES FAIR†

This paper is not written so much with the idea of actually settling at this time the question of standardization of motor dimensions and speeds for machine tools as it is with the idea of pointing out a method which if followed should accomplish much toward the standardization desired. Certain of the dimensions and speeds once standardized will result beneficially not only to the machine manufacturer but to the motor manufacturer and to the machine user as well.

FACTORS TO BE CONSIDERED IN STANDARDIZING MOTORS FOR MACHINE TOOLS

SPEEDS

- Constant Variable[2]
  - A. C.
    - Full load / Synchronous
    - Cycles / Phase / Voltage
    - Squirrel cage — High torque / Normal torque
    - Slip ring[4]
    - Internal resistance
  - D. C.
    - Full load / Light load
    - Voltage
    - Shunt / Compound [3] / Series [2]
- Adj'tble[1] Variable[2]
  - D. C.
    - Voltage
    - Shunt / Compound [3] / Series [2]
  - A. C.
    - Brush Shifting — Shunt characteristics / Series characteristics
    - Multi-speed[5] — Constant horsepower / Constant torque
    - Slip ring[4] — Multi-speed [4,5]

NOTE

1. Adjustable speed motors.—Infinite number of fixed speeds within their speed range.
2. Variable speed motors—speed varies with the load { series / compound / slip ring
3. Compound wound motor—speed varies with the load and proportion of series and shunt winding.
4. Slip ring motor.—If resistance is left in circuit, speed varies with load and resistance.
5. Multi-speed motors.—A limited number of fixed speeds, seldom more than four as 600, 900, 1200, 1800.

SHAFTS

Diameter
Keyway
Length

- Gear
  - Involute — Steel / Rawhide
  - Herringbone
  - Bevel, worm — Thrust
- Chain
- Coupling
- Belt

Special extensions / Double extensions — Auxiliary drive / Handwheel

FRAME

Bottom of feet to center line of shaft
Shoulder on shaft to center of feet
Overall dimensions of feet
Drilling of feet—dimensions and sizes of holes

DRIVE

- Gears
  - Peripheral speed — Normal for constant / Maximum for adjustable — Cost / Size
  - Minimum number of teeth, pitch, face bore

Chain, coupling, belt
Reversing, non-reversing, slow down, brake { Dynamic / Solenoid / Mechanical
Range of speed required { Cost / Size of motor — Diameter vs. Length
All geared drive for constant speed { A. C. / D. C.
Balance of rotating parts
Change gears—motor speed overlapping

GENERAL

Uniformity marking motor terminals
Uniformity control diagram
Protection of live parts
Covers for end shields, etc.

The importance of motor driven tools has now reached such proportions as to warrant most serious consideration of this subject.

There will, of course, always be demands for odd combinations of speeds and requirements and these it would be useless to attempt to standardize; but by far the majority of cases could be standardized under a heading that for con-

* Paper read at the National Machine Tool Builders Association convention, held in Worcester, Mass., April 23-24, 1914.
† Power and Mining Department, General Electric Co., Schenectady, N. Y.

venience might be known as normal, and our efforts should be bent toward standardizing these speeds and dimensions.

For years and under generally adverse circumstances, much progress has been made in the standardizing of certain machine parts, with results advantageous both to the machine manufacturer and to the machine user. For a long time it has been recognized as desirable at least on the part of a number of the machine tool builders that something be done toward standardizing certain motor dimensions, speeds, etc., for machine tool drive. For the past five or six years attempts have been made to standardize certain dimensions and speeds for machine tool motors, but these attempts have failed for various reasons. It would be of little use to analyze these past failures. Unquestionably there should be first of all a better understanding on the part of the machine manufacturer and the motor manufacturer of each others difficulties; and much work is essential before material progress along the line of standardization can be accomplished. With this in mind, I have prepared an outline which I think fairly presents the situation from the viewpoint of both sides and which must be considered if real progress or results are to be obtained.

It could not be expected that the electrical manufacturers would change existing standards of motor dimensions or speeds, nor do I believe it would be either desirable or practicable to do so on account of the confusion that would result; but I see no reason, if the machine manufacturer in conjunction with the motor manufacturer will give the subject the consideration it warrants, and do his part toward bringing about a better understanding of what is really desirable in the way of speeds and dimensions, why the motor manufacturer, in turn, cannot incorporate, at least in part, some of the dimensions and the speeds when bringing out new lines of motors. Obviously it would be just as impracticable for the various motor manufacturers to design their motors to a single set of dimensions as it would be for the machine manufacturers to design their machines to a single set of dimensions. Notwithstanding this, however, much can be done to improve the situation. The American Society of Mechanical Engineers has offered to cooperate and is willing to do everything within its power to help in this question of standardization. Before going further into the subject, it might be well to look at the outline given in the accompanying table that we may have a better understanding of the subject as a whole.

For the sake of convenience, I have divided the outline into five parts, namely, speeds, shafts, frame, method of drive, and general.

Speeds.—Under the heading of speeds, there is an almost endless number of constant, adjustable, and variable speed combinations available, but from this great variety, certain speeds should become the logical ones for the majority of drives. The direct current constant speed shunt motor speed, for instance, should logically be that of the alternating current sixty-cycle motor. Alternating current and direct current motor speed should be given in terms of full load or else in terms of both no load and full load. It is, of course, understood that the cycles fix the alternating current speeds, except as modified by slip, etc. Adjustable speed motors would naturally be higher in speed on the highest speed than a constant speed motor because the adjustable speed motor would only run a certain percentage of the time at high speed. Adjustable speed motors are nearly always geared and their speeds should be governed by a proper gear speed.

There should be little difficulty in arriving at a set of suitable speeds per horsepower to be known as standards for both constant and adjustable speed motors after properly considering the items as set forth in the table.

Shafts.—Obviously there should be little difficulty in arriving at a proper shaft diameter and key for a given horsepower and speed motor. The length of shaft might offer some difficulty, but a compromise length could probably be agreed upon. Special shaft extensions and double shaft extensions, whether for handwheel or power transmission, should be considered.

Frame.—A uniformity of dimensions under this heading is obviously impossible but much can be done to reduce the large variety of dimensions to perhaps two or three sets per frame instead of the dozen now existing. There is, of course, no reason why there should not be a uniformity in the size of the holes drilled in the motor feet per frame.

Drive.—It is not only important but absolutely necessary to consider seriously the items under this head in order to arrive at some basis upon which properly to determine the best speeds, shaft dimensions, etc., to standardize. Here we should consider such subjects as diameter of motor *versus* length, minimum speed *versus* size and cost, maximum variation for adjustable speed motor and its relation to minimum speed, cost, and size of motor.

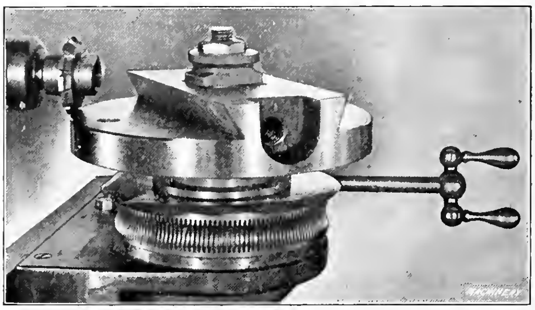
General.—Uniformity of making motor terminals, wiring diagrams, protecting live parts, etc., is of advantage to all concerned.

The machine user will derive considerable advantage from the standardization of motor speeds and dimensions as well as the machine manufacturer. The importance of the motor-driven machine tool with relation to production has become such that the method of applying the motor to the tool, in my opinion, warrants far more attention than has been given to it in the past by some of the tool manufacturers.

* * *

EDGE-ROUNDING ON A MILLING MACHINE

The simplest jobs are often the most troublesome. The Stockbridge Machine Co. of Worcester, Mass., had one of these simple jobs that caused considerable trouble for some time. It was the rounding off of sections of the edges of swivel-plates used in the heads of their shapers. The edge of the plate required rounding over for a section of about ninety degrees on each side of the swivel-plate. To round the edge over with a file, giving the same appearance to each side of the plate and stopping off at points uniformly distant from the center line, was a job that was not always correctly done. To secure uniformity on this job, the superintendent of the



Rounding the Edges of a Circular Plate

shop of the above company devised the little rig shown in the accompanying illustration. This consists of a worm-wheel mounted upon a vertical arbor, which was mounted on a milling machine at right angles to the spindle. The swivel-plate is placed above the worm-wheel, and is capable of being rotated by means of a worm turned by hand. On the spindle of the milling machine there is a quarter-round forming cutter, and by turning the work on the spindle by means of the worm and worm-wheel the edge is uniformly rounded. Lines are marked for the beginning and end of each cut so that the rounding may be started and stopped at the right places. In addition to doing the work better, it is also a much quicker method. C. L. L.

* * *

In Holland, a special branch of engineering is devoted to land reclamation, that is, reclaiming the land from the sea and protecting it by dikes. The people of Holland boast somewhat irreverently that God made the rest of the world but the Dutch made Holland. From twenty to twenty-five thousand acres of land are thus "made" every year, but there are still 250,000 acres of the best land under water, susceptible to reclamation, not including the great area under the Zuider Zee, the reclamation of which is a never-ending topic of discussion. The question is simply one of engineering and the necessary capital to carry it out.

MECHANICAL PRODUCTION RECORDING

AN ELECTRICALLY-OPERATED MECHANISM FOR INDICATING AND RECORDING MACHINE OPERATIONS

BY DOUGLAS T. HAMILTON*

Of the twelve principles of efficiency classified and arranged by Harrington Emerson, the sixth, *viz.*, reliable, immediate and adequate records, is an important factor of efficient production. Information or data which has been secured from biased sources is worthless. Records which are not classified or arranged in such a manner that they can be referred to readily have little or no practical value, and records which are incomplete or inadequate are a hindrance rather than a help.

As an example, a piece-rate price which is set by stop-watch observations is not always accurate because of the human element, which complicates the problem. Records, to be reliable, must be made over a considerable period of time so as to cover all the variable conditions of material, operators, etc. Furthermore, the human element should be eliminated as far as possible and mechanical means substituted.

Fig. 1. The Production Manager or Cost Clerk has Adequate Production Figures at His Finger Tips

The electrically operated instrument to be described in the following gives this desired result. It operates, of course, independently of the operator and records accurately any movement of the machine to which it is connected. It is made by Slocum, Avram & Slocum, Inc., engineers, 30 Church St., New York City.

Operating Mechanism and Connections

The mechanism of the "Productograph" consists primarily of magnets, which, when energized, attract needles that draw lines on a revolving chart. At the same time, the magnets actuate counters which record the number of lines drawn by the needles. Every tenth line on the chart is shown by a line a little longer than the rest, which greatly facilitates counting if the production of the machine between any two limits is desired. The needle point is made of German silver, and the chart of lead paper. The line drawn is very distinct and cannot be easily erased. No ink or other recording devices usually incorporated in instruments of this kind are necessary.

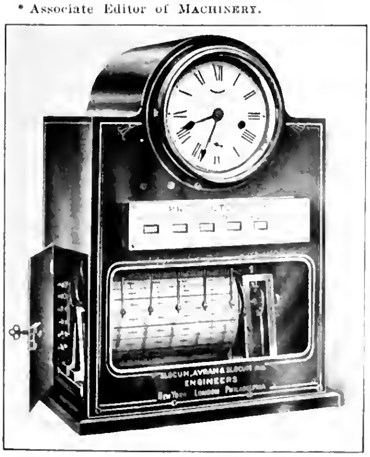


Fig. 2. The "Productograph"—a Machinery Efficiency Recorder

The movements of the machine under test are transmitted to the recording instrument of the "Productograph" by means of the switch shown in Fig. 3, which is attached to that portion of the machine on which a record is to be made. It consists of a small cast-iron box 3 by 4 by 1¼ inch, which is fastened close to any revolving shaft or part of which the motion is to be taken. Inside this iron case is a ratchet *A* which is held on the arm *B* and carries a cam *C* usually worked out in a ratio of 10 to 1 with the ratchet *A*, but it can be made, of course, to suit any desired speed. By a 10 to 1 reduction between the cam and the ratchet, it requires ten oscillations of the switch arm *B* to make one contact; hence one line is drawn on the chart every ten oscillations of the switch arm. Cam *C*, through a lever *D*, operates a plunger *E* in an air chamber which, in turn, causes the contact of two flat springs *F*. The cam then allows the plunger to return immediately to its original position, so that no matter in what position the machine is left at night there is no danger of the switch being short-circuited.

The connections from the switches to the instrument are made by ordinary wiring, and from each of the switches fixed to the machine a single wire is run to the corresponding terminal of the magnet coil in the "Productograph"; in addition, a wire which is common to all switches is connected to the source of electric supply and thence to the common terminal in the instrument. The wire used should in no case be less than No. 16 B. & S. wire gage, but the size depends largely on the distance of the switches from the "Productograph." The conductor should be well insulated and carried in cleats and when running under or near the machine should be enclosed in circular loops. The neatest installation that could be adopted, of course, would be to enclose all wires in metal tubing.

Power for operating the "Productograph" is of three different types. Dry batteries should not be used because they become exhausted too quickly. Storage batteries may be used with good results if properly attended to, but the best and most satisfactory method is the motor generator. This can be connected to an ordinary lamp socket, and is the best means of obtaining regularity of movement of the drum and the correct action of the recording needles. This, of course, is absolutely essential if a complete and accurate record of any machine movements is to be obtained.

Samples of "Productograph" Records made on Bullard "New Era" Vertical Turret Lathes

A five-point "Productograph" installed in the plant of the Bullard Machine Tool Co., Bridgeport, Conn., was attached to one of their "New Era" vertical turret lathes. Five movements of this machine were connected to the "Productograph," *viz.*,

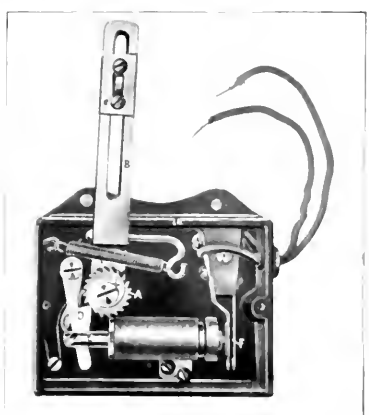

Fig. 3. Operating Mechanism of the Switch

* Associate Editor of Machinery.

the main head vertical feed, main head horizontal feed, table rotation, side head vertical feed and side head horizontal feed. By this means it is possible to make a comparison of the relative movements of the two heads vertical and horizontal in either direction and also to record the number of revolutions of the work table. Records have been made with the machine in operation on both steel and cast iron. The following gives the record that was made on a 0.40 to 0.50 per cent carbon machine steel forging.

Efficiency Record of Bullard "New Era" Vertical Turret Lathe on 0.40 to 0.50 Per Cent Carbon Machine Steel Forgings

The section of a "Productograph" chart shown in Fig. 5 shows a record of a Bullard vertical turret lathe on a run of two hours, approximately. This is part of a time study which covered a period of ten days and which was made while machining eighteen unannealed 0.40 to 0.50 per cent carbon steel forged disks, 24 inches in diameter, each weighing 405 pounds in the rough. The instrument was attached to five different motions of the vertical turret lathe, giving complete and detailed records of every operation. The first column of this chart gives the main head vertical feed; the second column, the main head horizontal feed; the third column, the work-table speed, or revolutions per minute; the fourth column, the side head vertical feed; and the fifth column, the side head horizontal feed. These various movements, except the table rotation, are recorded in thousandths of an inch.

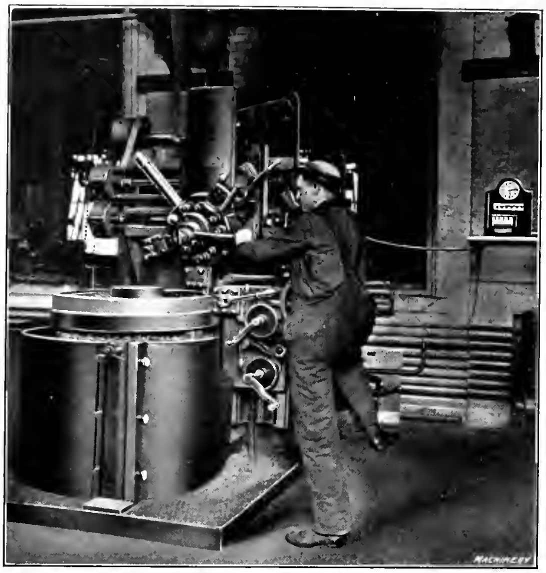

Fig. 4. "Productograph" recording Five Movements of a Bullard "New Era" Vertical Turret Lathe set up and in Operation on Large Cast-iron Flywheels

The section of the chart in Fig. 5 shows when the tools held in either head are cutting, when they are being used at the same time, the rate of feed, the cutting speed of the work and the lost time between cuts—in fact, every detail that usually requires an elaborate and expensive stop-watch test. This record also shows the use of the rapid traverse movements by the operator. The actual running time of the work chuck for the test made on March 4 is figured out as 276 minutes, and the actual running time of the tools, 230 minutes, giving a productive efficiency of the machine of 83 per cent. The time from 7 to 10 A. M. was spent waiting for tools and the machine was run from 10 to 5:30 P. M., or approximately 390 minutes. The productive machine time, therefore, is 230 minutes and the combined machine and operator efficiency figured out on this basis is 60 per cent. These records were taken during a time study period before the best tool set-up had been determined and do not show the high efficiency ultimately obtained. Only a section of this "Productograph" chart has been shown in the illustration, but it demonstrates how this instrument records every desired movement of the machine, and gives an excellent comparison of the relation of the various operations and machine movements.

The chips removed by this machine were at times 1¼ inch wide by 0.018 inch thick and the material was full of hard spots. Fig. 8 shows one of the interesting arrangements used for machining this machine steel forged disk. The flange joining the rim and hub had to be machined tapering, and to provide for this a guide strip was held in a toolpost in the main head which remained stationary. The side head was used for taking the cut, the saddle being unlocked and kept in action, while the tool was traversed horizontally by the feeding mechanism. The data for the particular set-up shown in Fig. 8 is as follows:

Operations	Start	Finish	Average
Feed of work in feet per minute starting at smallest diameter of disk	71	205	138
Feed of tool in inches	0.011	0.011	0.011
Depth of cut in inches	1	1¼	1 1/8
Pounds of stock removed per minute	2.7	9.8	6.25
Revolutions of work chuck per minute	39	39	39
Length of cut in inches	..	..	6½

Material—0.40 to 0.50 per cent carbon machine steel forging.

The weight of the solid blanks in pounds was 405; the weight of the blank roughed out by the first operation, 185 pounds; the weight of the stock removed, 220 pounds; the total roughing time on both sides of the forging, 88 minutes; and the weight of the stock removed per minute, 2½ pounds.

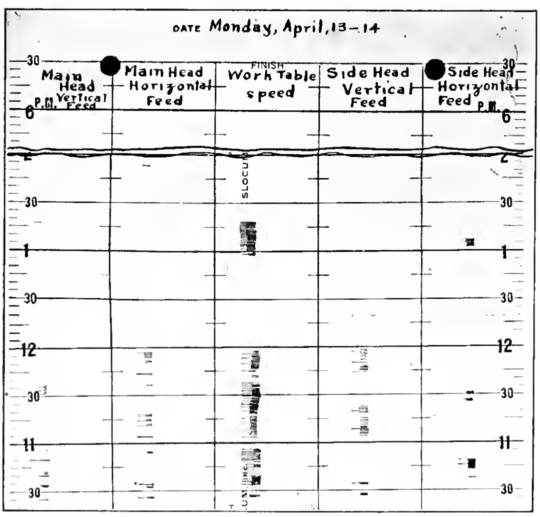

Fig. 5. "Productograph" Record of the Machining Operations of a Bullard Vertical Turret Lathe on a 0.40 to 0.50 per cent Carbon Steel Disk

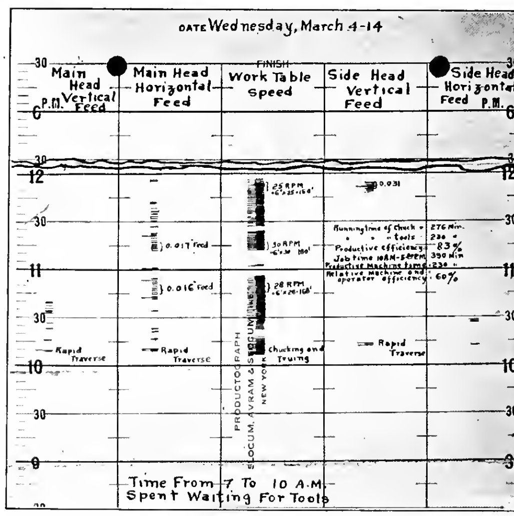

Fig. 6. "Productograph" Record of Machining Operations of a Bullard Vertical Turret Lathe set up and in Operation on a Large Cast-iron Flywheel

A "Productograph" Record made on a Bullard Vertical Turret Lathe—Machining a Cast-Iron Flywheel

Another job upon which a "Productograph" record was made in the plant of the Bullard Machine Tool Co. was a large cast-iron flywheel upon which five separate readings were made. For instance, the "Productograph" was connected by switches to the vertical shaft, rotating at an exact multiple of the table speed, to the cross-feed screw of the main head, to the down-feed screw of the main head, to the horizontal feed of the side head, and to the down feed of the side head. In this way, it was possible to secure relative

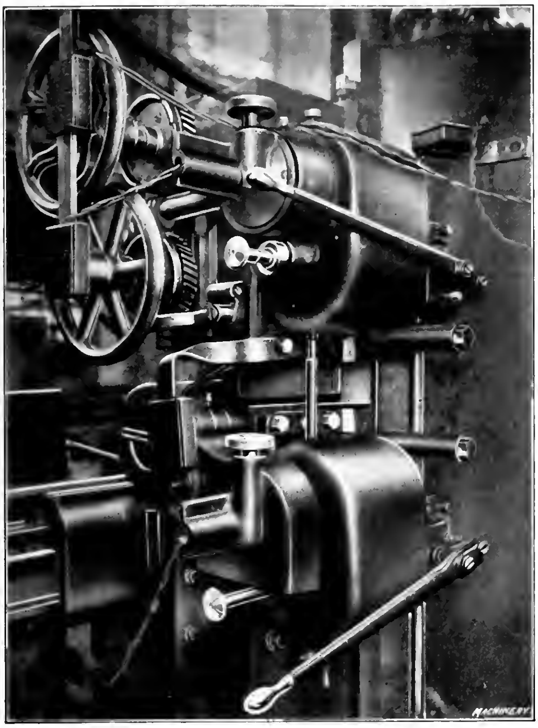

Fig. 7. The Movements of the Machine are transmitted electrically by Switches which are attached to the Operating Members

positions on the chart of these two heads and the time required for them to perform their individual operations.

On this job, a stop-watch test was also made to show how close the "Productograph" record was to the actual stop-watch test. The test started at 11 A. M. and was conducted as follows: Put wheel on table, 11:04; true up casting, 11:05; crown face with side head vertical feed of 0.131 inch per revolution, ¾ inch depth of cut and a table speed of five revolutions per minute, a forming attachment as shown in Fig. 9 being used. This enables the rough-turning and crowning operations to be accomplished without reversing the position of the work on the table. 11:07, face side of rim with main head, using a cross-feed of 0.083 inch per revolution of the work, and a cut ½ inch deep; 11:15, main head cut finished; 11:16, side head cut finished; 11:16, finish-face side of rim with main head—hand feed to just remove the sharp corners; 11:17½, set up for finish-crowning rim, five revolutions; 11:18, finish-crown rim at 0.245 inch feed per revolution; 11:19, set for boring hole with main head, feed 0.083 inch per revolution of the work; 11:22½, final cut of side head finished.

Continuing operations, bring side head for facing hub into position; 11:23, face hub, 16 revolutions of work at a feed of 0.083 inch per revolution and a depth of cut of ½ inch—horizontal feed used; 11:26, change speed to 20 revolutions per minute; 11:27, side head cut finished—stop to clear chips from beneath hub of work to allow boring tool to enter to the correct depth; 11:27½, continue boring at a feed of 0.083 inch per revolution, 29 revolutions of the work required; 11:28, change cutter in the boring tool; 11:28½, start second boring cut and finish-face hub with side head at a horizontal feed of 0.245 inch per revolution of the work; 11:30, finish-bore at 0.245 inch feed, rotating work at 48 revolutions per minute; 11:32, chamfer the hole with boring tool; 11:32½, ream hole 0.245 inch feed per revolution, work rotating at 39 revolutions per minute; 11:34, change cutters; 11:35, size hole with work rotating at 39 revolutions per minute and a down feed to the cutter head of 0.245 inch per revolution; 11:36½, chamfer hub with main head, 12 revolutions of work required using hand feed; 11:37, chamfer rim with main head—five revolutions required; 11:38½, take casting off machine; 11:40, casting off.

This casting, as tested with a scleroscope, indicated from 28 to 29 points hard. The weight of the casting before machining was 859 pounds, and after the first operation only, it weighed 722 pounds, indicating that 137 pounds of material had been removed in 40 minutes—the time required to complete the first operation.

Reference to the "Productograph" chart shown in Fig. 6 in comparison with the stop-watch test given will show that the instrument recorded not only the combination movements of the two heads, but also the revolutions of the work, indicating when the rapid power traverse was used; when analyzed it would also give the feed at which the cutting tools were operated.

The analysis of this chart, however, is not a simple matter and requires some study. The ratio of the gearing in the switches has to be taken into consideration and also any other ratios in the machine between the points where the switch is attached and where the movement that it is desired to record takes place. For instance, the vertical shaft on the Bullard vertical turret lathe does not rotate at the same speed as the table, but at an exact multiple of the table speed, so this ratio must be taken into consideration when figuring out the chart. However, as this information is all known beforehand it is simply a matter of using it as a constant when making the desired calculations.

Possibilities of the "Productograph" as an Efficiency Recorder

There are several different uses for the "Productograph" in the machine building plant or other manufacturing establishments. One very good application would be for setting piece-work rates. A test record can be taken over a long period of time so as to get both the machine and operator working at what might be called an average efficiency, which, of course, would be the only reasonable basis upon which to set a piece-rate. This record is made unconsciously by the operator so

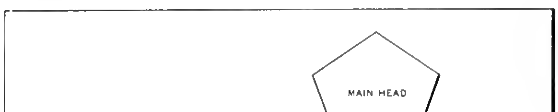

Fig. 8. Set-up on a Bullard Vertical Turret Lathe for machining a Beveled Surface on a Machine Steel Disk. For "Productograph" Record, see Fig. 5

that every move is recorded and the human element does not enter into the record at all; the result is, therefore, reliable.

From observations of this instrument on the Bullard vertical turret lathe, the following general conclusions are drawn: As a means of indicating the feed of the tools, the "Productograph" is of little value. Its application to the vertical turret lathe is satisfactory only in so far as it indicates the production in a certain specified time and the time required to turn

out each piece, also the production per day. This indicates the grade of the material, that is, whether it is hard or soft, and also whether the operator keeps the machine working to its best efficiency. By connecting various points of the "Productograph" with the different heads of the machine and its mechanical movements, it is also possible to trace whether the operator has followed the proposed layout or not. This is generally a vital point in the operation of a Bullard vertical turret lathe. There are certain combinations of tools in the main and side heads that give the best results for different jobs and this information is, as a rule, definitely obtained before the operator is set to work on the job. If he does not follow the outline suggested, he, in many cases, drops down below the estimate production. Of course, in the nature of things, he will not condemn himself and it is therefore impossible for the foreman to determine the reason for the decrease in production. The "Productograph" shows this up forcibly. It would seem that this point alone would warrant its installation in plants where large numbers of parts are to be turned out per day or year, on machines of the type where a certain specified order of operations has to be followed.

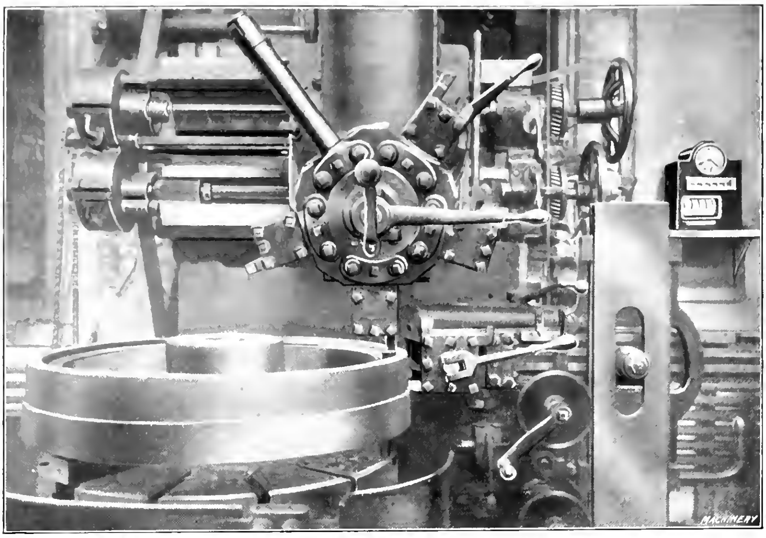

Fig. 9. Facing and Turning Operations taking place simultaneously. The Chart, Fig. 6, shows that this has been recorded

Probably the most important field of the "Productograph" is for machines which are set up and in operation on one piece of work and are run on that continually, and where the production from the machines per day is the only point on which a record is to be kept. The chart gives the information that the manager of a plant desires, and as it comes from an unprejudiced source it is of unquestionable value. Furthermore, it shows this record in such a manner that a manager can immediately find out whether a machine is working efficiently or not. For instance, as soon as a machine breaks down, the "Productograph" stops recording. A "live" manager will then call up the foreman to find out first hand what is the matter and just why the machine is not working. Suppose ten minutes or more after, the machine is still inoperative, the manager again calls up the foreman. This has the effect of making the foreman feel the responsibility of his position, and he thereafter makes it a point to see that a machine which has broken down receives immediate attention. This tends to increase the value of factory discipline and increases production and efficiency.

Of course, any mechanical instrument of this kind will not raise the production of a plant, but it forms the basis upon which scientific methods of management can be properly conducted. It shows clearly what part of the investment is idle and what part non-productive, and in reviewing the charts from day to day the average efficiency of machines and operators can easily be obtained. It also shows up many other points as regards efficiency of foremen, operators, machines, etc., which it would be impossible to obtain without its use. While in a sense it is a detector of production as much as a recorder, it discloses defects and hence, instead of being a hindrance to an operator, it is really a help. The information is taken from the "Productograph" charts and entered upon daily and monthly cards, from which a comparison of the efficiency of the various machines in the shop can be easily obtained. If these records are properly kept up, they form a basis also for piece-rate working systems and other efficiency standards, as well as exact cost systems.

* * *

It is probable that the first attempt to transmit power through any distance was by means of a rope. The first application of rope for power transmission was for hoisting and this suggested the possibility of using the same method for transmitting power from one revolving shaft to another. A single rope was originally used which was essentially a sort of round belt running in a grooved sheave. The next development consisted of the application of a flat leather belt running on cylindrical pulleys, where a greater frictional surface was required for transmitting larger amounts of power. In modern practice rope drives are used to transmit high powers by the application of a number of strands of rope. The drive may either be arranged on the English system, where the required number of separate ropes are used; or on the American system, where a single endless rope is employed, which is carried back and forth over the pulleys to provide the required amount of driving contact.

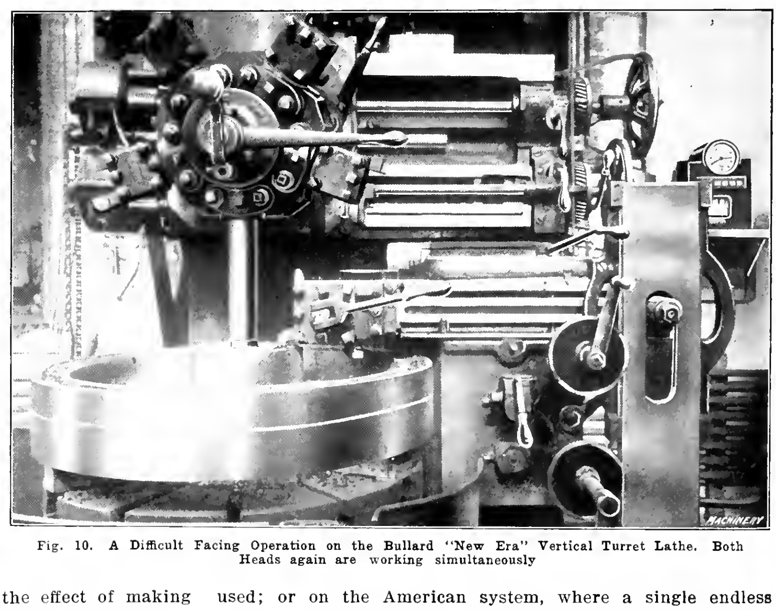

Fig. 10. A Difficult Facing Operation on the Bullard "New Era" Vertical Turret Lathe. Both Heads again are working simultaneously

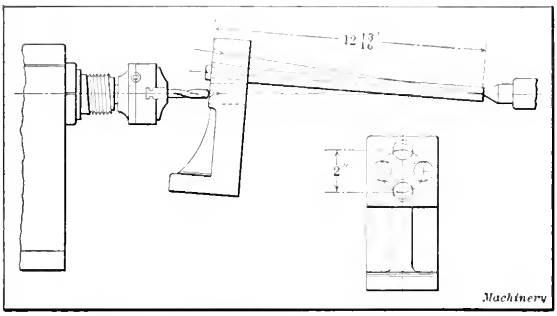
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

A DIFFICULT DRILLING OPERATION

A rather novel way of accomplishing a difficult operation is shown in the accompanying illustration. The work consists of a bracket, in which it was required to drill four holes equally spaced around the circumference of a 2-inch circle; the holes had to be inclined at such an angle that their center lines would come together at a point 12 13/16 inches from the front face of the bracket. This job was handled very satisfactorily by first drilling a hole at the center of the circle around which the four small holes were to be drilled; the center hole was square with the face of the bracket and was for the purpose of receiving a stud 12⅞ inches in length. The stud was centered at the further end to receive the tail center of the lathe, thus locating the face of the bracket 12 13/16 inches from the tail center.

The four small holes to be drilled around the circumference of the 2-inch circle were now laid out and center-punched, after which the work was ready for the drilling operation. The stud was located against the tail center of the lathe and the holes centered to 5/16 inch with a combination center drill. When the holes had been drilled and reamed the bracket was taken off the stud and mounted on a plug in a draw-in chuck, then counterbored a short distance to the size of the drill that was to be used. After this work had been done, the bracket was replaced on the stud and carefully drilled and reamed to the finished size. In preparing for the



Method of handling a Difficult Drilling Operation

drilling operation, the work was blocked up on the lathe bed to nearly the right height, but as the piece was of light weight it was an easy matter to hold it in line with the drill and also keep the stud against the dead center of the lathe. The work could be further supported by bringing the lathe carriage up against the back of the bracket.

Buffalo, N. Y. RICHARD WILCOX

AN UNUSUAL LATHE JOB

The machining of "outside" jobs that are beyond the capacity of the machines at hand frequently presents problems that require a different solution from those encountered in the regular shop work. A lathe job of this kind is shown in the accompanying illustrations which indicate the manner of machining this unusual piece of work at the Pond Works of the Niles-Bement-Pond Co., Plainfield, N. J. The special shaft to be machined has the following dimensions: Length over all, including square portion, 27 feet; diameter of threads, 10½ inches; lead, 3½ inches; half of cylindrical portion threaded right hand and half left hand; square part, 7 inches square.

As there was no lathe available with sufficient capacity and the necessary length of bed, two Pond 36-inch triple geared lathes that stood on adjacent foundations were selected for the job. From an inspection of the illustrations it will be seen that the headstock of one lathe and the tailstock of the other were removed and the beds were brought into proper alignment. To prevent endwise motion of the beds, straps were used to join the end legs, the front strap being shown at *A* in Fig. 2. The same illustration also shows at *B* how the two lead-screws were joined by a suitable coupling for the purpose of feeding the tail-end carriage by power.

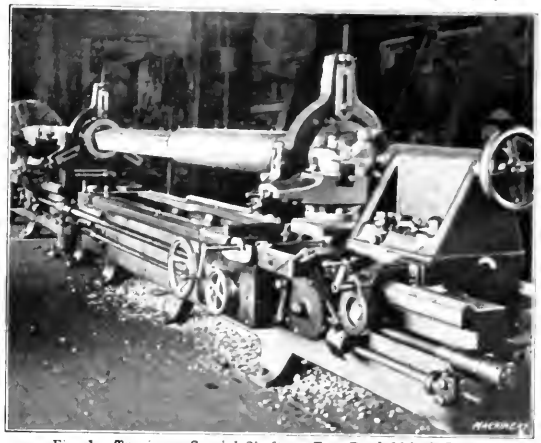


Fig. 1. Turning a Special Shaft on Two Pond 36-inch Lathes

It will be observed that bushings of ample proportions are provided for the steadyrests, which carry the principal weight of the shaft. The machining was accomplished in the usual manner, the shaft being turned end for end in order to reach the portion between the gap in the beds. The square part was machined on a planer after the shaft was rough-turned all over in the lathe.

Plainfield, N. J. ALFRED SPANGENBERG

SQUARE KEY VS. RECTANGULAR AND TAPERED KEYS

The article of this title which appeared in the March number of MACHINERY brought to mind certain experiences with keys on machine tools which may throw some further light upon the subject. It appears to the writer that a little more

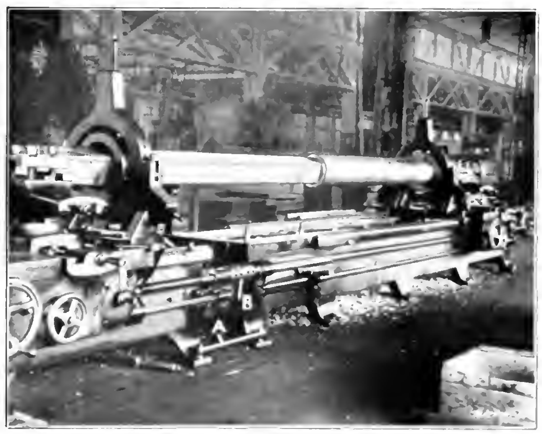

Fig. 2. Arrangement of the Leg Straps and Lead-screw Coupling

investigation of the work actually done by the keys, and not so much in the way of drafting-room calculations would result in more efficient designs, this being particularly true in the case of keys and bearings. Take, for instance, a pulley which is driven with a reversing motion, as in the case of belt-driven planers. A square key soon becomes loose both in the pulley and shaft, owing to the fact that the keyway is

too shallow to stand the strain. In repairing, it is necessary to compensate for wear in a way which makes the keyway both wider and deeper, but results in the use of a rectangular shaped key. Where this practice has been followed no further trouble was experienced and the shaft and pulley showed no signs of weakness.

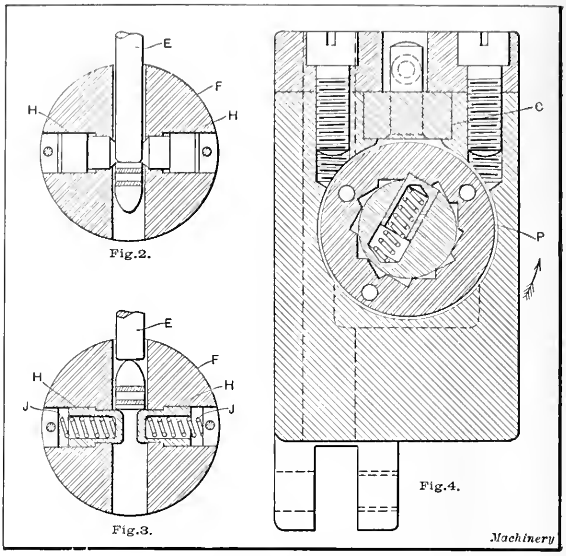
Sliding members on spline shafts should have keyways of rectangular design in order to give more wearing surface on the side of the key, and will stand the strain of the drive better. There should be a key on each side of the shaft, as sliding members are less likely to stick, and wear is more equalized, especially in the keyways. This practice will be found to give satisfactory results on the shafts used on the upright drills with four or more heads, on cold cutting-off machines and a variety of other machine tools. As Mr. Wiweke says, a square key "fills the bill" and I agree with him in most cases, and also that keys should be made of larger size than is the present practice.

The chief objection to tapered keys is that they are sometimes very hard to remove. This difficulty is not experienced with straight keys, and such keys can be securely held in place by using a small set-screw as a retainer, carried in a hole tapped through the hub of the pulley. Such a design is used by a well-known firm of machine tool builders who manufacture draw-cut shapers. As for the weakening of the shaft by the keyway, I have never seen a shaft break at the point where the keyway was cut, and I have had experience in operating some very heavy planers. I have, however, had considerable trouble through small keys working loose, due to the fact that the keyseats were made too shallow. I have also seen cases in which the corner of the cast-iron pulley has broken off at the keyway, and other cases in which the key has failed by shearing.

Dover, N. J. J. L. Diggory

AN AUTOMATIC FEED FOR BULLETS AND SLUGS

A device that feeds lead bullets or slugs to press tools in a uniform direction, regardless of the way in which it receives them, is shown in Fig. 1. The device is attached to a Waterbury-Farrel press with 4½-inch stroke, and the bullets enter the tube *A* from a hopper located above the press. The hopper is equipped with an agitator tube and a lever for reciprocating this tube, which is moved up and down through the bullets and drops them into the tube *A*. The bullets are taken from the tube *A* by the slide *C*, which is operated by the cam *D* fastened to the cross-head, and carried under the descending punch *E*. The punch-holder *L* is also carried by the cross-head. Should a bullet enter the tube *A* with the rounded side downward, as is the case with the first and third bullets shown in the tube *A*, it is pushed on through dial *F* and into the feed pipe *G* which carries it to the dial plate of the press. The dial, in turn, carries it under the working tools, and such operations as swaging or sizing are performed on it. The construction of the dial *F* and its action when a bullet happens to enter it in this position is shown in Fig. 2. The plungers *H* are chamfered on the end and the punch *E* forces them back against the action of the springs *J*, the



Figs. 2 to 4. Details of Feed Dial F and Clutch P

bullet dropping through the dial into the tube *G*. Should a bullet be in an inverted position, the action of the device is shown in Fig. 3. The flat bottom of the bullet rests on the straight portion of the plungers *H*; this prevents further descent of the punch *E*, spring *K* contracting back of it to take up the motion of the cross-head.

Carried in bracket *L* is the rack *M*, which meshes with the pinion *N*. The index plate *O* is doweled to dial *F* and the clutch *P* is fastened to sleeve *R*. Fiber friction washers *S* are used to prevent breakage should anything out of the ordinary happen. A section through clutch *P* is shown in Fig. 4.

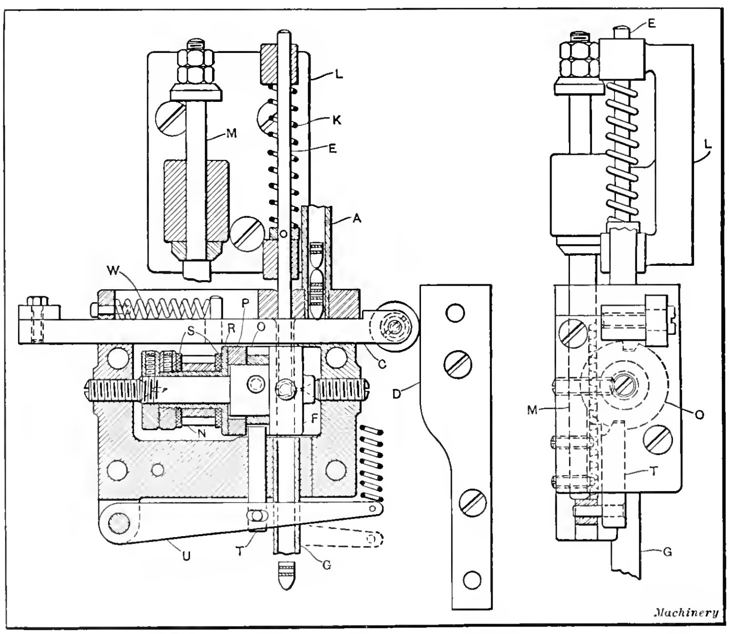


Fig. 1. Automatic Feed Mechanism for Bullets and Slugs

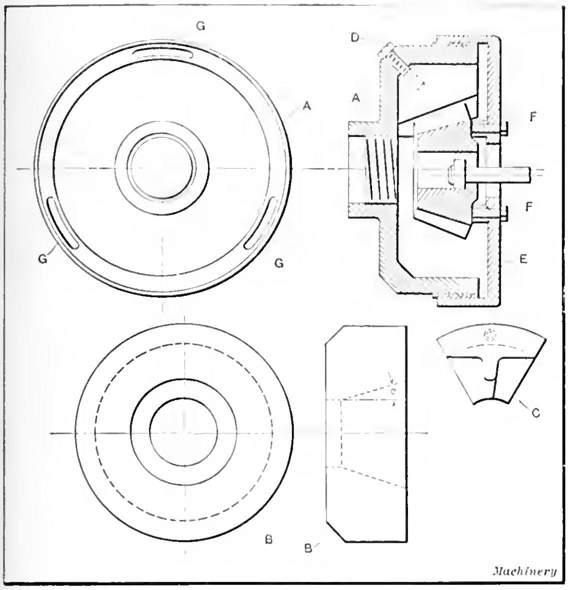
When the cross-head descends, the rack *M* revolves the clutch in the direction shown by the arrow in Fig. 4. The dial *F* is held by the plunger *T* which enters a hole in the index plate *O*. When within ¼ inch of the end of the down stroke (this position is shown in Fig. 1) the rack *M* strikes the lever *U*, pulling out the index plunger *T*. The rack descends far enough to give it time on its return stroke to move dial *F* before the returning index plunger can re-enter its former index hole. On the return stroke, the lost motion of the rack in its bracket gives time for the withdrawal of punch *E* before dial *F* is revolved, and this lost motion can be adjusted so that it reaches the highest point of the up stroke just as the dial *F* has revolved through 180 degrees to its other index hole. However, the friction washers *S* will allow for slippage should the rack carry too high. Referring to Fig. 3, it can be readily seen that the bullet is turned end for end when dial *F* is moved through 180 degrees. The bullet drops out of the dial and down pipe *G* to the machine dial in the same direction as the bullet entering in the opposite direction.

The dial F is carried on hardened centers to give accurate alignment, easy adjustment and light turning. The spring W is used to return the slide C. LAWRENCE FAY

BEVEL GEAR CHUCK

The accompanying illustration shows a chuck which I recently designed for holding bevel gears while grinding the hole. After the chuck A has been made, it is screwed onto the spindle of the machine and finished by grinding. The ring B is next made with the angle a equal to the root angle



Chuck for holding Bevel Gears while grinding the Bearing Hole

of the bevel gear that is to be held in the chuck. Three jaws are cut out of this ring with teeth milled as shown at C. These jaws are made of a good grade of steel in order to enable them to stand up under hard usage. Holes are drilled and tapped in the jaws and the jaws are fastened in the chuck at 120 degrees from each other, one of the cap-screws used for this purpose being shown at D.

The chuck cover is shown at E, the gear being held in the chuck by the cover and screws F. To grind a bevel gear, the jaws are put in the chuck first and fastened by means of cap-screws passing through the three slots G, the screws being left loose enough to allow the jaws to adjust themselves to the gear. The bevel gear is next put into place and the cover screwed down on top of it. After the first gear has been set in place, the cap-screws D are tightened to hold the jaws ready for receiving subsequent gears. Care must be taken in putting gears in the chuck to see that there are no burrs left at the bottom of the teeth of the gear, as this would interfere with the action of the jaws in locating the work properly. The gear finished in this chuck will run within 0.001 to 0.002 inch true.

Farrell, Pa. JOHN BLANAR

PREVENTING WEAR OF CONCRETE FLOORS

About the only objection to the ordinary concrete floor is the fact that the wear to which it is subject—that is, the purely mechanical attrition causes dust. This may, however, be avoided by scrubbing the floor with a stiff brush or broom, letting it dry, and then laying on a coat of a solution of water-glass in three to four times its volume of water. The solution is applied with a long-handled whitewash brush. The more dense the concrete, the thinner the solution may be, and no more of it should be made than can be applied in an hour. When the floor is again dry, it should be scrubbed with water and a coarse cloth. Then a second and a third coat of water-glass solution should be applied, each time letting the floor dry, scouring it with clean water and a heavy cloth. The water-glass should soak into the pores of the concrete and form with the alkali therein an insoluble chemical compound. Any water-glass that remains on the surface is unchanged, and can be washed or scrubbed away. This treatment will increase the durability of the concrete, and make it much more desirable as a floor material.

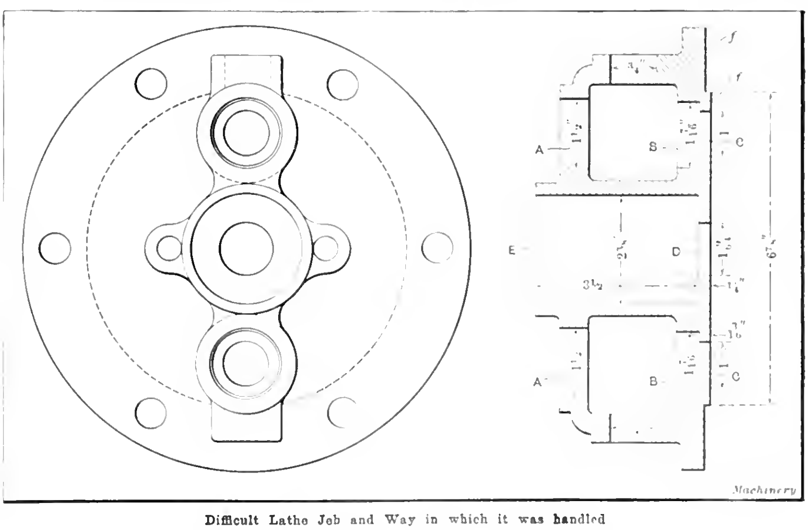
Dresden, Germany. ROBERT GRIMSHAW

RAPID PRODUCTION LATHE WORK

The accompanying illustration shows plan and cross-sectional views of a piece of work in which it was required to machine the holes A, B, C, D and E in a lathe. The first step in machining these castings was to chuck the work and finish the surfaces f, making the diameter of the boss 6⅞ inches. The boss formed in this way was then used to hold the work in a plate jig. The plate jig was first located centrally on the faceplate of the lathe by means of dowel pins, and the hole E was then bored to size and finished to the required depth, the metal at the bottom of the hole being left ¼ inch thick. The hole D was next bored.

The jig was then shifted to bring one of the holes A central and again held in position on the faceplate by dowel pins. It will be noticed that the finished size of the hole A is 1/16 inch larger than hole B, but both holes would be the same size in the rough casting. The hole A was first bored to a diameter of 1 7/16 inch, this size being carried nearly to the right depth in hole B. The tool was next moved away from the operator a distance of 0.221 inch and the hole C bored, the size obtained in this way leaving a little metal for reaming. Without changing the setting of the tool, the carriage was moved to the right so that the tool would clear the work. The tool was then moved toward the operator a distance of 0.252 inch and the hole A rebored to the required size.

The thickness of the plate jig was 11/16 inch, and adding the 3/16 inch required at the bottom of hole B gives a total distance of ⅞ inch as the required length of the pilot on the counterbore used to finish the bottom of the hole B. If this tool is pushed in until the end of the pilot is even with the back of the jig, the required thickness of metal will be left. I handled this operation without any trouble by proceeding as follows: A surface gage was set with the hook scriber 5



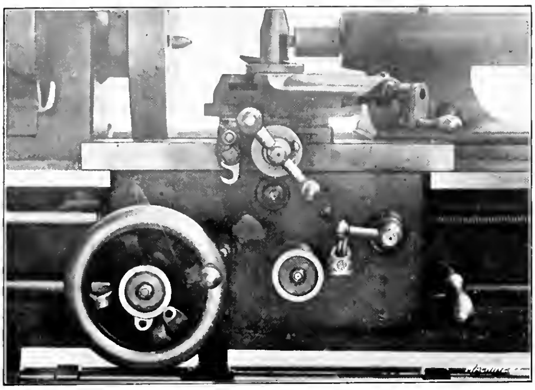
Difficult Lathe Job and Way in which it was handled

inches high, the surface gage being set against the faceplate of the lathe. The end of the pilot of the counterbore was then set at this distance from the faceplate. The counterbore was made with a taper shank to fit in the tailstock spindle, and by using the graduations on the tailstock spindle to work the tool in 5 inches from the original setting the desired thickness of metal was left at the bottom of the hole *B*.

In finishing the holes *A*, *B* and *C* on the opposite side of the casting, the work was simply turned through 180 degrees and then once more secured in place in the plate jig. The 3/4-inch holes in the side walls of the casting were machined in a drill press. The wide-awake mechanic will find that there are lots of jobs that could be handled in this way with a saving of time and expense. C. H. L.

NO MORE BROKEN FEED PINIONS

During the past ten years that I have been teaching machine work, I suppose that no less than twenty-five times I have torn down a lathe, turned up a pinion and gear, and in some cases repaired the rack, all in a hurry to get the lathe ready for the class the following day. Some years ago I wrote a letter to the makers, saying that I thought it would be a great improvement if they equipped their lathes with "fool proof" aprons. I got back a very curt reply telling me that a lathe of the quality of those built by Blank & Co. was too fine a tool for an amateur to work on. However, the apron gear would be sent for about $8 and express charges,



A Simple Method of preventing Feed Pinions from being broken

if desired. I understood then why the apron gear had ninety-nine teeth in it and required compound indexing to cut it.

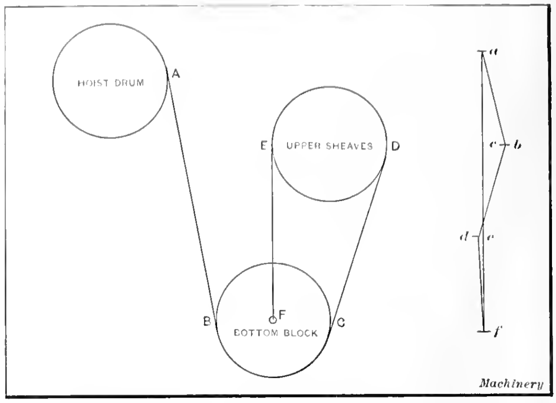
Recently I discovered a very simple method of preventing the breakage of feed pinions. As shown in the accompanying illustration, there are two ears fastened to the wheel and the feed knob. When the feed is out, they are opposite; also, the lock hangs on a stud screwed into the apron and locks the feed nut open. I always keep the lock in one place or the other and find it much easier to move it to suit the workman than to fix the lathe after he has gotten in both feeds and broken the feed pinions.

Menomonie, Wis. F. Hillix

A KINK FOR CRANE DESIGNERS

When laying out a crane trolley it is desirable to locate the bottom block with a fair degree of accuracy. The following outlines a graphical method by means of which the correct position of the block can be determined with ease and rapidity. The accompanying illustration shows a "three-part" lift arrangement, and it is required to find the position of the bottom block as it hangs from the drum and upper sheaves. The location of the drum and sheaves has been fixed and in determining the location of the bottom block, a position for the block is assumed which makes *AB*, *CD* and *EF* represent the directions of the ropes connecting the drum and upper sheaves with the bottom block.

After the position of the block has been assumed, it is necessary to determine whether the assumed position is satisfactory. This is done by the graphical method illustrated herewith. The method of procedure is as follows: Draw a line *ab* parallel to *AB*, making this line of some definite length. Next draw a line *cd* parallel to *CD*, and then draw *ef* parallel to *EF*. The lines *cd* and *ef* are made of the same length as the line *ab*. This is due to the fact that the tension is practically uniform in the rope. If the position of the bottom block has been properly assumed, the closing line *af*



Graphical Method of locating a Crane Trolley Bottom Block

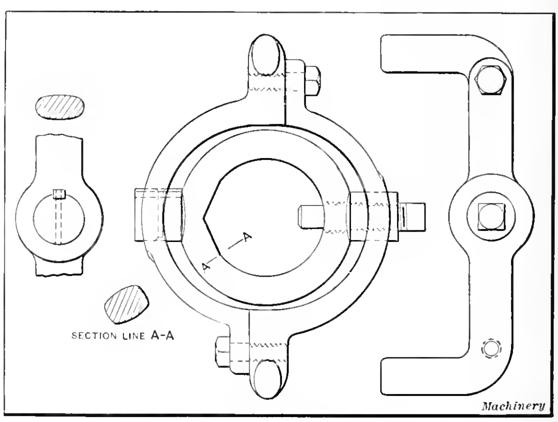
will be vertical; or in other words, the resultant of the rope tensions must lie in a vertical plane. If the line *af* is not vertical, a new position must be assumed for the bottom block and the same process gone through, the operation being repeated, if necessary, until a satisfactory position for the bottom block has been found. This method can be used for any arrangement of ropes.

Toledo, Ohio Carl E. Schirmer

EQUALIZING DRIVING DOG

The accompanying illustration shows a driving dog with equalizing arms, which will be seen to consist of two rings. The inner ring is provided with a set-screw for fastening the dog to the work, and two trunnions which are a sliding fit in holes in the outer ring. In this way the two rings are flexibly connected to each other; the set-screw passes through the center of one of the trunnions and a key is attached to the opposite trunnion to prevent the rings from turning in relation to each other. It will be seen that the outer ring is made of two parts which are held together by means of cap-screws. In using this dog, it is necessary for the work to be placed nearly in the center of the inner ring as the equalizing feature is only sufficient to compensate for an eccentricity of 3/8 inch. The capacity of the dog is for work up to 3 inches in diameter. It would of course be possible to make the same type of dog in sizes to suit a variety of different classes of work.

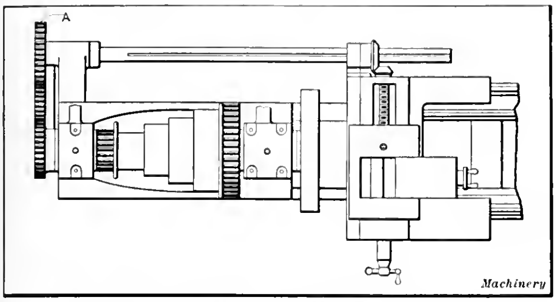
Waterveliet, N. Y. Martin H. Ball



Driving Dog with Equalizing Arms

CUTTING A SPIRAL ON THE ENGINE LATHE

In the April number of MACHINERY, Russell K. Annis described a method employed in cutting a spiral groove in a disk and illustrated the attachment applied to a Lodge & Shipley lathe to adapt it for this operation. The accompanying illustration shows an attachment applied to a Fay & Scott lathe to adapt the machine for handling the same



Spiral Cutting Attachment for a Fay & Scott Lathe

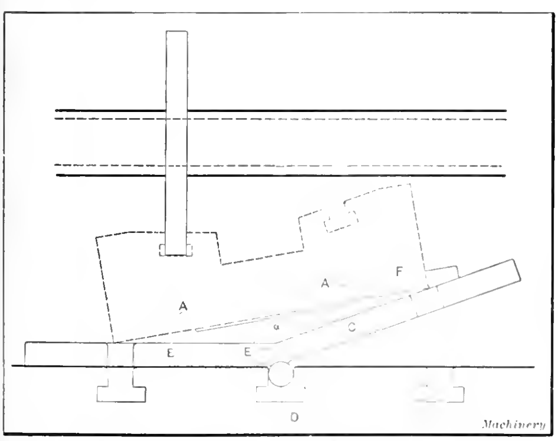
class of work. It will be evident from this illustration that motion is transmitted to the cross-slide through spur gears at the end of the lathe and bevel gears at the cross-feed screw. The gear *A* is a change gear, different gears being employed for cutting spirals of various leads.

The attachment was designed to cut a spiral groove of two inches pitch in a fiber disk. In the writer's opinion this design is superior to the one described by Mr. Annis because only one cross-feed screw is required, which is also used for the regular work done on the lathe. In the attachment described in the April number of MACHINERY a separate cross-feed screw is required for each different lead of spiral that it is required to cut.

Dexter, Me. E. W. TATE

FIXTURE FOR MILLING T-SLOTS AT AN ANGLE

The fixture which forms the subject of this article was designed for milling two T-slots in a long casting, the T-slots being milled in two surfaces which are inclined to each other at an angle *a*. The work is located in the proper position for milling the T-slots by means of the two finished bases *B* and *C* of the fixture, which are machined in the correct relation to the locating surfaces *A* and *F*. A rod *D* is fastened to the base of the fixture at the intersection of the two bases; this rod fits in the T-slot of the milling machine table and holds the fixture in alignment as it is swung from one side to the other. Recesses *E* are cut to allow room for a brush to be used to sweep away chips and dirt from under the fixture, so that it will fit properly against the milling machine table.



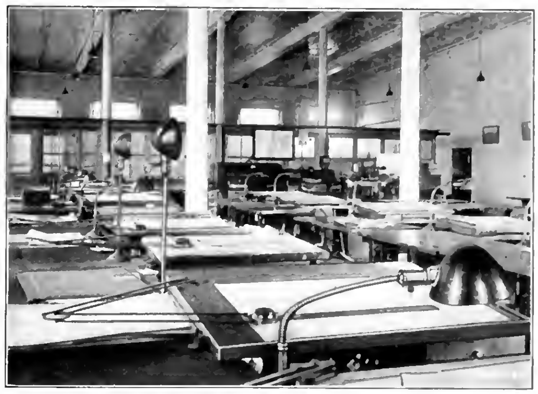
Fixture for milling T-slots in Surfaces Inclined at an Angle

In starting to mill a piece of work, the casting is located against the finished face *F* of the fixture, and clamped in place with ordinary straps. The fixture is clamped to the milling machine table with the regular form of T-bolts. In milling the T-slots, two separate operations are involved; first, a cut is taken with a plain cutter as shown in the illustration, after which a second cut is taken with a T-slot milling cutter. In using the plain cutter, the cut is taken across the casting, and the table is then returned to the starting position, the quick return being used for this purpose. The fixture is next swung into position for milling the second slot, and clamped in place. The cross-feed is then employed to bring the cutter to the correct position, after which the second slot is milled. The cross-feed stops should be set so that all successive pieces will be uniform, without requiring attention from the operator. After milling the straight slots, the T-slot cutter is used in a vertical milling attachment. The operation is the same as in milling the plain slots except that the T-slot cutter will mill on both the forward and return movements of the table. Consequently, in milling the T-slots, the fixture will be indexed after completing the cut to provide for milling the second T-slot on the return of the table.

Providence, R. I. C. KNOWLES

GENERAL AND INDIVIDUAL ILLUMINATION FOR THE DRAWING-ROOM

It seems to be a most difficult problem to illuminate a drawing-room satisfactorily. Theoretically, at least, a soft, uniform, indirect light approximating daylight is to be desired, but the installation of such a system of lighting in an old room presents difficulties. In refitting as a drafting-room, a room for many years used for other purposes, the general scheme of lighting shown in the accompanying illustration has been employed with satisfactory results. The draftsmen



General System of Drawing-room Illumination and Individual Lights for Each Table

use the light without fatigue and the general illumination gives a bright, cheerful room.

As will be noted from the illustration, each desk is individually lighted by means of a 32-candlepower carbon lamp with frosted bulb. This lamp is supported in an 18-inch flexible arm fixture attached to the table at such a point as to be out of the way. A parabolic reflector, also adjustable, is used to direct the light onto the board in such a way as to prevent reflection into the eyes of the draftsmen. During the day the flexible arm is straightened up so that the lighting arrangement is entirely out of the way.

General illumination is by means of suspended 100-watt metal filament lamps. This system has been in use for about two years and on the whole with very satisfactory results. The arrangement, in addition to providing suitable illumination, is neat and mechanical in appearance. The wiring is carried along in conduits under each desk, the terminals being brought up through the floor where necessary. This eliminates unsightly wires coming down from the ceiling to the individual desks.

Holyoke, Mass. W. M. FLEMING

MULTIPLE THREAD CUTTING

The following outlines a method of using the compound rest for cutting multiple threads. Suppose you have to cut a double square thread of ¼-inch pitch and ½-inch lead. Turn the compound rest so that it is at right angles to the cross-slide of the lathe and set the threading tool in the usual way. Now take the first cut, using the cross-feed screw to feed the tool into the work. Having taken a cut on the first thread, turn the compound rest crank to move the tool forward an amount equal to the pitch of thread to be cut, which is 0.250 inch in the present case. The graduated collar on the rest is conveniently used for this purpose. Next take two successive cuts on the second thread and then bring the rest back to the starting point and take a cut on the first thread. This is repeated until both threads are finished.

The only thing that the operator has to remember is to move the compound rest a distance equal to the pitch for each of the different multiple threads. If the screw in the rest is not provided with a graduated collar, scribe a line on the slide of the rest and onto its base. Then move the rest forward until the lines are separated by an amount equal to the pitch of the thread to be cut. These two lines can then be used in moving the tool backward and forward in the way previously described for a rest equipped with a graduated collar. The writer has found this method convenient for handling an occasional job of multiple thread cutting. There are no special fixtures to make and the lathe can be started and run continuously until the work is finished.

Richmond, Ind. FRANK A. HIATT

CLEARANCE ALLOWANCES FOR HEXAGONAL NUTS

The accompanying illustration shows the position of a hexagonal nut located close to a wall or boss, and the table gives the clearance allowance necessary to enable different sizes of nuts to be turned in such a position. The table is based on a movement of the wrench through an angle of 60 degrees. The information given has been found particularly convenient for reference in cases where the space available for the wrench is limited. The figures give the minimum clearance allowance in all cases.

MINIMUM CLEARANCE ALLOWANCES FOR HEXAGON NUTS

Size of Nut A, Inch	Distance B, Inch	Size of Nut A, Inches	Distance B, Inches
¼	7/16	1¼	1⅜
⅜	⅝	1⅜	1½
½	¾	1½	1⅝
⅝	⅞	1¾	1⅞
¾	15/16	2	2 1/16
⅞	1 1/16	2¼	2 5/16
1	1 3/16	2½	2½
1⅛	1 5/16	3	2 15/16

Rochester, N. Y. H. P. RESTON

SLATE DRAWING BOARDS

In making preliminary sketches illustrating details on a large scale or explaining the details of a piece of machinery or part of a structure to customers, engineers, draftsmen or salesmen, nothing can be more satisfactory than the old-fashioned slate, pencil and sponge. Slate drawing boards of this kind are used by a tool manufacturing company in the western part of Massachusetts, and are said to be very satisfactory. A piece of slate about 3 by 5 feet in size is set in a solid frame, the edges of which are accurately finished so that a T-square and triangles can be used in the regular way. The slate drawing board can be used in place of the ordinary drawing board and detail paper; it is more economical and meets every requirement in making rough sketches and outline drawings. Small sharp slate pencils should be used, these pencils being kept pointed by means of an ordinary sandpaper pad.

A number of these slate drawing boards are used by the firm referred to in the preceding paragraph. Some of these are made of relatively thin slate, in which case a board support is provided in the frame under the slate to eliminate danger of breaking it. The frame is set on trestles of a convenient height. Some of the slates are also supported in an almost vertical position and the frames in which they are held are not provided with a board back. Consequently, it is possible to use both sides of a slate supported in this manner. The support is so constructed that the slate can be swung to from 10 to 20 degrees from the vertical.

Portions of drawings on such a slate can be readily removed and the remaining portions not only present a neat appearance but remain clear and sharply defined for an indefinite length of time. The great economy effected by having two or three of these slates about any drafting office will be readily appreciated, as everyone knows what a lot of paper is used up in preliminary work. In the course of a year, this saving of paper would easily pay for the slates several times over. Slate drawing boards of this kind can be purchased from any dealer.

Winter Hill, Mass. FRANK H. JONES

CUTTING SPIRALS ON THE LATHE

The article by Russell K. Annis entitled "Cutting a Spiral on a Lodge & Shipley Lathe," which appeared in the April number of MACHINERY, reminds me of another method which I saw used in a jobbing shop a number of years ago. A short shaft was journaled in brackets at the back of the lathe and the left-hand end of this shaft was fitted for a change gear. A disk turned to a circumference of eight inches was mounted on the shaft and one end of the main spring of a clock was attached to this disk. The other end of the spring was fastened to the cross-slide of the lathe, the cross-feed screw having been removed and a weight provided to pull the slide forward. In this way the cross-slide was held forward against the spring at all times.

Rotation of the disk caused the cross-slide to be moved over at the rate of eight inches for each complete revolution of the shaft. Consequently, by employing change gears on the shaft, it was possible to adjust the attachment to cut a spiral of the desired pitch. The spiral could be cut either right- or left-hand by employing the feed reverse in the headstock.

The shop in which this method was employed also had a lot of chucks to machine. These chucks were used on some sort of wood-working lathe and had a tapered hole 4 inches in diameter at the large end, the taper of the hole being approximately 75 degrees included angle. It was required to cut a coarse buttress thread inside this hole, and the clock spring arrangement previously described was used in connection with the lead-screw, enabling what would otherwise have been a difficult job to be handled with considerable rapidity.

Later, this attachment was put into a more permanent form by placing a gear of eight inches pitch circumference on the shaft and providing a rack on the cross-slide to mesh with it. This rack and gear was substituted in place of the disk and clock spring, but not until the original device had proved its utility by producing several hundred of the spiral chucks.

New London, N. H. GUY H. GARDNER

DIFFERENT METHODS OF DRAWING A GIB

In reply to W. Butz's question in the April number as to the correct method of drawing a gib, his illustration *A* is considered correct. Since the side view is larger than the end view, the first glance at the former will give the determining impression to the workman. At *A*, the workman sees the extreme lines in the side view and he also sees two other lines, one solid and the other dotted. He at once realizes that there is something else to the gib which is not shown in the side view; then he will look more closely at the end view, obtaining at once the over-all dimension of ¾ inch and the necessary bevel.

In the illustration *B*, the side view appears somewhat similar to a rectangular bar and the workman is likely to take the size 5/8 inch and the size 3/16 inch without looking further, thus getting a bar that will be impossible to finish to the required size. Also he sees an angle of 60 degrees and is likely to waste some time in guessing how to chuck it to plane the bevels. If the workman has had no more education than that obtained in the sixth or seventh grade, he will be at a loss to know how to figure out the complement of the angle 60 degrees.

Illustration *C* brings the worst predicament of all. While at first glance, the side view appears identical with the corresponding view *A*, the dimensioning is vague and incomplete. The workman as a rule is not versed in trigonometry, even if he has had training in that subject in the schools, owing to the fact that he has little use to handle that subject in his work. Taking the dimension of 11/16 inch, he will potter around making sketches in order to obtain the missing dimension on either side.

Draftsmen often take for granted that the workmen has had an education equal to his own. But the workmen, as a rule, are recruited from the sons of men already employed in the shops, and at the age of fifteen or sixteen years, so that their education is necessarily incomplete. The simpler the drawing is, with complete dimensions accurately placed, the quicker and more correctly will the workman grasp the idea of what is intended to be made.

Dallas, Tex. SIDNEY HETHERINGTON

HOW ANOTHER PIECEWORK RATE WAS SMASHED

I have enjoyed reading the short article in the April number of MACHINERY, entitled "How a Piecework Rate was Smashed," and am tempted to write of my own experience with a piecework job. While working as a bench hand in a factory making various electric recording instruments, I was given the job of straightening some very thin aluminum tubes about 1/8 inch in diameter and 6 inches long. These tubes were used to convey ink to the pen of the instrument and had to be absolutely straight. The foreman and best mechanics had studied over the job each time a lot came through, but the best method they could find was to roll them between two surface plates. The tubes were so thin, however, that many of them were crushed; indeed it was not unusual to spoil 20 per cent of the work.

Well, I was given this job at a price of 25 cents per hundred and started to work. It seemed as though I spoiled every other tube. I then began to experiment. Finally I hit upon the idea of holding one end of the tube in the spring chuck of a bench lathe, starting up the lathe and then drawing my hand along the tube to the end. The result was a perfectly straight tube in an instant. I finished the lot of 4000 in about six hours; also taking care that the "boss" did not see my method. Then I took the work up to him.

He nearly collapsed when he looked at the pile of finished tubes and saw only a dozen or so broken. He rolled them back and forth to see if they were really straightened. Then he asked how I had done the job. This was where my trouble commenced, for I would not tell how I did the work, or submit to a cut, so I was allowed to resign. I got my $10 for six hours' work, but I never found out whether or not the company discovered my method. Some of the workmen knew it and I suppose they told after I left. J. A. D.

DIMENSIONS OF SPUR GEAR RIMS IN RELATION TO THE PITCH

I have to sketch and estimate the weight of a great many spur gears in the course of a year, and to facilitate this work I have prepared a table covering the thickness of rim, the depth of the bead inside the rim, and the breadth and thickness of the outer ends of the arms of the gear. This table, which is presented herewith, is very useful to me and I offer it in the hope that it may be of service to other readers of MACHINERY. It will be seen that the sizes are given in connection with both the circular and diametral pitch of the teeth, as well as the correct face width for each pitch.

In many cases the information furnished to the designer is very meager, and in the case of gearing this is particularly true. To the lay mind, a gear wheel is "about so big and has a certain number of cogs." This paucity of specific information in regard to matters of fundamental importance is the bane of the designer's life. If, however, he is fortunate enough to be given the horsepower, speed and approximate diameter of the gears, the accompanying table will be found useful. Experience alone will teach the designer the most satisfactory pitch to assume for a given set of conditions, but reference to the table will show the correct face width of the gear for the pitch assumed. The designer is now ready to figure the horsepower which the wheel will transmit. Lewis' formula is as good as any and better than some formulas that are in quite general use.

Reference to the table will now enable him to determine the thickness of the rim and the size of the bead and arms of the pulley. In the matter of estimating the weight of the gear, the use of the table eliminates about one-half the calculation that would otherwise be necessary. The number of cubic inches of metal having been found, this is multiplied by the constant 0.27 in the case of cast iron and 0.29 for steel, the result being the weight of the gear in pounds. The usual constants for the weights of a cubic inch of iron and a cubic inch of steel are 0.26 and 0.28, respectively. Experience has shown me, however, that the higher constants are more accurate for gear work, taking care of the excess weight resulting from rapping the pattern in molding. In very large gears, with arms of I-section, made with cores, allowance must also be made for the core shrinkage and consequent thickening of the metal sections. In large gears this allowance often amounts to between 150 and 200 pounds. The fillets in large gears should be figured separately by referring to MACHINERY'S Data Sheet No. 59, and the result obtained added to the weight of the gear as figured from the table.

DIMENSIONS OF SPUR GEAR RIMS IN RELATION TO THE PITCH

Machinery

Oakdale, Pa. EDGAR H. TRICK

PATENTABLE INVENTIONS

The address of Prof. Hutton, referred to in the April number of MACHINERY, appears to discuss two distinct topics: "Data" is the subject of the first three basic questions propounded; and "Patentable Inventions," the subject of the

fourth basic question. The distinction between these subjects is quite clearly brought out by the judicial opinion in Fuller & Johnson Co. vs. Bartlett, 68 Wis. 73, a recognized case concerning the relation of employer and employe as regards patentable inventions. The opinion reads: "The mere fact that in making the invention an employe used the materials of his employer, and is aided by the services and suggestions of his co-employes and of his employer in perfecting and bringing the same into successful use is insufficient to preclude him from all right thereto as inventor. The same is true of an invention conceived wholly by an employer and then perfected under his supervision by the aid of the mechanical skill of his employes. These propositions are sanctioned by numerous adjudications."

"The difficulty with the contrary assumption arises from confounding the machine with the invention which it embodies. Of course there must be a machine that will operate before it can be patented. That implies material, workmanship and skill combined. But such combination, of itself, is not enough to secure a patent. It must also embody an original conception of a new and useful method of doing a specific thing. It is this conception, so embodied, evolved from the inventive faculties of the inventor which constituted the invention in question. The law gave him the exclusive property in it. He still retains it except in so far as he has parted with it or agreed to part with it. The material, workmanship and skill which embodied the invention remain the property of the plaintiff (the employer). The workmanship and skill are both the results of instruction, experience and knowledge. They are acquired by being learned. They may aid and stimulate invention, but are no part of it."

The Federal Supreme Court and other courts have decided, even where one is employed to perfect, improve and to develop new devices, that the employer can acquire no exclusive title to inventions made by the employe in the course of the latter's employment, unless the employe is bound by a specific contract to assign such inventions. (Besides the above noted case see also Hapgood vs. Hewitt 119 U. S. 226; Barber vs. National Carbon Co. 64 C. C. A.; Slemmers Appeal 58 Pa. 155.) If the person who is engaged to improve and to develop new devices is privileged to hold title to such inventions, how much more should the subordinate be entitled to his own inventions and to whatever advantage he may secure through them, when such inventions are made entirely outside of his sphere of action—services not contemplated in his contract of hire. The reference data, including drawings, appear to partake of those attributes—material, training, knowledge, skill—which the court said belong to the employer.

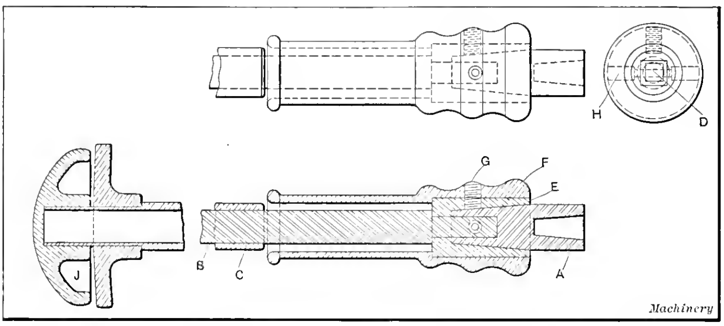
If the principles above set forth are controlling, then the six reasons back of the ethical practice suggested by Prof. Hutton have no application to his fourth basic question. If a draftsman really *invents* something of value to his employer, the latter should not feel that he is being "held up" because that employe invokes his legal rights to secure the best advantage from his creation. If the invention is so important that the employer's operations are literally "held up" for the lack of it, it certainly must be worth something more than the weekly stipend of the draftsman, which would probably have continued even though no invention had been made. It should be gratifying, at least, that the improvement had been made by an employe rather than by a competitor.

Upon what theory does the possession of ample resources or of an adequate plant entitle an employer to the fruits of an employe's inventive creations? The resources may be running to waste and the plant may be dying of dry rot. An employe who devises an improvement or creates a new output which turns the waste into channels of usefulness is as much entitled to a share in the returns which he has produced as the man who helps a weak concern to its feet by supplying necessary capital. Why should not employers subscribe to a code of ethics which embodies a professional obligation not to appropriate the valuable inventions made by their employes?

Central Falls, R. I. EDWIN C. SMITH

SAFETY DEVICE FOR LIGHTNING SCREW-DRIVERS

The present forms of "lightning" screw-drivers are much faster and handier to use than a common screw-driver, but the designers and manufacturers of these tools have overlooked an important feature. Men who have to use these screw-drivers are continually pinching their hands in them, and to avoid these small but painful accidents it was suggested that some sort of guard be developed. The accompanying illustration shows the upper and lower ends of the screw-driver in which the tool-holder is marked *A*. This tool-holder is fastened to the driving screw *B* by means of a small pin *D*. The tool-holder *A* revolves in a brass sleeve *E* which is fastened in the aluminum guard and handle *F* by the grub screw *G*; this screw passes through the sleeve and guard holding them firmly together. The hole shown at *H* allows the pin *D* to be driven in or removed when it is necessary to take the tool apart.



Cross-sectional View through Screw-driver showing Safety Device and Aluminum Handle

The sleeve *C* comes down to the lower handle and is the part which was formerly responsible for pinching the workman's hand. This has been overcome by the provision of the guard *F* which allows the sleeve *C* to move inside it. This guard has been thoroughly tested and has proved satisfactory in every respect; it takes up very little room and makes the tool only a trifle heavier than one with a wooden handle. In addition to the protection afforded, the guard is the means of increasing the speed with which the operator works, as he is not afraid of pinching his hand in the screw-driver. The illustration also shows the upper handle of the tool which is usually made of wood. If the screw-driver happens to fall on the floor, the wooden handle is likely to break and cause a lot of trouble in patching up the broken handle or making a new one. To avoid this difficulty, an aluminum handle has been substituted in place of the wooden one. It will be seen that the handle is recessed at *J* in order to reduce the weight.

APPROPRIATION FOR MUSEUM OF SAFETY

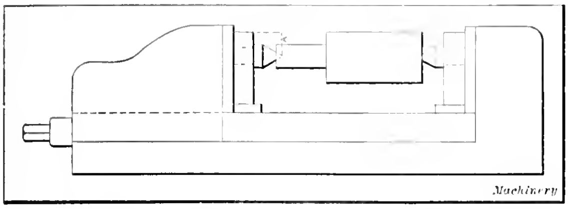
The American Museum of Safety, an institution devoted to the safety, health and welfare of industrial workers and the advancement of science and industry, with headquarters in New York City, has been placed on a footing with the Metropolitan Museum of Art and the American Museum of Natural History by the New York Legislature, which has authorized the Board of Estimate of New York City to contribute not more than $50,000 yearly to the expenses of the museum. Eventually the trustees hope to erect a noble building in which to house the museum's exhibits of safety appliances, anatomical models, occupational dusts, charts, photographs, slides, etc. The museum has a special charter from the State of New York and this latest substantial recognition of its usefulness indicates that its dream may be realized in the not distant future.

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

SHAPER CENTERS

In a great many shops shaper centers are not always available, and often, when they are, they cannot be used for work that should be shaped on centers, on account of the shank of the work being too short to leave room for a dog. The accompanying illustration shows a pair of centers which work very satisfactorily, being especially suitable for machining small blanking punches where the punch is shaped right

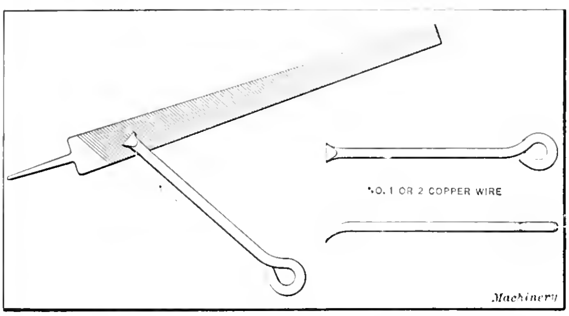


A Useful Form of Centers for Use on the Shaper

up to the shank. These centers may not look practical to many people on account of the work having a tendency to slip, but experience showed that they stood up satisfactorily under a 1/8-inch chip 2 inches from the center. This cut was taken without clamping the jaws much tighter than would be necessary for holding work between the jaws of a vise. Another good point is that in shaping different polygons, a protractor or square can be set on the bed of the vise and the side of the work, thus enabling the operator to proceed without resorting to the use of cut-and-try methods. The distance *A* on the drawing should be made an even fraction of an inch—say 1/2 inch or 3/4 inch—as this helps greatly in setting the tool. C. G.

FILE CLEANER

An excellent file cleaner can be made by flattening a piece of No. 1 or No. 2 copper wire, and bending the flat side over as shown in the accompanying illustration. An eye is formed at the other end to provide a handle, and the flat end is



Efficient Form of File Cleaner made of Copper Wire

ground down to a thickness of about 1/32 inch. This sharp edge is pressed on the file and moved back and forth in the direction of the milling. It soon takes the impressions of the milling and cleans out all residue that is held in the teeth.

Downieville, Cal. CLARENCE I. SIMMONS

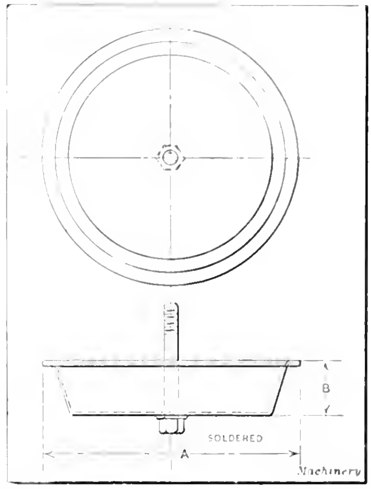
SPACING LETTERING AND SECTION LINES

In the January number of MACHINERY, R. F. Pohle describes a very good method of spacing the section lines on drawings. I have had experience with another method of doing this work which I consider even better than the one described by Mr. Pohle. I take a Starrett V-thread gage which can be obtained with any number of divisions to the inch from six to sixty, inclusive, so that any desired spacing can be obtained. The gage is pressed onto the paper and leaves impressions in which the point of the pencil is located preparatory to drawing each section line. The lines are drawn with a T-square and triangle in the usual way. I have used this method for a number of years and thought that it might prove of value to readers of MACHINERY. The gages are not expensive so that a draftsman can afford to buy those having the spacings which he has occasion to use quite frequently. They are of compact form so that they occupy very little room in the instrument case.

Los Angeles, Cal. GUSTAV STEINKE

DRIP-CUP FOR COUNTERSHAFTS

In most factories an oil-cup is fastened to each hanger or countershaft to catch surplus oil and prevent it from dripping onto the floor. These cups are usually cast-iron devices which are cumbersome and have been known to injure men passing underneath, owing to the cup having worked loose through vibration. I recently saw a drip-cup made of sheet metal which seems to meet all requirements without having the objectionable features of the cast-iron cups. Reference to the accompanying illustration will show that this cup is fastened to the hanger by a bolt and it is made of such light material that the tendency for it to work loose through vibration is practically eliminated. The diameter *A* and depth *B* of the cup can be made to suit the requirements of individual cases. Thousands of these cups are in use in the factory referred to and they have been found to be entirely satisfactory.

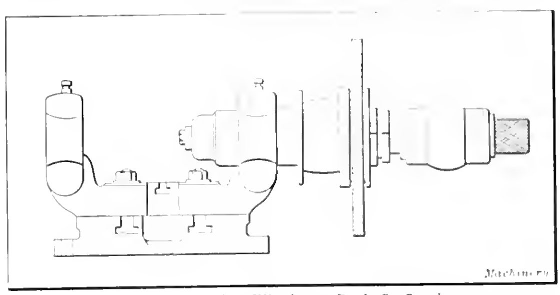


Sheet Metal Drip-cup for Use on Countershafts

G. A. A.

CHANGING WHEELS ON B. & S. GRINDERS

It is frequently necessary to change the wheels on a grinding machine to meet the requirements of different classes of work, and unless the operator is careful the wheels are likely to be broken. The writer has found that by clamping one bearing in the grinder stand—allowing the arbor to over-



Method of changing Wheels on B. & S. Grinders

hang—rigid support is provided and both hands are free for use in removing one wheel and mounting a new one in its place. The idea is clearly shown in the illustration without requiring further description.

Bristol, Conn. LEWIS L. LEIGH

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

TO ROLL ROUND TUBING TO OVAL SHAPES WITHOUT BENDING OR TWISTING

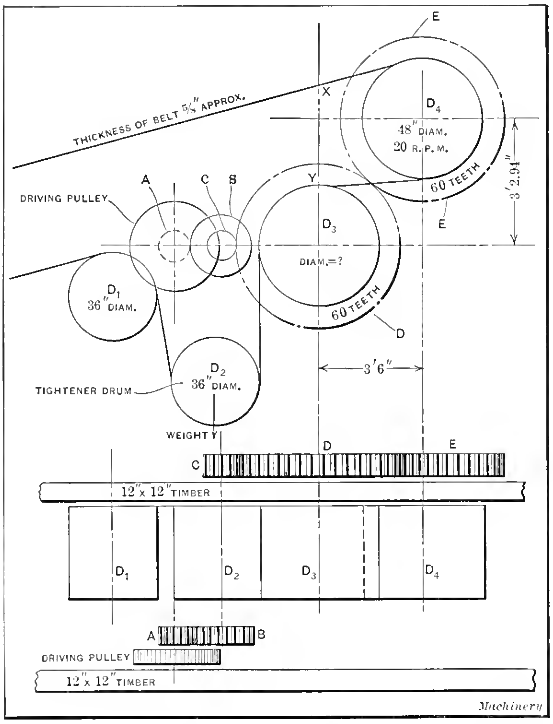
K. G.—Can you tell me how to roll round tubing to an oval shape without bending or twisting? The tubing is 22 gage by ½ inch diameter. We force it through a set of rollers which can be set to the size desired.

The question is referred to the readers for suggestions.

BELT CONVEYOR PULLEY DIAMETERS

O. E. B.—The illustration shows drums and gearing designed to drive a belt conveyor 430 feet long center to center, rise 4½ inches per foot and carrying approximately 600 tons of stone per hour. In order to get proper belt contact without excessive diameters of head drums, the construction shown was adopted. The driving pulley is mounted on the same shaft as gear *A* and drives the drum D_4 through the train of gears *A*, *B*, *C*, *D* and *E*. The gears *D* and *E* are of the same diameter and the belt is approximately ⅝ inch thick. The question is, should the drum D_3 be larger than D_4 or not? If larger, how much so? I believe that D_3 should be slightly larger than D_4 but cannot decide how much. If we assume that the speed of a point about a center varies as the distance from that center, it follows that a point on the inside of a belt travels 6.65 feet slower per minute than a point on the outside when D_4 makes 20 revolutions per minute. The speed on the inside is approximately 251 1/3 feet and the speed on the outside about 258 feet per minute.

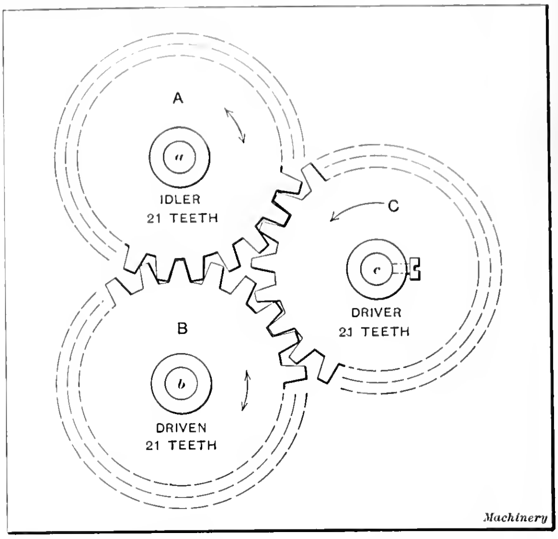
A.—The diameters of drums D_3 and D_4 should be the same. The fact that D_3 drives the belt from one side and D_4 from



the opposite side need not be taken into consideration. The speed of the belt should be figured on its pitch line, that is the center line of the belt. The belt theoretically travels at the rate expressed by $2\ (R + t) \times 3.1416 \times$ R. P. M. in which *R* is the drum radius and *t* one-half the belt thickness. This travel rate evidently should figure out the same for both drums; hence, both drums should be of the same diameter.

REVERSING GEAR

W. E. D.—The illustration shows a reversing gear in which the three gears have the same diameters and numbers of teeth—21. *C* is the driving gear; *B*, a driven gear and shifting gear; and *A*, a shifting gear. *A* and *B* are always in mesh and one or the other is slid on the shaft into mesh with *C*. I desire to make gears *A* and *B* smaller than *C* and would like a formula for determining the diameters and numbers of teeth of *A* and *B* which will have the same relation to *C* as they have in the illustration. In other words, I wish to



shift *A* or *B* into mesh with *C* without changing the angular positions of the gears.

The problem is submitted to the readers for discussion.

DESIGN OF CRANE-LADLE HOOKS AND TRUNNIONS

J. P. P.—The accompanying illustration Fig. 3 shows a crane-ladle with cast steel trunnions riveted to it, these trunnions being engaged by cast steel crane hooks. The total weight of the ladle when filled with molten steel is 120,000 pounds. I would like to see the results of calculations to determine the required diameter *d* of the trunnions and the dimensions d_1 and *t* of the crane hooks. What I would particularly like to know is the approved method of making these calculations. I was recently called upon to design trunnions and hooks for this ladle and have worked the problem out, but would like to check my results.

Answered by William L. Cathcart

The crane hook engaging each trunnion carries a load of $120{,}000 \div 2 = 60{,}000$ pounds. The ladle and its trunnions may be considered either as a simple beam, supported by the hooks and loaded at the inner ends of the trunnions, as in Fig. 1; or each trunnion may be regarded as a cantilever, supported at the ladle and bent upward by a force $P = 120{,}000 \div 2 = 60{,}000$ pounds. In either case, the bending moment *M* at the trunnion support is equal to the product of *P* and its distance from that support. The total length of the trunnion is given as 4½ inches, which would make *P* act at a distance $p = 2\frac{1}{4}$ inches from the support. The trunnions are to be of cast steel. In some very carefully conducted tests of this metal, Prof. Bach of Stuttgart* found an elastic limit of 33,467 pounds per square inch and an ultimate tensile strength of 61,543 pounds per square inch. In the calculations given below, an allowable working stress of 10,000 pounds per square inch is used, that is, the factor of safety is 6. Under the downward thrust of the weight and the upward pull of the hook, the trunnion bends upward, being thus in tension on the lower side and in compression on the upper. The general formula for bending at any section of the trunnion is $M = SI \div c$, in which $M =$ bending moment at the section considered = moment at the support, as above; $S =$ allowable working stress; $I =$ moment of inertia of the cross-section of the trunnion at that point; and *c* the distance of the most remote fiber of that cross-section from the neutral axis, which axis lies in the plane of the

* Zeitschrift des Vereines deutscher Ingenieure, June 10, 1899.

cross-section and passes through its center of gravity, that is, through the center of the trunnion.

For a trunnion 4½ inches long and of diameter d, $p = 2\frac{1}{4}$ inches and $M = P \times p = 60{,}000 \times 2.25 = 135{,}000$ inch-pounds. Substituting this value in the formula, as above, and $I = \pi d^4 \div 64$, $c = d \div 2$, and $S = 10{,}000$ pounds per square inch:

$$135{,}000 = 10{,}000 \times \frac{\pi d^4}{64} \times \frac{2}{d}$$

$$d^3 = 137.5$$

$$d = 5.16 = 5\frac{3}{16} \text{ inches (approximately).}$$

For other lengths of trunnions, the diameters computed in this way are given in Table I. In machine members subjected to repeated shocks, factors of safety of 10 for wrought iron and 15 for steel are frequently used. A fairly high factor—possibly greater than 6—is advisable in this case; first, because the trunnions are to be castings, a condition which always involves some uncertainty—although this element is decreasing with the progress in heat-treatment—and, second, because they may at times be suddenly overloaded either in emergency or through careless handling. For example, if the full ladle were lifted very quickly, its weight would become a suddenly applied load having, in strain and stress, twice the effect of a static load. Again, if the ladle while lowering were suddenly checked, its kinetic energy would produce an additional and suddenly applied load whose magnitude would depend on the velocity of descent and might be relatively large. Finally, the trunnion is abraded and worn by the hook at the middle.

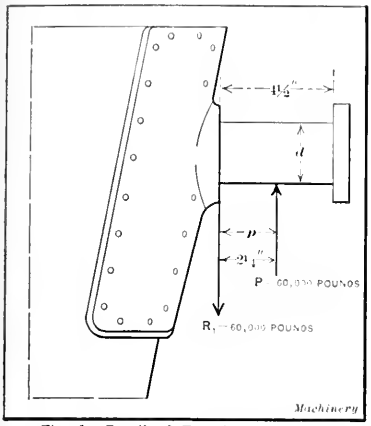


Fig. 1. Detail of Trunnion attached to Crane Ladle

Dimensions of the Crane Hook

Practice as to dimensions of crane hooks varies considerably. Taking an allowable stress of 10,000 pounds per square inch, there are given in Table II the desired dimensions, computed from the formulas of A. E. Holcomb, as stated in Kent's "Pocketbook," 1912. The tabulated trunnion lengths are those for which the diameters were calculated. The extreme width b of the hook, Fig. 2, plus the clearance, is the factor that determines which of these lengths is practicable. It will be seen that, according to these formulas and with this working stress, it is not possible to design a 30-ton crane hook for a trunnion 4½ inches long, when both are of cast steel. Under average conditions of service, the working stress for cast steel hooks of this size should not exceed 11,500 pounds per square inch, while that of wrought iron may be 17,500 pounds per square inch, and 23,000 pounds per square inch has been used for hammered steel. The hook meets the same shock and sudden overload as the trunnion. A low working stress in the latter makes the diameter large; a large diameter increases the leverage of the load on the hook, and, as a consequence, the width and depth of the latter. Further, the calculations assume the load to be central, that is, on the vertical line passing through the center of the opening. If the hook is inclined and the load is farther than this from the rear of the hook, its leverage will be increased. The dimensions of the first three hooks have been given for comparison; the last will meet the conditions with a trunnion length of 6 inches and very limited clearance.

TABLE I DIMENSIONS OF TRUNNIONS AND VALUES OF BENDING MOMENTS

Length of Trunnion, Inches	Bending Moment, Inch-pounds	Diam. of Trunnion d, Inches
5	60,000 × 2.5	5⅜
5½	60,000 × 2.75	5½
6	60,000 × 3	5 11/16

Machinery

The dimensions in Table III have been calculated for cast steel trunnions and hooks of hammered steel, using a working stress for the latter of 15,000 pounds. With the trunnion lengths given these hooks would serve.

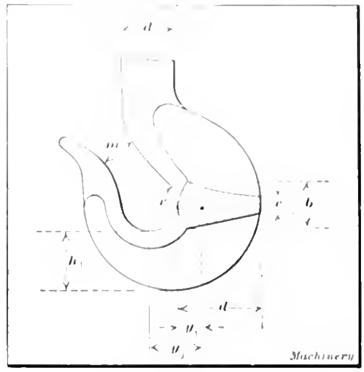

Fig. 2. Diagram of Crane Hook showing Required Dimensions

Maximum Stress in Crane Hooks

The dangerous section of a crane hook is that cut from the back by a plane passed horizontally through the center of the opening; and the maximum stress in that section occurs at the point nearest the center of the hook. The width m of the entrance to the opening is usually three-fourths the diameter of the latter, and should be just great enough to pass readily the rope, chain, or trunnion which the hook is to engage. Therefore, this width determines the radius r of the opening. If the load is central, its eccentricity or leverage is the horizontal distance from the center of the opening to the center of gravity of the dangerous section. Since this leverage should be as low as possible, the radius r should be as small and the inner side of that section (trapezoidal) as wide as practicable, in order to bring the center of gravity of the

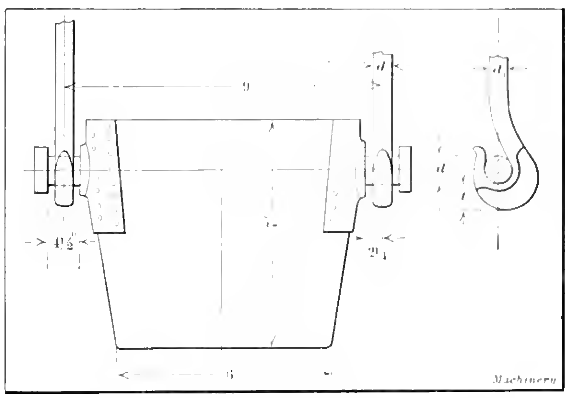

Fig. 3. Crane Ladle for which Dimensions of Trunnions and Crane Hooks are required

section as near as may be to the center of the opening. Until within a comparatively recent period, there has been no accurate theoretical analysis of the relations of these various dimensions. As a consequence, designers have been compelled to trust to formulas based partly on rational and partly on empirical grounds. Experience gained in practice has necessarily been the main reliance, since theory has supplied only the principles governing the action of an eccentric load on a straight bar.

In recent years the true stresses in a curved bar have been analyzed by Prof. C. Bach, of Stuttgart, and more completely by Prof. Karl Pearson* and E. S. Andrews of London University. Practical tests for the investigation of the truth of the theory of Pearson and Andrews have been made by Prof. John Goodman† of the University of Leeds and by Prof.

* "Theory of the Stresses in Crane and Coupling Hooks." Published by Dulau & Co., London.
† Proceedings of Institution of Civil Engineers, Vol. CLXVII.

Walter Rautenstrauch* of Columbia University. In testing a crane hook, the width m as marked in Fig. 2 of the entrance to the opening of the unloaded hook is first measured with the utmost possible accuracy. Then, gradually increasing loads are applied to, and removed from, the hook. Between each of these successive loadings the dimension m is measured. Finally, a limit is reached at which it is found that the measurement taken does not coincide with that of the unloaded hook, that is, that the point of the hook has not sprung back to its original position after the removal of the load, and hence that permanent set has occurred, the last load applied having exceeded the elastic limit of the metal at the point of maximum stress in the dangerous section. In the investigations noted above, there was found a marked agreement between the elastic limits of the hooks tested, as shown by actual loads in the testing machine and as computed from the Pearson-Andrews formula. Prof. Rautenstrauch gives the results presented in Table IV for hooks received from a number of manufacturers.

TABLE II. DIMENSIONS OF THIRTY-TON CAST STEEL CRANE HOOKS

Machinery

This table shows, in most cases, a practical agreement between this theoretical elastic limit and that given by test. For the larger hooks, with one exception, it indicates also that, for their rated capacity, the factor of safety is absent—a result which is due unquestionably to the use of a formula for the stress in a straight bar as the fundamental basis of their design. These tests and those of Prof. Goodman were made about four years ago, and progressive makers have doubtless considered them in their designs. It appears, then, that the Pearson-Andrews analysis, the application of the theory of the stresses in a straight bar to those in a curved bar, like a crane hook, will give inaccurate results, the magnitude of the error increasing with the curvature of the bar. This error seems to be due mainly to the assumption of a uniform distribution of the stress due to tension, while, on the contrary, the theory shows that the intensity of this stress is relatively great at the inner side of the section and decreases rapidly toward the outer, being analogous in this respect, as Prof. Goodman has pointed out, to the stresses in a thick cylinder subjected to internal fluid pressure. This increase in the tension at the point of maximum stress would account largely for the reduction in the assumed factors of safety of the old method. While this theory has been criticised somewhat adversely by a few authorities, the results of the tests cited above make it advisable to test the dangerous section of the proposed hook by the Pearson-Andrews formula:

TABLE III. DIMENSIONS OF THIRTY-TON HAMMERED STEEL CRANE HOOKS

Working stress — 15,000 pounds per square inch

Trunnions		r	m	d	b	c	d_1	h_1
Length, Inches	Diameter, Inches	Inches	Inches	Inches	Inches	Inches	Inches	Inches

5½	5½	3¾	5⅝	7 7/16	4 15/16	1⅝	3 3/4	5 7/16

Machinery

$$S_t = \frac{W}{A}\left\{\frac{y_o}{R_1 F_2}\left[\frac{1}{\left(1-\frac{y_1}{R_1}\right)^{\frac{5}{4}}} - F_1\right] + 1\right\}$$

* Transactions of American Society of Mechanical Engineers, Vol. XXXI.

Referring to Fig. 2, the notation in the preceding formula is as follows:

S_t tensile stress, in pounds per square inch, at point of maximum strain in the cross-section;
W load on hook in pounds;
A area of cross-section in square inches;
y_o distance from load line to center of gravity of cross-section;
R radius of gyration of cross-section;
R_1 radius of curvature at center of gravity of cross-section. Usually in hooks, $R_1 = y_o$.
y_1 distance from center of gravity of cross-section to point of maximum tensile stress;
F_2 a function whose value, for the usual hook sections, Prof. Goodman gives as $\frac{Ry_1}{1.2 R_1^2}$;
F_1 a function whose value Prof. Goodman gives similarly as $1 + 1.1 F_2$.

This formula is more tedious than difficult in its application. For example, take the hammered-steel hook for a trunnion 5½ inches in diameter, whose dimensions are given in Table III. For this hook, $r = 3¾$ inches, $d = 7\ 7/16$ inches, $b = 4\ 15/16$ inches, and $c = 1⅝$ inch. For simplicity, neglect the curvature of the inner and outer sides of the section of the hook, although in designing, this curvature should be carefully considered. Neglecting it, we have:

$$A = d(b + c) \div 2 = 24.4 \text{ square inches.}$$
$$W \div A = 60{,}000 \div 24.4 = 2459$$
$$y_1 = d(b + 2c) \div 3(b + c) = 3.1 \text{ inches.}$$
$$y_o = y_1 + r = 6.85 \text{ inches}$$
$$R = \sqrt{\frac{d^2}{18} \times \frac{(b^2 + 4bc + c^2)}{(b + c)^2}} = 2.04$$

Taking $R_1 = y_o$:

$$F_2 = (Ry_1) \div 1.2y_o^2 = 0.11$$
$$F_1 = 1 + 1.1F_2 = 1.121$$
$$y_o \div R_1F_2 = y_o \div y_oF_2 = 1 \div F_2 = 9.1$$
$$1 - y_1 \div R_1 = 1 - y_1 \div y_o = 0.54$$
$$(0.54)^5 = 0.0461$$
$$\sqrt[4]{0.0461} = 0.46 = (0.54)^{\frac{5}{4}}$$

Substituting the required values in the formula, we have

$$S_t = 2459\left\{9.1\left[\frac{1}{0.46} - 1.121\right] + 1\right\}$$

= 25,955 pounds per square inch.

The Pearson-Andrews formula thus gives a maximum tensile stress which is 73 per cent greater than the working stress used in designing this hook. This maximum stress is, however, for the designed load, well within the elastic limit of the metal, which should be at least 50,000 pounds. With a suitable factor of safety, the formulas used in this case for the tabulated dimensions of hooks will give sufficient strength.

TABLE IV. TESTS OF CRANE HOOKS—LOADS AT ELASTIC LIMIT IN POUNDS

Rated Capacity, Tons	Material	Capacity by Test, Pounds	Capacity by Pearson-Andrews Formula, Pounds
30	Cast steel	56,000	55,080

Gas flames are used to burn the fuzz from the thread or yarn used in knitting stockings. The yarn is passed through the flame at the rate of 300 feet a minute. The singeing process makes the yarn soft and silky, giving the stockings a smoother and more highly finished appearance than would be possible without it.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

DETRICK & HARVEY PLANER

The accompanying illustrations show a large open-side planer built by the Detrick & Harvey Machine Co., Baltimore, Md. Reference to these illustrations will show that the machine is equipped with an auxiliary housing by means of which it may be converted into a planer of the usual form. Fig. 1 shows the machine equipped as an open-side planer; and in Fig. 2, the auxiliary housing is shown set up in place, this illustration showing the machine operating as a standard planer. A good idea of the arrangement of the drive will be obtained by referring to the side view of the machine shown in Fig. 3. The capacity is for work up to 96 inches high by 132 inches wide between the housings, and work up to 24 feet in length can be handled. When the auxiliary housing at the left-hand side of the machine is removed, the cross-rail is run back in its housing and the machine operated as a standard open-side planer. Operated under these conditions, the capacity is for work 96 inches high by 96 inches wide, and up to 24 feet in length.

The table is direct connected to the motor without the use of belting. The motor is of the reversing planer type and equipped with a contactor panel and master switch, two field rheostats, the necessary grid resistance and a pendant switch and circuit breaker. The cutting and return speeds may be independently adjusted. A 220-volt direct-current motor is used for raising and lowering the cross-rail. This motor is equipped with a reversing controller, a panel with a double throw switch and a contactor connected to the controller, so that the controller handle may be turned to the "off position" before the motor can be started after the failure of the voltage.

The planer bed is a massive casting with two V-ways and a flat way at the center. The bed has six longitudinal vertical ribs which extend the full length of the bed under the ways; these ribs are tied together at short intervals by double web girths of box section. The distance between centers of the V-ways is 70 inches. A bearing 10 by 102 inches in size is finished on the bed and the main housing is tongued and bolted to this bearing. The bed for the auxiliary housing is bolted to the side of the bed of the machine, and the upper surface of this auxiliary bed is brought exactly parallel with the ways. It is fitted with T-slots to which the housing is secured. The table is of the box type. The upper surface is carefully machined and the guides are fitted to the ways in such a manner that the table is always maintained perfectly level. T-slots and cored openings are provided for holding the work. The table is so constructed that chips are prevented from dropping into the openings in the bed. The table is driven by two forged steel driving racks, each of which has a face width of 9 inches. The reversing stops can be quickly adjusted to give any desired travel up to 24 feet.

Fig. 1. Detrick & Harvey Convertible Planer, with Auxiliary Housing removed for Use as an Open-side Planer

The main housing is of rectangular box section and provided with suitable connections for attaching the cross-rail housing and its braces. The auxiliary housing which carries the outer end of the cross-rail is of curved box section. It is possible to slide this auxiliary housing to and from the planer bed through a distance of 36 inches, this adjustment being made by hand. When the cross-rail and ties to the main housing are run clear, it is possible to remove the auxiliary housing without difficulty, in order to enable the machine to carry work of more than 132 inches in width. The cross-rail housing is attached to the main housing by

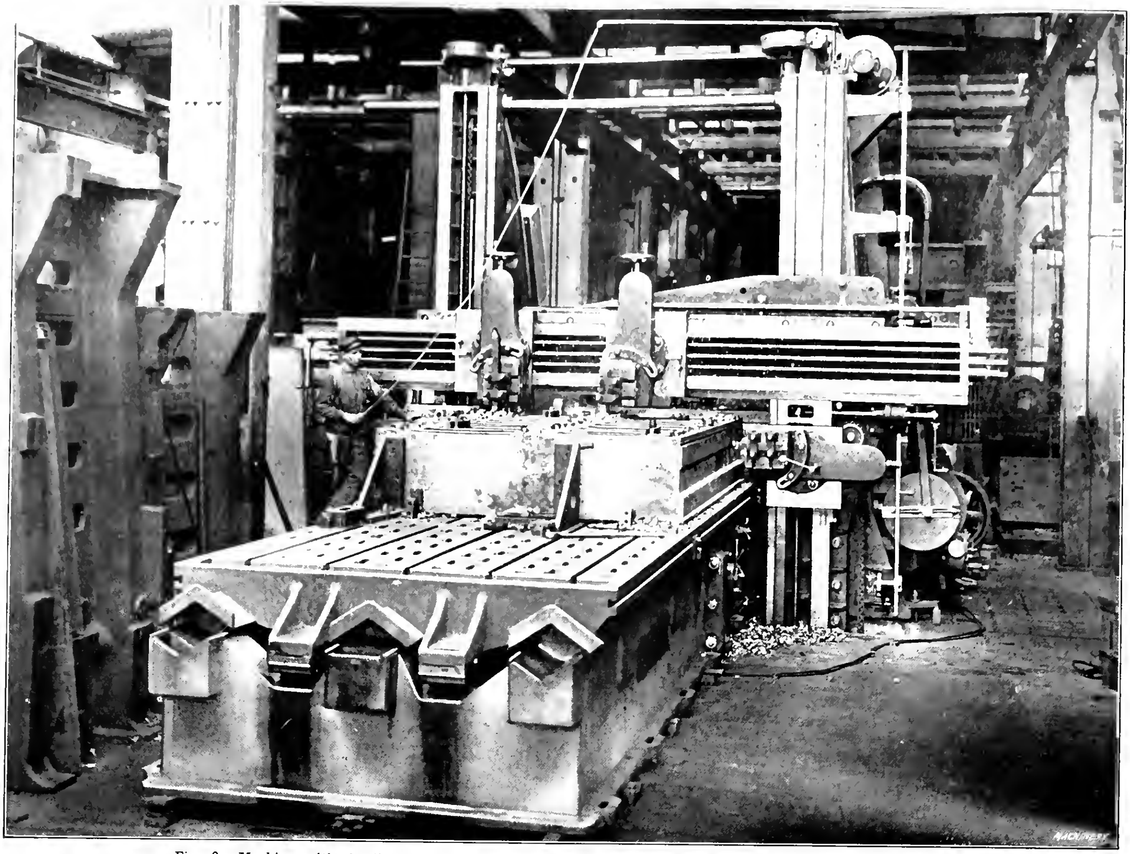

Fig. 2. Machine with Auxiliary Housing in Place, converting it into the Equivalent of a Standard Planer

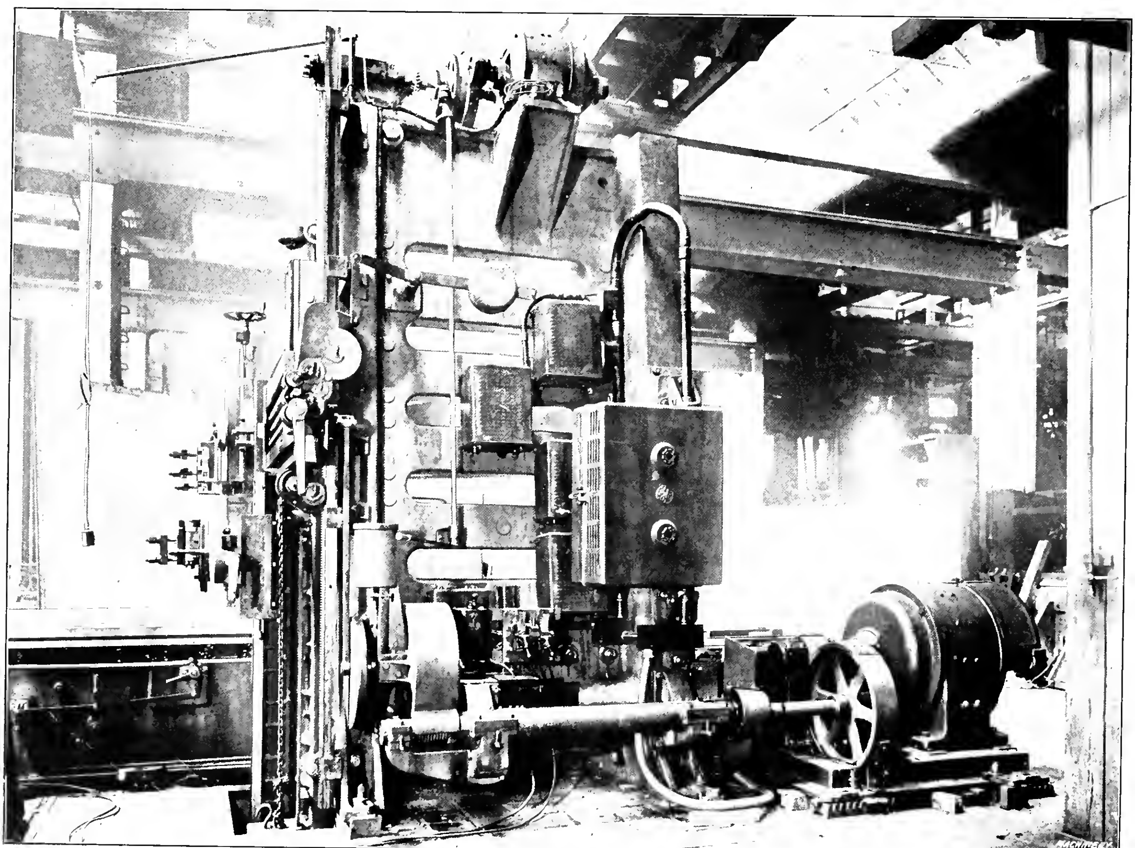

Fig. 3. Side View of Convertible Planer shown in Figs. 1 and 2 illustrating Arrangement of Drive

one vertical leg. This housing carries the cross-rail on its upper or horizontal leg. The vertical leg has a bearing of 12½ feet on the main housing, to which it is bolted. This vertical leg is faced to carry one of the side heads. The cross-rail is braced at the rear by a triangular casting extending back to the inner face of the main housing.

The cross-rail has a sliding fit in the housing to which it can be securely clamped in any desired position. It has a face width of 24¾ inches and carries two tool heads. The cross-rail can be run back through its housing by hand to clear the outer housing, when it is desired to operate the planer as an open-side machine. Four tool heads may be used, two of which are mounted on the cross-rail and one on each of the vertical housings. The heads on the cross-rail are equipped with independent automatic feed in all directions. The heads weigh about 1800 pounds each. The side heads have a vertical feed by hand or power of 96 inches with a horizontal adjustment of 22 inches. These heads are counterbalanced. The four heads are so arranged that they can be used simultaneously on work of any width which comes within the capacity of the machine.

The reversing motor is coupled to a shaft that is geared to two driving shafts. Each driving shaft is provided with a phosphor-bronze spiral pinion 21 inches long that engages a forged steel rack which is rigidly secured to the under side of the table. The steel bevel gears have a face width of 8 inches, and the face of the steel spur gears is 6 inches. The cutting speed is from 20 to 30 feet per minute and the maximum return speed, 60 feet per minute. The cross-rail is raised and lowered by screws geared to the smaller motor provided for this purpose. This motor also furnishes the power for the tool-head feeds through a positive friction device which only consumes power when feeding. The traverse of the cross-rail is obtained by screws driven by hand. The table, cross-rail and tool heads are equipped with suitable stops to prevent over-running. All of the gearing used in the machine is of steel or bronze and the control apparatus is located within easy reach of the operator.

This planer was subjected to careful tests in the manufacturer's shops before being shipped. A box-shaped steel casting about 3 feet square and 12 feet long was planed on three sides simultaneously. The four tools took the maximum cut with the maximum feed that is obtainable with modern high-speed steel. A finishing cut was then taken on the three sides and when calipered, the finished width of the casting did not vary more than 0.001 inch. The test piece was then turned over and finished on what had formerly been the under side. After completing this operation, the piece was again calipered, and it was found that the finished height did not vary more than 0.001 inch. These operations were conducted with the auxiliary housing in place, and after they were completed, this housing was removed and the same test conducted with the machine operated as an open-side planer. The results obtained were equally satisfactory.

"AMERICAN" HEAVY SERVICE SHAPER

The working efficiency of any shaper depends primarily upon its ability to perform all classes of work at the highest speeds and coarsest feeds practicable, and at the same time to produce a finished product of dependable accuracy. To obtain these results a shaper must combine ample power, rigidity and a suitable range of cutting speeds and feeds, with a high standard of workmanship. Therefore, the relative or comparative value of a machine of this type must be determined by a careful consideration of these features, both individually and collectively, the ultimate decision being given in favor of the machine in which these points are developed to the highest degree. When designing the new "American" heavy service shaper, these conditions were borne constantly in mind by the American Tool Works Co., Cincinnati Ohio, with the consequent result that the objectionable features of former designs have been superseded by new features of proven efficiency. The workmanship is of the same high standard that has characterized this company's products in the past, a complete system of jigs and templets being used, which insures accuracy of the highest standard, as well as the absolute interchangeability of parts. The limit of error allowed is only 0.001 inch up to the full capacity of the machine.

Power

One of the first points considered when laying out this new shaper was that of power input. The approximate power a shaper of this size would require for performing the heaviest classes of work was determined, and then sufficient extra power was added to provide a safe working margin. Consequently, this machine is provided with greater power than will ever be required for the average heavy work, and when doing such work it will not be constantly working up to the limit of its capacity. Before deciding on the stroke range, a very thorough investigation was made to determine the proper cutting speeds for metals of various kinds and lengths. As a result of this investigation, a range of eight strokes from 6.5 to 90 feet per minute was provided, this range being in geometrical progression and calculated to give the best results on all classes of work. It will be interesting to note here that while a wider range could easily have been furnished, it was found that a slower speed than 6.5 feet per minute is entirely unnecessary and a faster one than 90 feet per minute impracticable, on account of the excessive vibration caused by the rapid stroke and the undue wear on the machine. Therefore, by confining this range to productive limits a closer speed increment is obtained, which, in turn, gives the machine a higher working efficiency. The length of stroke may be easily changed at will without stopping the machine, the device for positioning the stroke being located on the ram near the head; and it may be operated while the machine is running. A pointer on the ram traveling along an index shows the length of stroke as set.

The Ram and Rocker Arm

The ram and rocker arm are of an improved design, which provides a very rigid and efficient construction. The rocker arm is rigidly connected to a pivot shaft at the bottom of the column, which supports all the weight of the arm and other parts, thus relieving the ram from any dead weight and eliminating undue vibration. The connection between the rocker arm and ram is by means of a double link which is arranged so as to pull down on the ram during the cutting stroke, thus tending to neutralize the upward thrust of the tool. The rocker arm is made in a complete U-section for its entire length and is further strengthened by heavy transverse and cross ribbing. The ram is very heavy and is designed for uniform rigidity throughout its entire length of stroke. It is thoroughly braced by internal ribs, and has long wide bearings on the column with a continuous taper gib having end screw adjustment for taking up the wear.

One of the most vital features of this shaper, and one which is absolutely essential to the life and accuracy of the machine, is the use of full length taper gibs for taking up the wear. These gibs are arranged for end screw adjustment, by means of which a perfect full length bearing can be constantly maintained and the rate of wear kept down to a minimum. The importance of this feature cannot be overestimated, for the rate of depreciation of a machine tool is directly proportionate to the rate of wear in its bearings. The full length taper gib undoubtedly affords a more efficient and convenient method of taking up wear than is provided with flat gibs, which require the use of a series of set-screws for adjustment. Full length metal-to-metal contact is impossible with the latter type of gib. Moreover, it is also very difficult to make the necessary adjustment. With this full length taper gib construction, the original degree of accuracy can be retained throughout the life of the machine, and a full length metal-to-metal contact is assured at all times.

The Cross Feed

The cross feed is both automatic and variable, providing a nicely graded range of thirty-two graduated feeds from 0.006 to 0.200 inch per stroke of the ram. Feeds can be changed and accurately set while the machine is running, by means of a conveniently located knurled knob. The feed is thrown in or out, and also reversed through a knob on the feed plunger. The reversal of the feed at the opposite end of the

ram stroke is accomplished by a plunger in the face of the swinging gear on the bonnet. This plunger engages either one of two holes in opposite sides of the gear. Whether the feed takes place at the beginning or end of the stroke depends upon which hole is engaged by the plunger. All parts of the feed mechanism are compact and present a neat and symmetrical appearance; and all of the gears in this mechanism are securely covered. An automatic safety device is provided, the connection between the feed mechanism and cross-feed screw being made by means of a fiber adjustable friction. This forms a "fool proof" feature which will protect the feed works from damage should the tool accidentally be fed into the cut, or the apron be fed into either end of the cross-rail. This fiber friction can be adjusted to

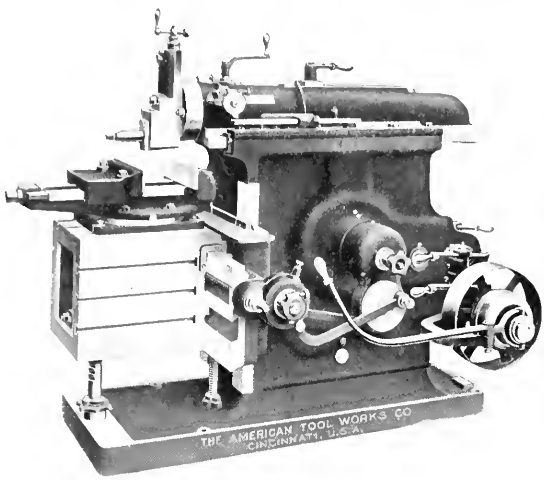

Fig. 1. Front View of American Heavy Service Shaper

pull the heaviest cut without slippage and it is not affected by atmospheric conditions, temperature, or the action of oil.

In order that the unusual power of this shaper may be utilized to advantage, every part of the machine has been designed to afford the greatest rigidity and to easily withstand the severe stresses that the use of this high power would impose upon the various parts. The column is unusually deep and wide, tapering slightly toward the top and giving the machine a neat, graceful and substantial appearance. It is strongly braced internally, the braces being so disposed as to meet the heaviest strains. The column is further reinforced outside on the line of strain, by a wide, deep rib cast integral with the wall. The top of the column projects at the front and rear and provides an exceptionally long bearing for the ram. The base is of large proportions, very deep and strongly ribbed, affording an excellent foundation for the machine. It is of the extension type, with a pad at the end to receive the table support. It is of pan construction both inside and out to catch oil drippings, thus protecting the floor and foundation. Means are provided for draining off the oil collected on the inside.

The Table

The table is made in a complete box section, and is therefore not liable to spring or deflect when heavy work is bolted on its side. The T-slots are all planed from the solid; and the side slots are set in the horizontal plane, thus obviating the possibility of the work bolted to the side dropping down on the base when the clamping bolts are loosened. The top of the table extends over and bears upon the top of the apron, thus increasing its rigidity and preventing dirt from working down between the table and saddle. This construction also removes the strain from the clamping bolts and, at the same time, adds a considerable amount of working surface to the table. In order to further safeguard the bearings of the rail and column, a dirt guard of pan construction is fastened to the rail, which catches chips and dirt that might otherwise work into the bearings. Felt wipers are provided on both ends of the saddle which remove the dirt and chips from the top of the rail, and at the same time lubricate the surface. This table is firmly fitted to the apron by means of five bolts, three at the top and two at the bottom. The rigidity of this connection is further materially increased by two dowel pins extending through the top of the table into the saddle. These pins permanently locate the table in its proper position on the saddle, and also greatly increase its rigidity by preventing vibration under a cut.

The cross rail is of box form, very heavy and strongly ribbed, and of exceptional length, which gives the table a long horizontal range of travel. Three extra wide bearings for the apron are provided, which insure rigidity at that point. The rail is bolted to the column by clamps and bolts of improved design, which prevent its dropping away when the binder bolts are loosened. A stationary elevating screw of large diameter is provided, a ball thrust bearing being used on the elevating nut to facilitate the elevation of the rail. This screw enables the machine to be set on a concrete or other floor without requiring a hole to be bored through to accommodate the travel of the screw.

The head is operative at any angle within an arc of 100 degrees and has a convenient and efficient locking device. The down slide is fitted with a continuous taper gib having an end screw adjustment for taking up wear. The down feed is of unusual length, the feed-screw having an adjustable graduated collar, reading in 0.001 inch. A large toolpost is supplied for using holders with inserted bits and has a tool-steel toolpost screw and tool-steel serrated back plate. The table support furnished with this shaper represents quite a radical departure from established practice. It consists of a notched bar supplied with an adjustable nut at the bottom, and is operative throughout the full traverse of the rail. The notches are spaced one inch part and are engaged by a spring plunger after the rail has been properly adjusted, any further adjustment necessary being accomplished through the nut at the bottom of the notched bar which bears on the planed surface of the base. This support is rigid and positive and provides the further advantage of relieving the

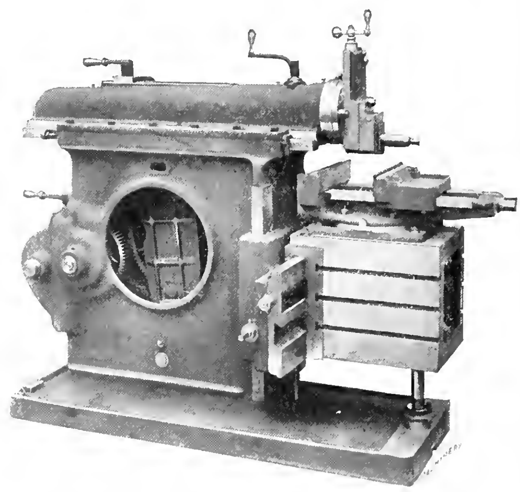

Fig. 2. Opposite Side of Machine shown in Fig. 1

rail of the weight of the table and work, thus insuring a high degree of accuracy in the work produced and less wear on the bearings.

Keyseating Capacity

The rocker arm is made with a double section at the top, which in connection with the large opening through the column permits a shaft four inches in diameter to be passed under the ram for keyseating. Larger shafts may be keyseated by setting over the table to allow the shaft to pass outside of the column, using the head set on an angle. The vise is of a heavy pattern and the jaws are deep and wide. They are faced with steel and provide an unusually large opening. The vise is clamped by four bolts to the swivel base, which is graduated in degrees, the latter being exceptionally large, covering nearly the entire area of the table

top to which it is clamped by four bolts. The vise screw has a bearing at both ends and is always in tension when holding the work.

Method of Lubrication

Special attention has been paid to the thorough lubrication of all working parts, thereby insuring long life and satisfactory service from the machine. The ram slides are oiled by means of a gravity system, oil reservoirs being provided in the ram and clamps from which felt wipers take their supply of oil and distribute it through grooves to the extreme ends of the slides, thus doing away with a multiplicity of oil holes. The felt wipers also effectually strain the lubricant, thus insuring clean oil at all times. The ram slides are provided with felt wipers at the front of the column, assisting in perfect lubrication and also preventing oil from dripping down over the front of the machine. A large quantity of oil is stored in a pocket cast integral with the rocker arm, which, with suitable means for distribution, insures thorough lubrication of the crank-pin and sliding block in the rocker arm. A felt strip inserted in the crank-pin journal insures constant lubrication.

The material used throughout is said to be of the best obtainable for the purpose used. All gears are cut from the solid with special cutters, each gear being cut with a separate cutter especially adapted to the number of teeth in the gear. This method insures a quiet running machine with a minimum of wear on the gears. The pinions are all made of

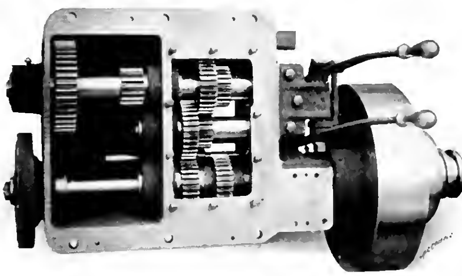

Fig. 3. Gear-box Unit for Machine with Single Pulley Drive

bar steel and the bevel pinions are planed from the solid steel. All shafts are made of crucible steel and accurately ground, and all running bearings are bushed, thus providing for easy renewal in case of wear. The bearings for the driving pulley and bull wheel are very massive and are cast integral with the column. The cone pulley is supported by a large steel sleeve which eliminates all belt pull from the driving shaft. This sleeve is provided with an efficient automatic oiling arrangement which supplies a continuous flow of oil through the journals. The steel bushing is very long, extending well into the pulley and eliminating the necessity of an outboard bearing.

The Speed Box

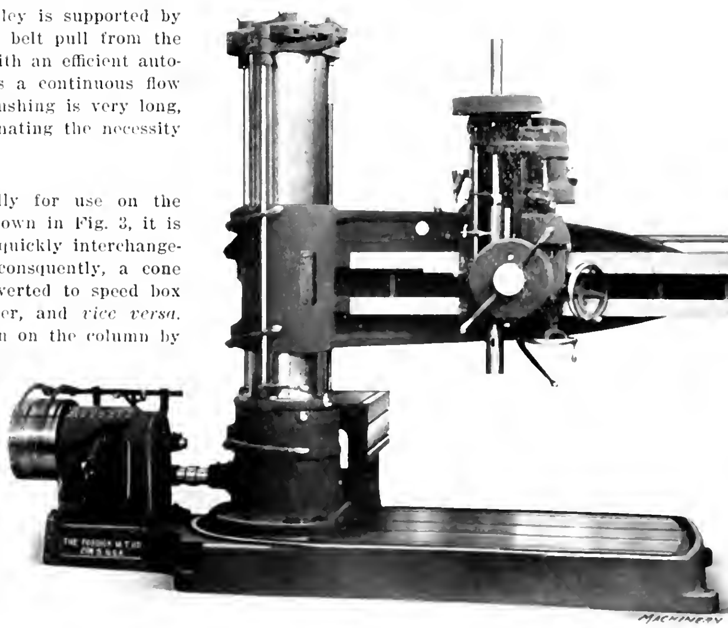
The speed box was designed especially for use on the "American" heavy service shaper. As shown in Fig. 3, it is a complete unit which is absolutely and quickly interchangeable with the cone pulley drive unit; consquently, a cone pulley driven shaper can be readily converted to speed box drive without any complications whatever, and *vice versa.* This unit is located in its proper position on the column by means of dowel pins and is held firmly in place by ten large bolts. The speed box drive provides four changes of speed, which, combined with the back-gear drive, produces a total of eight different cutting speeds for the ram. The speed changes in the box are accomplished while the machine is running, by means of seven heat-treated steel gears, the teeth of which are machine-rounded to facilitate meshing, and two operating levers which are located so that the operator can handle them without effort.

One of the features of this mechanism that should certainly appeal to the operator is the fact that there is not a loose running part in the whole speed box. Every gear is tight on its shaft; consequently, the oiling troubles common to practically all other mechanisms of this kind are absolutely eliminated. All shafts are of crucible steel; they are of large diameter and given a large center bearing which materially increases their rigidity and reduces the overhang of the gears. All shaft bearings are phosphor-bronze bushed and are oiled by means of an efficient gravity oiling system. A recessed bushing is used which forms a retainer for the oil, which, in turn, is fed to the bearing by means of a strip of felt placed in a slot cut lengthwise in the bushing. This felt not only filters the lubricant, but regulates its flow and prevents it from running out and being wasted. A return oil groove cut in the bushing also tends to keep the oil circulating to and fro in the bearing, thus preventing its escape. To further insure the efficiency of this mechanism, it has been designed so as to be oil-tight in order to permit the transmission to run in oil. Thus a very quiet and long lived drive is provided.

A long friction lever, extending well to the front of the machine for operating convenience, controls a large diameter friction incorporated in the driving pulley, by means of which the machine can be started or stopped instantly. Acting in unison with the friction clutch is a friction brake located on the opposite side of the box, which stops the ram instantly when the friction clutch is thrown out. The countershaft has tight and loose pulleys 14 inches in diameter by $3\frac{3}{4}$ inches face width for cone drive, and 14 inches in diameter by 5 inches face width for speed box drive. The regular equipment includes a vise, countershaft, all the necessary wrenches and an automatic safety stop. This shaper can be equipped with power down feed, a circular attachment, a mold maker's vise and table, a tilting top for the box table, a universal table with a tilting side, a four-speed gear box and electric motor drive when so desired.

FOSDICK HEAVY RADIAL DRILL

In the August, 1913, number of MACHINERY, the three-foot heavy radial drill made by the Fosdick Machine Tool Co., Cincinnati, Ohio, was illustrated and described. Since that time, this company has added to its line a 5-foot machine of similar design which is illustrated herewith. To provide for handling the lubricant for heavy drilling and tapping operations in steel, a liberal oil channel is cast around the base. This channel extends completely around the column and



Fosdick 5-foot Heavy Radial Drill

drains into a reservoir of ample proportions. This construction provides for the full ribbed cross-section at a point immediately in front of the column where the greatest rigidity is required; and it also allows the T-slots to extend back beyond the front of the column, thus making the full working surface of the base available.

Another feature of the machine is the table which is also provided with oil channels draining into a pocket at one corner. This arrangement eliminates the necessity of employing a pump and piping. The column is of the double tubular type with a fixed inner column extending to the top. The arm is of pipe and beam section designed in such a way as to give the maximum resistance to torsional and bending strains. The clamping levers are located at the front where they are convenient for the operator. The head is easily run along the arm by means of a compound ball bearing spiral gear. The feed box is placed low on the head, giving support to both sides of the worm, which is mounted on a ball thrust bearing and runs in oil. All feed changes are made with a single lever.

DIAMOND MOTOR-DRIVEN SURFACE GRINDERS

The Diamond Machine Co., Providence, R. I., has recently re-designed its line of automatic surface grinders. The construction of the machines has been improved in many ways, although the general design and method of operation remains essentially the same. One important change has been made,

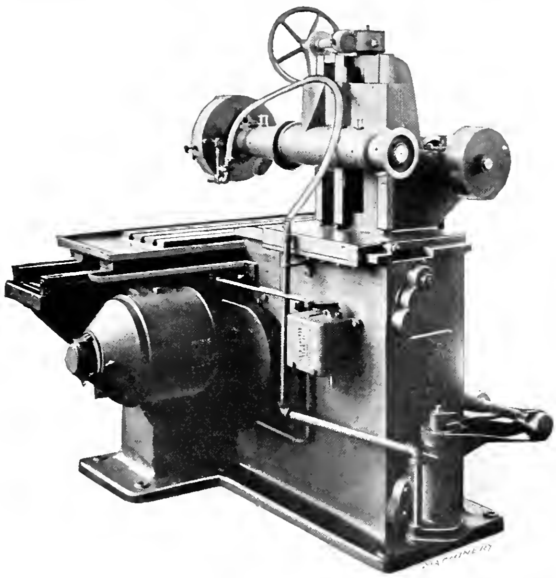


Fig. 1. Diamond Motor-driven Surface Grinding Machine

however, *i. e.*, the application of electric motor drive on machines of this type. It will be seen from the illustrations that the motor drive eliminates the use of countershafts and overhead belting. Either direct- or alternating-current motors can be used.

Two motors are employed which are of a special type developed for the Diamond Machine Co. One of these is a 2-horsepower constant speed motor running at 1200 revolutions per minute; and the other, a ½-horsepower, high resistance frame, specially wound reversing motor which runs at 600 revolutions per minute. The 2-horsepower motor drives the spindle and the ½-horsepower motor is for the table. Controllers for both motors are mounted at the front of the grinder. The spindle drive is accomplished by belting from a drum fastened to the motor shaft direct to the pulley on the driving shaft of the machine. The belt is kept tight by an idler. The remainder of the transmission is the same as on belt-driven machines, power being transmitted from the driving shaft to the spindle by a second belt. The table is driven by the reversing motor through a cloth pinion which

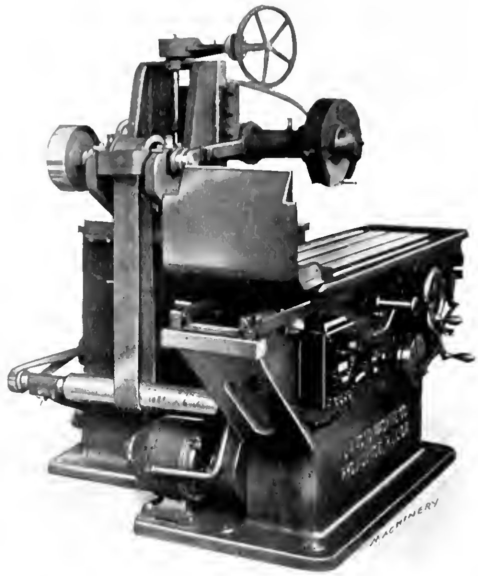

Fig. 2. Opposite Side of Machine shown in Fig. 1

transmits power through an idler gear and bronze pinion to a gear on the feed pulley shaft.

HARRINGTON "UNDER" MILLING MACHINE

The style B "under" milling machine built by the Harrington Machine Co., Erie, Pa., is shown in the accompanying illustrations. This machine is especially designed for milling drop-forging dies and for other classes of irregular open work. A taper cutter is used to give the die the desired clearance in all directions, and as the cutter is on the bottom or under side of the work, the term "under milling machine" has been applied.

The table is provided with movable chucking jaws which are tongued into grooves in the table. They may be removed and clamps used for securing larger work than comes within the capacity of the chuck jaws. The longitudinal and traverse travel is obtained by square threaded screws fitting in bronze nuts. Adjustment for wear is provided so that lost motion can always be taken up. The spindle is of high-carbon steel with the seat for the collet hardened and ground. It runs in three bronze bearings which are made adjustable

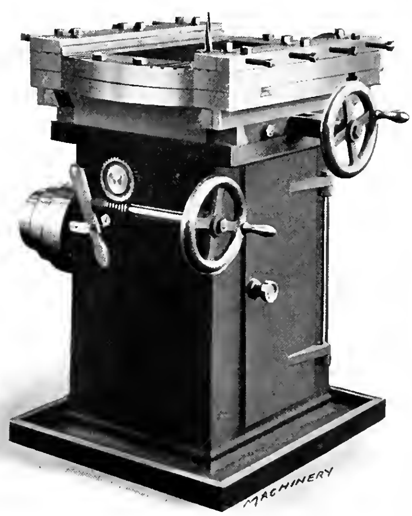

Fig. 1. Harrington "Under" Type of Milling Machine for Die Work

Fig. 2. Opposite Side of Machine shown in Fig. 1

for wear, and is driven by bevel gears which transmit power from a three-step cone pulley. The gearing is completely encased to exclude dirt and chips. The capacity is for cutters 1 3/16 to $1\frac{3}{8}$ inch in size. The table can be raised to use the small part of the cutter for milling sharp corners. The longitudinal traverse is 14 inches and the transverse traverse is 7 inches. The rotary table top enables angle lines to be followed. The floor space occupied is $42\frac{1}{2}$ by $44\frac{1}{2}$ inches, and the weight of the machine and countershaft 1920 pounds.

BARNES DRILLING AND TAPPING MACHINE

The Barnes Drill Co., 814 Chestnut St., Rockford, Ill., is now building a 20-inch all-geared drilling and tapping machine which is provided with a self-oiling system. The all-geared feature provides for building a machine of heavy construction, with exceptionally high power for its swing. This combination of high power with the self-oiling feature, makes a machine of unusually high efficiency. Every bearing, with the exception of the spindle sleeve, is self-oiling and there are eight changes of geared speed and eight changes of geared feed, all of which are under instant control of the operator from the front of the machine. All gears are fully enclosed, thus meeting the requirements of modern safety laws. The capacity of the machine is for high-speed twist drills from $\frac{1}{4}$ to $1\frac{1}{4}$ inch and these drills may be driven to their maximum capacity.

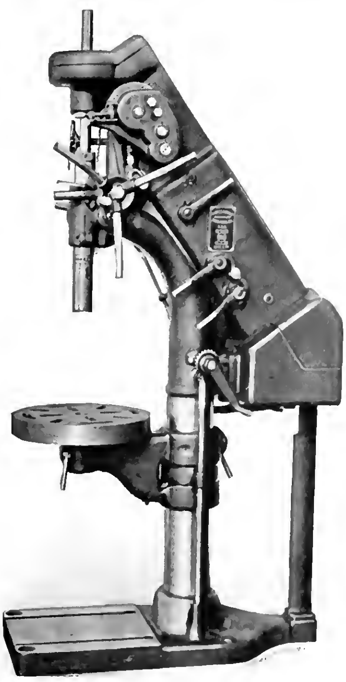

Fig. 1. Barnes 20-inch All-geared Drilling and Tapping Machine

The machine is equipped with back gears and automatic stop for the geared feeds, and the same machine is also built without back gears. Reversing friction clutch gears and automatic reverse may also be provided when so desired. Both types of machines can be equipped with motor drive and for fast high-speed drilling with drills less than 1 inch in diameter, special crown gearing is provided to double the spindle speeds. The oil for the self-oiling system is delivered by a geared pump which draws the lubricant from the reservoir of the machine and distributes it to all gears and

Fig. 2. Opposite Side of Machine shown in Fig. 1

bearings, including the crown gears and gears in the feed box. This self-oiling system is used by the Barnes Drill Co. under license from the Kearney & Trecker Co., of Milwaukee, Wis.

It will be seen from the illustrations that the frame of the drill is of unusual design and that it is of exceptionally massive construction. The spindle is made of machinery steel, double splined and ground to size; it is fitted with a special ball thrust bearing. The spindle is counterbalanced and the nose is extended to bring the drift hole below the sleeve. The graduations on the sleeve are in inches and millimeters. The gears for the speed changes are located on the diagonal shafts; they are cut from special chrome nickel steel bar stock and tempered, the stock used for this purpose having a tensile strength of 270,000 pounds per square inch. The eight changes of speed—four of which are obtained without the back-gears—may be easily and quickly obtained without requiring the drill to be stopped. These changes are made by simply operating the proper shifting lever, which is within easy reach of the operator when standing at the front of the machine. The back-gears are operated by a small lever which is also accessible from the front

of the machine, and may be instantly engaged or disengaged while the machine is running.

Either of the eight changes of geared feed may also be obtained while the spindle is running idle by placing the index lever in the proper notch on the segment. The feeds are indicated in plain figures so that there should be no danger of mistake. A safety device prevents overloading and reduces the chance of breaking the drill. The star-wheel lever which controls the hand feed is entirely different from the common ratchet lever. It operates through a pinion meshing with an internal gear, the ratio being 4 to 1. This makes the star-wheel handle equivalent to a common lever of four times its length. The star-wheel also acts as a quick return lever, thus eliminating the necessity for using a ball handle for this purpose. The machine is usually equipped with a round table but a square table with an oil channel can be substituted. The table is raised and lowered by a crank which operates the elevating screw through bevel gears. The table can be swung around on the column and clamped in any position. The machine has an automatic reversing mechanism which is a very desirable feature.

For tapping operations, the friction clutch gears give reverse speeds of $1\frac{3}{4}$ to 1 and these gears are located at the driving end of the machine instead of on the spindle. As the machine is geared down to 13 to 1 in front of the clutch gears, this eliminates the excessive wear and tear which would result if the clutches were placed directly on the spindle. The machine has an automatic reversing mechanism for depth tapping. The trip can be set so that when the tap has reached any required depth, the spindle is automatically reversed, thus backing out the tap at an increased speed. The shifting lever can also be set so that when the machine is tripped—either automatically or by hand—it will return to the neutral position, thus stopping the spindle instead of reversing it. The small hand trip lever shown in the illustration is always ready for instant use if it is desired to reverse the machine or stop the spindle at any point in the operation. When the machine is to be motor-driven, a 2-horsepower motor running at about 1200 revolutions per minute is recommended for use on this 20-inch drill. This arrangement possesses the well-known advantages of individual motor drive.

CARROLL-JAMIESON LATHES

The Carroll-Jamieson Machine Tool Co., 257 Davis St., Batavia, Ohio, is now building the 14-inch tool-room and manufacturing lathe illustrated in Fig. 1; and also the 13-inch back-geared screw cutting lathe shown in Fig. 2. The name of the first machine referred to indicates the scope of work for which it is intended, while the 13-inch screw cutting lathe was particularly designed to meet the requirements of automobile repairing and general machine shop practice. A careful study of the requirements of this class of work showed the designers of this machine that it was necessary to provide a heavy, rigid construction to stand up under the varied classes of work for which a tool is used in service of this nature. Having made this brief introductory statement, the features of the two lathes will be taken up in some detail. The 14-inch lathe shown in Fig. 1 is equipped with a selective sliding gear mechanism and single pulley drive. The head is absolutely oil-tight and dust-proof and the gearing runs in an oil bath. All of the gearing in the head is cut from high-grade steel blanks and then heat-treated and hardened. The driving pulley runs in an extended bronze bushing which relieves the driving shaft of strain and undue wear. The handwheel at the top of the head controls eight changes of speed and the back-gears are engaged by means of the vertical lever seen immediately below and to the right of the handwheel.

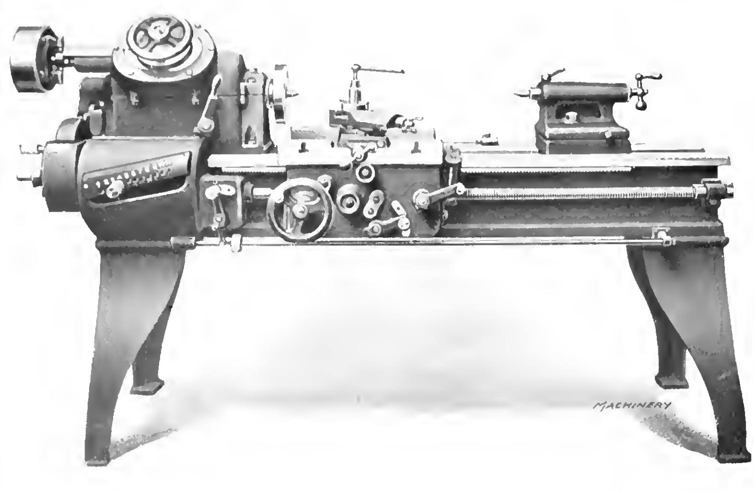

Fig. 1. Carroll-Jamieson 14-inch Tool-room and Manufacturing Lathe

The geared head was particularly designed to facilitate rapid production. It has already been mentioned that the handwheel on the head provides for obtaining either of eight changes of speed; these speeds are in geometrical progression and the change can be made instantly while the machine is running at its highest rate of speed. The arrangement of the gears by which these speed changes are obtained is shown in Fig. 3. The main driving gear stops automatically when the handwheel is pulled forward and it is impossible for any two speeds to be engaged at the same time. The gears in the head have short, stub teeth; the spindle is made of special hammered crucible steel and is finished by grinding. The bearings are bushed with a special hard bronze and scraped to an accurate fit; and provision is made to compensate for wear. The head is substantially ribbed to secure the necessary rigidity and all bearings are self-oiled. The quick-

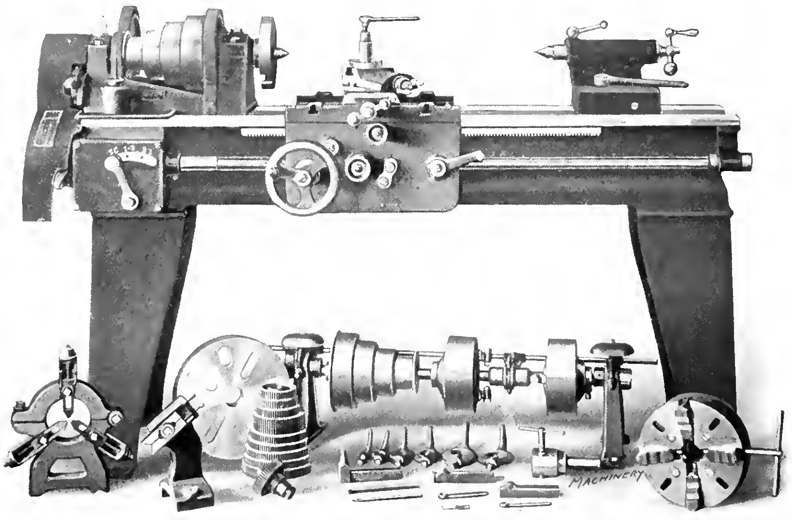

Fig. 2. Carroll-Jamieson 13-inch Back-geared Screw-cutting Lathe

change gear mechanism is of simple construction and provides for cutting threads from 3 to 64 per inch including all standard and odd threads as well as 11½ pipe threads. Reverse is provided in the head as well as the apron. Fig. 4 shows the arrangement of the back gears and the lever for throwing them in or out of engagement. All bearings in the apron which carry moving shafts are bronze bushed. The alignment of the spindle is accurate to 0.0005 inch in 12 inches and the error in boring and turning operations will not exceed 0.001 inch in 12 inches

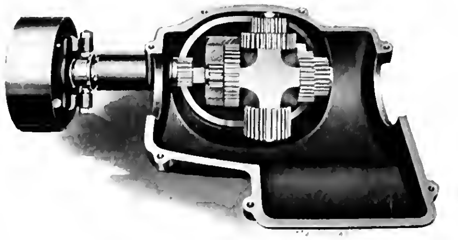

Fig. 3. Arrangement of Speed Change Gears on 14-inch Lathe

The head of the 13-inch back-geared lathe shown in Fig. 2 is fitted with a hardened steel spindle which is accurately ground to size. The spindle runs in chilled cast-iron bearings which are scraped to an accurate fit. The error in the alignment of the spindle does not exceed 0.001 inch in 12 inches. It will be seen that the machine is driven by a 4-step cone pulley which is arranged to carry a 2-inch belt. The machine is back-geared in the ratio of 7 to 1. The tailstock is of the cutaway pattern, permitting the compound rest to be swung around to an angle of 90 degrees. It is fitted with a 1 11/16-inch sleeve which is bored to No. 4 Morse taper. The tailstock can be set over for turning tapers. The carriage is gibbed at both the front and back and the cross-slide is 6 inches in width. The cross-feed screw has the usual graduated collar reading to 0.001 inch and the compound rest is graduated to 360 degrees. The apron has power cross feed and longitudinal feed, and there are three changes of feed obtained through sliding gears which are secured by placing the lever in either of the three stations on the feed box. Change gears are provided for cutting from 5 to 36 threads per inch, including 11½ pipe thread. There is also one extra compound gear to cover all odd and special threads from 3 to 72 per inch. The regular equipment of the lathe consists of a large and a small faceplate, a follow-rest, a steady-rest, a compound rest, a full set of change gears and double friction countershaft.

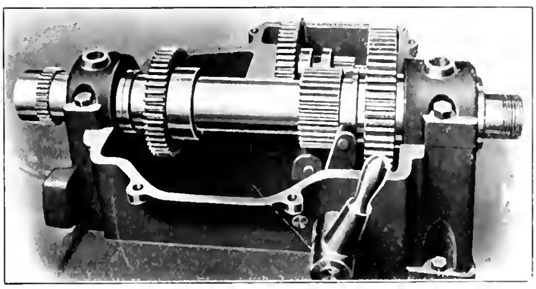

Fig. 4. Back-gears on 14-inch Lathe and Lever for throwing them into Engagement

Experience with the work that comes to the average garage shows that there is not enough large size work to warrant investing in a lathe swinging over 14 inches. The large lathe is not convenient for the general run of repair work and it is only occasionally that a job is met with which is too large to be handled on the 14-inch lathe. To meet the requirements of these occasional jobs which exceed the capacity of a lathe of this size, the Carroll-Jamieson Machine Tool Co. has designed an attachment for increasing the swing of its 13- and 14-inch lathe. Equipped in this way, the 13-inch lathe swings 18¾ inches over the ways—which is ample for the maximum requirements of garage work—and the 14-inch lathe swings 22 inches over the ways. This attachment can be placed on a lathe as quickly as a steady-rest and will be found a very convenient equipment for the repair shop. The spindle is accurately lined and will handle boring and turning operations with a high degree of accuracy. The nose of the spindle conforms to the nose on the lathe spindle so that the same faceplates, chucks or centers can be used. The attachment takes up 8 inches on the lathe bed. The attachment consists of head and tail piece, the compound rest, swivel block and one steel gear that fits the nose of the lathe spindle and drives the intermediate gear of the attachment. When the attachment is received it is ready to place on the lathe.

INGERSOLL-RAND AIR COMPRESSOR

The steadily increasing use of low-grade fuel oil for power purposes has led the Ingersoll-Rand Co., 11 Broadway, New York City, to add to its line the oil engine driven air compressor, which is illustrated herewith. This unit is of the direct-connected straight line type and in this respect it is somewhat similar to the standard line of small compressors built by this company. The main frame is designed for a splash system of lubrication; it is wholly enclosed and provided with removable covers. The feature of greatest interest is the design of the driving end of the unit. This consists of a single oil engine cylinder set behind the air cylinder and direct-connected to the air piston by means of an extended piston rod. The general design follows a type known as the "hot bulb engine" which is really a development of the Diesel engine, and combines high thermal efficiency with simplicity of construction.

No auxiliary air compressors are employed and this, combined with a lower working pressure, makes an ideal equipment for compressed air service. The power cylinder is of the single-acting, two-cycle type. It is water jacketed and provided with an efficient system of lubrication. A torch is provided for heating the ignition bulb preparatory to starting the engine, but after the compressor is well under way, the use of this torch is unnecessary. The fuel is automatically injected into the combustion chamber by means of a small pump operated by the main shaft. It enters in the form of a finely atomized spray and is immediately ignited by the hot bulb, thus dispensing with the use of an electric sparking device. The stroke of the fuel pump is regulated by a centrifugal governor located in the flywheel: and this regulates the amount of fuel injected into the cylinder, making it proportional to the load. This method of regulation is supplemented by a regulating device on the intake of the air cylinder.

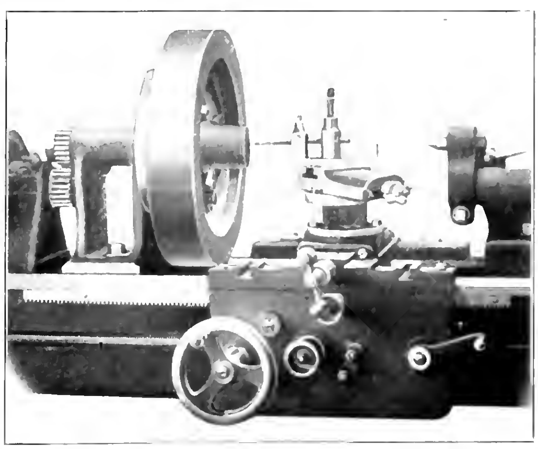

Fig. 5. Attachment for increasing the Swing of Carroll-Jamieson 13- and 14-inch Lathes

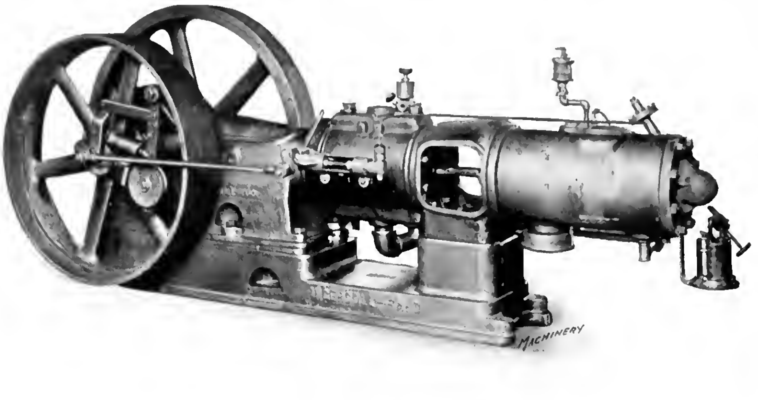
The method of operating this unit is accompanied by none of the losses common to many two-cycle gasoline engines, in which part of the incoming charge follows the exhaust gases through the outlet ports. This is due to the fact that the

fuel is not vaporized by an outside agency and introduced with the air used for "scavenging"; but is injected directly into the cylinder at the end of the compression stroke, as previously mentioned. This means that pure air is used during the scavenging period of the stroke, with the result that the inlet and outlet ports can be arranged in such a way that more thorough scavenging is effected without any loss of fuel. The absence of a carbureter with its needle valves, springs and delicate adjustments, which require constant attention to suit varying atmospheric conditions is also a material advantage.



Ingersoll-Rand Oil Engine Driven Air Compressor

Another feature of the engine is the provision of means for inducing a small quantity of water from the cylinder jacket into the combustion chamber. This water performs the function of regulating the temperature in the cylinder, thereby preventing an undue rise in the temperature of the piston and cylinder walls, which would be liable to result in a disassociation of the fuel oil. This practice reduces the maximum pressure in the cylinder but slightly increases the mean effective pressure, making a smooth running and highly economical engine. The amount of water injected is regulated according to the load on the compressor. At present, this unit is made in but one size which has a capacity for 66 cubic feet of free air at 100 pounds pressure and 73 cubic feet at 80 pounds pressure, when running at 325 revolutions per minute. Under average operating conditions, the fuel consumed at this speed is about 2.2 gallons of kerosene per hour. The engine is adapted for the use of either kerosene, fuel oil or distillate. The unit occupies a floor space of 8 feet 10 inches by 2 feet 5 inches and the weight is 3000 pounds.

NEWTON LOCOMOTIVE LINK GRINDING MACHINE

Front and rear views of a link grinding machine which was recently built by the Newton Machine Tool Works, Inc., Philadelphia, Pa., for use in the Baldwin Locomotive Works, are illustrated in Figs. 1 and 2. When it was necessary for locomotive builders to grind links which were required to be hardened, the operation was the cause of considerable trouble. The nearest approach to economical production was obtained by taking a heavy planing machine, equipping the rail with a grinding spindle and mounting the link to be ground on a swiveling table which was oscillated by a guide traveling in a straight channel, the angle being adjustable to suit various radii. A brief consideration will make it evident that this method gave only approximately accurate results.

To enable this operation to be handled more efficiently, the machine which forms the subject of this article was designed and built by the Newton Machine Tool Works. This machine possesses a material advantage over the equipment referred to in the preceding paragraph, in that the table carrying the link can be adjusted for depth of cut and from side to side, without disturbing the radius control. The machine has a compound spindle slide. The smaller slide, which is at the front, has a reciprocating motion of ⅝ inch which permits of the use of large diameter grinding wheels having a face broad enough to cover the entire surface to be finished. The secondary slide has a vertical feed to permit of using small diameter wheels which are required, owing to the slight amount of clearance, and which are too small to provide the requisite strength if made the full length of the finished surface. This feed works vertically and has an automatic reverse for both directions of travel. In operation, the links are placed on pins attached to the top table which, in turn, is held parallel by pull pins at each end. The radius bracket shown in Fig. 2 is adjusted to the required location which is determined by a scale. The drive for the spindle and for the table travel are independent and can be varied to suit different requirements. The maximum capacity of the machine is for links up to 120 inches radius by 5 inches face, and the weight of the machine is 12,000 pounds. The accuracy of the work done by this machine is well up to the standard of other modern machine tools, while that of the planer attachment was merely approximate.

Fig. 1. Operating Side of the Newton Link Grinding Machine

Fig. 2. Rear View of Newton Link Grinding Machine

STANDARD WIRE DRAWING MACHINES

A wire drawing machine which is built in four sizes by the Standard Machinery Co., Elmwood Ave., Auburn, R. I., is illustrated in Figs. 1 and 2. These machines are adapted for drawing steel and copper wire as well as wire of the precious metals, and are particularly suited for drawing steel wire from 5/8 inch down. The machine illustrated is the smallest size; it has a drum 22 inches in diameter by 8½ inches high, the drum operating at a lineal speed of 50 feet per minute. The "draw-out" drum which performs the preliminary operation operates at 19 feet per minute. This machine occupies a floor space of 4 feet 6 inches by 7 feet 6 inches and has an approximate weight of 4000 pounds.

It will be seen from Figs. 1 and 2 that the machine is driven by a single pulley, this pulley being provided with a friction clutch. The driving shaft is back geared to the large spur gear shown in Fig. 1. On the same shaft with this gear there is a bevel pinion which meshes with the large bevel gear on the vertical spindle that drives the drum. The machine is started by engaging the friction clutch which is controlled by the handle at the extreme left of the machine. The handle at the extreme right is for the purpose of engaging an internal clutch located inside the drum, which sets the draw-out drum in motion.

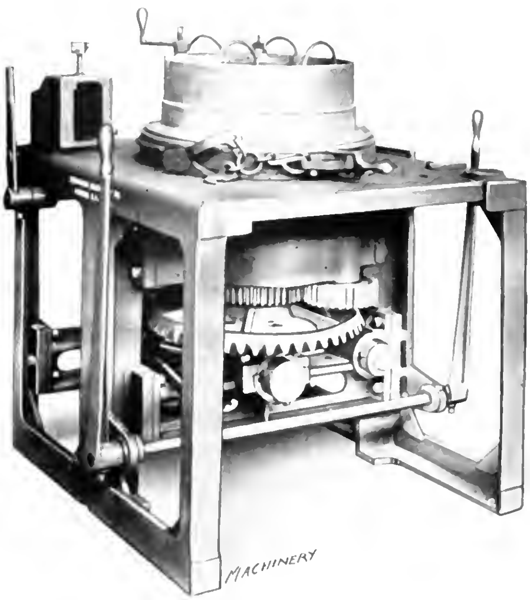


Fig. 2. Closer View of the Machine showing Arrangement of the Drawing Drums

The die is supported in a holder shown at the corner of the table. In preparing for a drawing operation, the stock is pointed so that it can be put through the die and have a length of 3 inches extending out to be gripped by the tongs. This pointing of the stock is done by either a hand or rotary swager or by any other suitable method, a hydraulic squeezing press being used in some cases. After the stock has been pointed and threaded through the die in this way, it is gripped by the tongs and the internal clutch is then engaged to start the draw-out drum. When the draw-out drum has made one-half revolution, the lever shown in Fig. 2 engages a trip which disengages the tongs, causing them to release their hold on the work. The machine is then stopped and the end of the wire, which has been drawn out, is brought up and clamped to the main drawing drum, after which the machine is again started and the drawing operation completed.

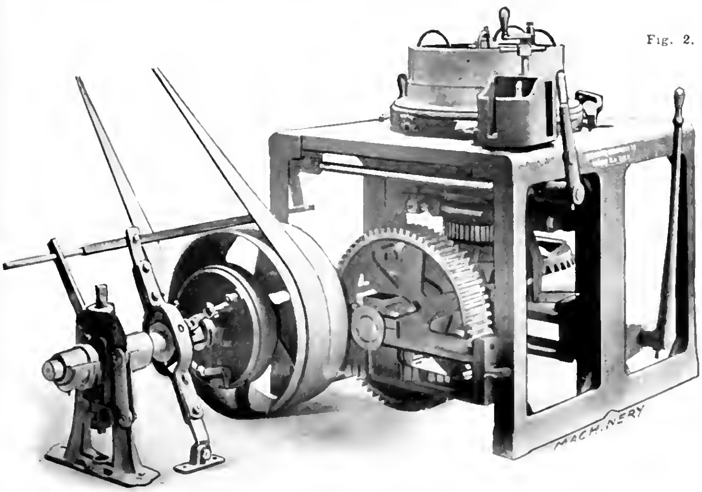

Fig. 1. Wire Drawing Machine built by the Standard Machinery Co.

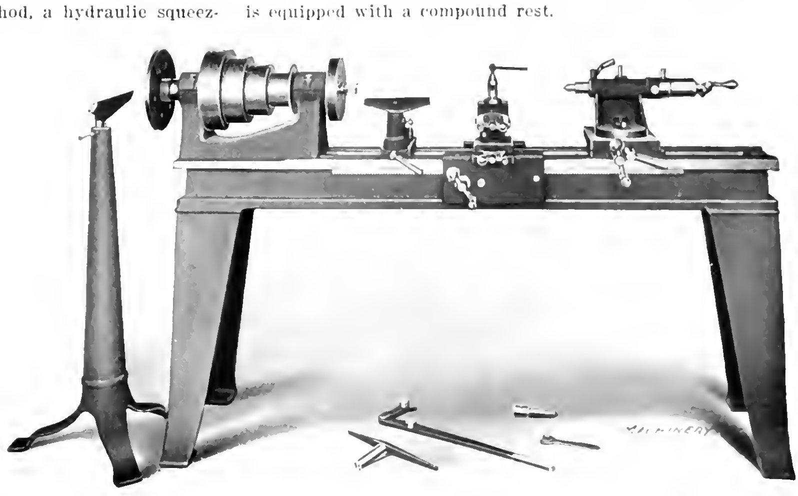
Various methods of lubricating the work are employed. Some use waste and silk wiper cloths saturated with oil, these being placed on the work at the far side of the die and supplying the necessary lubrication. Others rub a special palm-oil soap on the wire. In some cases it is found advantageous to pass the wire through a bath of oil that is set upon the table of the machine.

BLOUNT PATTERNMAKER'S LATHE

The patternmaker's lathe which forms the subject of this article is a recent product of the J. G. Blount Co., Everett, Mass. This machine swings 16 inches and has a bed 6 feet in length. The spindle is hollow and forged from high-carbon steel; it runs in self-oiling bronze bushed bearings. The outer end of the spindle is threaded to receive a faceplate for turning work of large diameter and the tripod rest shown at the left-hand end of the lathe is provided for use in connection with work of this nature. In addition to the usual hand rest, the lathe is equipped with a carriage that has rack and pinion feed. The carriage has hand operated cross feed and is equipped with a compound rest.



Blount Patternmaker's Lathe and Tripod Rest for Use in connection with the Faceplate

The tailstock has screw and lever feed and is made with a graduated base so that any required taper may be bored or turned. A taper pin provides for bringing the tailstock back into alignment. The base of the tailstock is provided with a slide and the tailstock may be fed crosswise by operating a ball handle. The equipment of the lathe includes a plain countershaft with tight and loose pulleys or a friction countershaft with two friction pulleys.

C. & E. RATCHET WRENCH

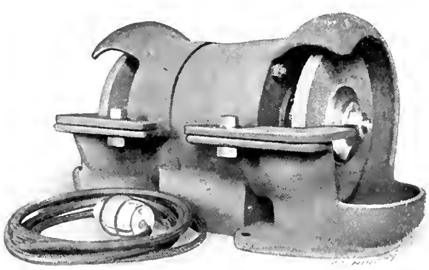
The combination ratchet and alligator wrench illustrated herewith is a recent product of the C. & E. Mfg. Co., Marshalltown, Iowa. This wrench has only three working parts and is made of drop-forged carbon steel. It is strong and not likely to get out of order. There are four different sizes of ratchet jaws provided, any of which may be put on the

The "Marshalltown" Wrench made by the C. & E. Mfg. Co.

wrench by turning the handle through part of a revolution. The ratchet feature enables the wrench to be operated through a half revolution and is particularly convenient in removing nuts in cramped positions. The ratchet jaws have capacities of ⅜, 7/16, ½ and 9/16 inch, respectively.

FORBES & MYERS BENCH GRINDERS

In the August, 1913, number of MACHINERY the polyphase grinder made by Forbes & Myers, 178 Union St., Worcester, Mass., was briefly described. In response to a demand for a lighter machine of similar type, which can be used on electric light circuits, this company has added four new models to its line. In designing these machines, particular attention has been paid to the starting current in the smaller sizes. The motor will develop a full 1/6 horsepower, but the current is small enough so that there is practically no danger of burning out the fuses when attached to a lamp socket. The construction of the rotating element is similar to that of the standard polyphase machines. The grinders are made with two forms of frame, one of which



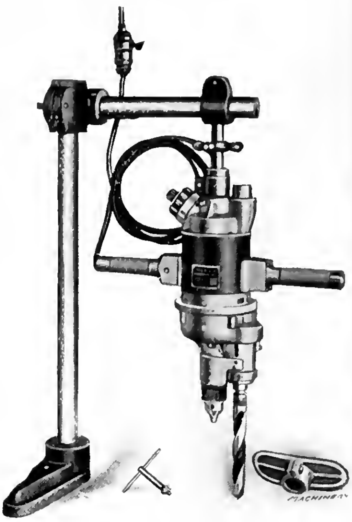
Forbes & Myers Bench Grinder for Operation on Lighting Circuits

has a water basin, adjustable tool rest and wheel guards, while the other is similar with the exception that the guards do not extend over the top of the wheels. The equipment includes two wheels 6 inches in diameter by ½ inch face width and 10 feet of reinforced lamp cord.

The larger sized machines of this line are equipped with ½ horsepower motors which may also be used on a lighting circuit, although they are really larger than should ordinarily be used in this way. A simple and reliable centrifugal device is used to open the circuit of the starting winding when the motor has come up to the required speed. The grinders equipped with the ½ horsepower motors are also provided with wheels 6 by ½ inch in size, and are powerful enough for grinding lathe and planer tools and handling a variety of other machine shop work.

STOW TWO-SPINDLE DRILL

Stow Mfg. Co., Binghamton, N. Y., is now manufacturing the two-spindle, two-speed drill which forms the subject of this article. One of the spindles of the tool is fitted with a Jacobs chuck for handling straight shank drills up to ½ inch in diameter. This spindle runs at 450 revolutions per minute. The other spindle takes Morse taper shank drills up to ¾ inch in diameter and runs at 225 revolutions per minute. The tool can also be arranged so that it is possible to remove the chuck from the small spindle and mount it in the large spindle. With this tool, the small spindle provides high speeds for driving small drills, while the large spindle provides ample power for drilling larger sized holes. The spindles of the tool can be easily reversed so that it can be used for tapping operations. Either direct- or alternating-current motors may be provided and the motors are suited for connection to an ordinary lighting circuit.

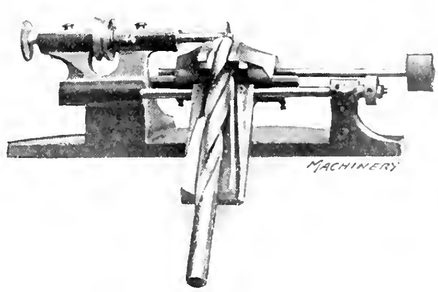


Stow Two-spindle Two-speed Drill

MATHER TWIST DRILL SLOTTING MACHINE

E. B. Mather, 1415 Lake Ave., Rochester, N. Y., is exploiting a patented method of slotting the point of twist drills and the machine used for this purpose. The machine is shown in the accompanying illustration, and by its use a small slot is ground across the point of the drill. This is said to give the drill several important advantages over a twist drill with a point of the standard form. The drill cuts faster and it is claimed that the feed pressure and torque are materially reduced, with the result that the slotted drill operates about 50 per cent faster than a drill of standard design. It is also said that the drill will operate longer before it requires re-grinding, and that when drilling in brass there is no tendency for the drill to catch as it comes through.

Tests of these slotted drills were recently conducted in the experimental engineering laboratories of Sibley College at Cornell University. Drills ½, 5/16 and 3/16 inch in diameter were used, one set of drills being slotted and the other left plain, but neither set of drills had been previously used. The feed pressure required was determined by applying the pressure through a piston rod connected to a piston



Machine for slotting Twist Drills by the Mather Process

working in an oil cylinder. The use of a pressure gage enabled the feed pressure to be determined. The torque was determined by a spring balance used in connection with a radial arm. The results of the test showed that the slotted drills cut at a higher speed than the plain drills were capable of reaching under the same feed pressure. The power required to drive the slotted drills was somewhat greater, but the quality of the work was about the same in both cases. The torque was considerably less for the slotted drill. Another series of experiments was conducted to determine the tendency of the slotted drill to run out as compared with that of the plain drill. The results showed that the slotted drills were superior to the plain drills in this respect.

HESS-BRIGHT BALL BEARING

The Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa., has added to its line what is styled the Bright "2-RO" ball bearing which is illustrated herewith. This bearing was particularly designed for use in automobiles and for other classes of service in connection with bevel gears, where a bearing is required for carrying both thrust and radial loads.

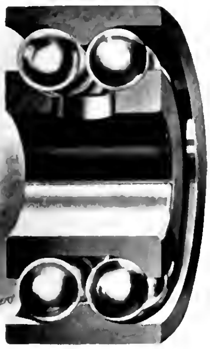


Fig. 1. The Bright "2-RO" Ball Bearing

Simplicity is the striking feature of the design of this bearing. The inner and outer races are of forms which lend themselves readily to accurate grinding. The balls are of the usual degree of accuracy found in a high-grade ball bearing and have two points of contact. The arrangement of the filling opening provides for filling the races with balls, and when the bearing is completely assembled the points of contact are so far from the filling opening that there is no danger of the balls striking the edge of it. It is stated that the location of the opening is such that it does not weaken the race.

The angle of both the thrust and radial loads, or the combination of two such loads, is such that the balls are kept away from the filling opening and this condition is further

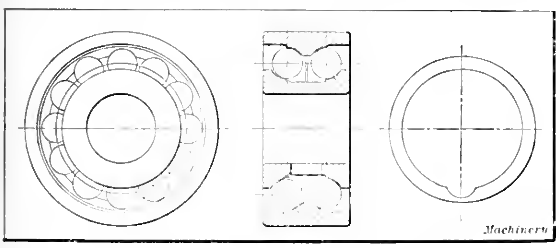

Fig. 2. Details of the Bright "2-RO" Ball Bearing

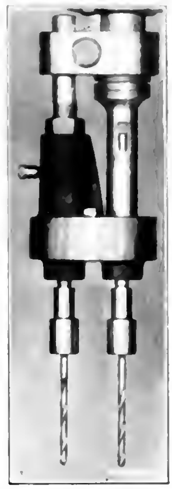
assured through the action of centrifugal force. The split inner ring is in no sense a separator; its function is to simply float between the two rows of balls and keep them away from the filling opening. It is only in unusual cases that the ring is required, as at such a time when an undersized ball stops opposite the filling opening; under normal conditions none of the balls enter the opening when the bearing comes to rest.

Assuming that the mounting is properly aligned, the bearing has a high capacity for carrying radial loads, as such loads are uniformly distributed over two rows of balls. The bearing also has a comparatively high capacity for carrying thrust loads in either direction, the thrust load either way being sustained by one full row of balls. This, of course, assumes that the mounting is properly lined up. If this condition is not fulfilled, a uniform distribution of the load will not be secured, and the bearing will not operate at its maximum efficiency.

SELLEW TWO-SPINDLE AUXILIARY DRILL HEAD

A simple form of auxiliary drill head especially adapted for use in connection with small sized sensitive drilling machines, where a number of holes are drilled in fixed locations, is illustrated herewith. It will be seen that one of the drills is held in a spindle which has a taper shank carried in the spindle of the drilling machine. This taper shank is geared to the second spindle of the drill head. Above the driving gears there is a hub extension, and the head is clamped by a single screw in the yoke block which fits the quill of the drilling machine. Lightness and simplicity are the distinguishing features of this drill head, and its application on a machine effects a considerable increase of capacity on those classes of multiple drilling operations which come within its range. This two-spindle drill head is the latest product of the Sellew Machine Tool Co., Pawtucket, R. I.



Sellew Two-spindle Drill Head

STEVENS TURRET TOOLPOST

Fig. 1 shows a lathe turret toolpost which is made by A. H. Stevens, 138 Thacher St., Hornell, N. Y.; and Fig. 2 shows the toolpost in use on a lathe. It will be seen that it consists of a turret which carries several tools, any one of which can be quickly brought into the operating position. The toolpost is fastened directly to the cross-slide of the lathe and may be quickly put in place or taken off. It is of compact and rigid construction. The turret is only free to revolve in one direction and is positively locked to prevent the thrust of the tool turning it.

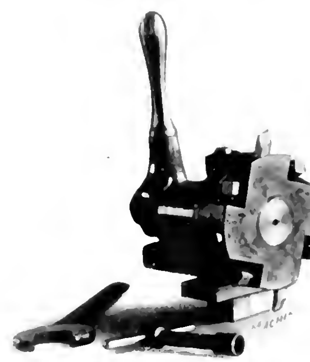


Fig. 1. Stevens Turret Toolpost

Two simple movements of the lever are sufficient to change the position of the turret; moving the lever toward the operator revolves the turret and moving it away from him locks the turret, which is automatically located after being brought to an approximate position. The pin encased in the base is of hardened tool steel and engages a slot in the turret; there is no tendency to spring, as the turret is located

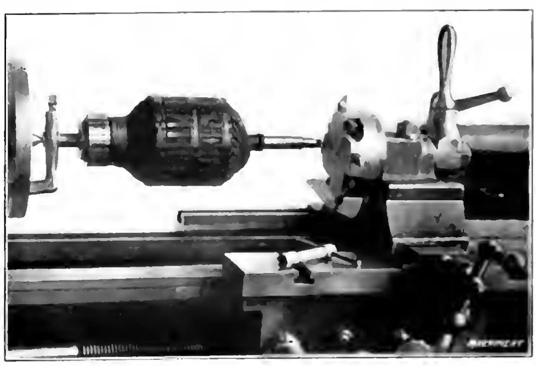

Fig. 2. Stevens Turret Toolpost in Operation on the Lathe

directly over the support. It will be evident to the reader that this toolpost is intended for machining those classes of work where several successive operations are performed, and its use saves a considerable part of the time occupied in changing tools.

GARDNER COMBINATION PATTERNMAKER'S MACHINE

The experience of the Gardner Machine Co., Beloit, Wis., with the disk grinding machines and roll sanding machines of its manufacture, has led to the combination of these two types of machines in a single unit. This is known as the No. 20 combination patternmaker's machine. The machine is

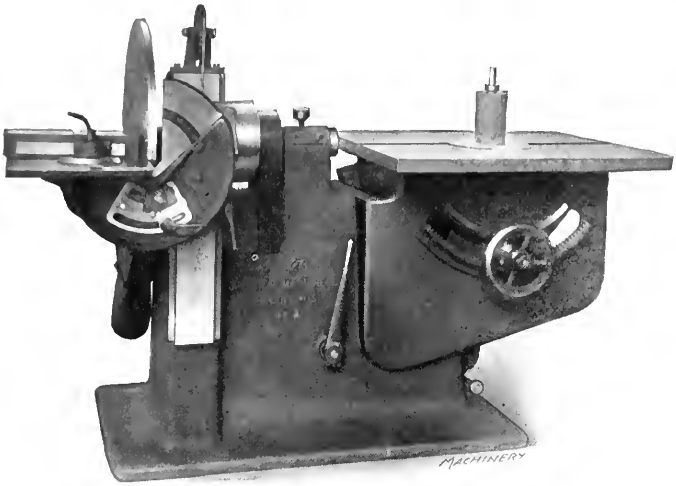

Fig. 1. Gardner Combination Disk Grinder and Roll Sander for Use in the Pattern Shop

shown in Fig. 1 with both the roll sanding spindle and adjustable work table set at right angles. Fig. 2 shows both ends of the machine in operation, and it will be noticed that in this illustration both the roll sanding spindle and the work table are shown set at an angle, in order to illustrate the adjustment which is possible. These adjustments are particularly convenient in many classes of patternmaking work where it is desired to finish surfaces at an angle with each other.

At the disk wheel end, the machine is equipped with a wheel 30 inches in diameter which runs at 950 revolutions per minute. This wheel is faced with "netbac" garnet paper which is attached to the wheel without requiring the use of an arbor press, or the wheel to be removed from the spindle in order to have a new disk applied. A universal work table is provided, which is mounted on a dovetail slide back of the cutting plane of the disk wheel. The table may be raised or lowered and instantly locked in any desired position, the use of a counterweight within the column of the machine enabling the position of the table to be adjusted without undue exertion on the part of the operator. The table is also provided with angular adjustment in relation to the face of the disk wheel, the table being shown at right angles to the wheel in Fig. 1 and set at an angle in Fig. 2. A graduated segment at the end of the table provides for making accurate angular settings, and one turn of the handwheel locks the table in the desired position. The axis about which the table swings is so arranged that the edge remains close to the face of the disk wheel regardless of the position in which the table is set. This is a particularly advantageous feature when working on small size patterns.

There are three work gages provided for use in connection with the table. One of these is a universal angle gage which is particularly serviceable in producing patterns having compound angles and for squaring up patterns. As its name implies, the duplicating gage is used for producing duplicate pieces and for generating parallel surfaces. The circle generating gage is used in connection with the production of round shaped pieces which are usually handled on the lathe. Its use enables external arcs of various radii to be accurately produced.

The sanding roll at the opposite end of the machine is used for generating and finishing internal curves which have been roughed out on a band saw. The piece is finished complete on this machine, which does much of the work usually performed by hand carving or on the lathe, but in a fraction of the time which would be required by either of these methods. Four different diameters of rolls are provided, all of which are 7 inches in length. As the diameters vary from 2 to 6 inches, it is evident that the smaller rolls must be driven faster in order to give a suitable cutting speed. This speed variation is provided for, the range of spindle speeds available being from 2000 to 6000 revolutions per minute. The sanding rolls are made of cast aluminum and accurately balanced. They are covered with a sheet of "netbac" paper which is cut at an angle, so that the joint runs in a complete spiral around the roll instead of being on a straight line. This does away with the vibration which would be caused by having the joint on a straight line. When the "netbac" paper on the roll becomes worn, it is merely necessary to soak the roll in water for a few minutes to soften the cement, after which the abrasive paper is peeled off and a new sheet substituted.

The roll spindle has a vertical reciprocating motion of 1/8 inch for the purpose of avoiding the production of ridges

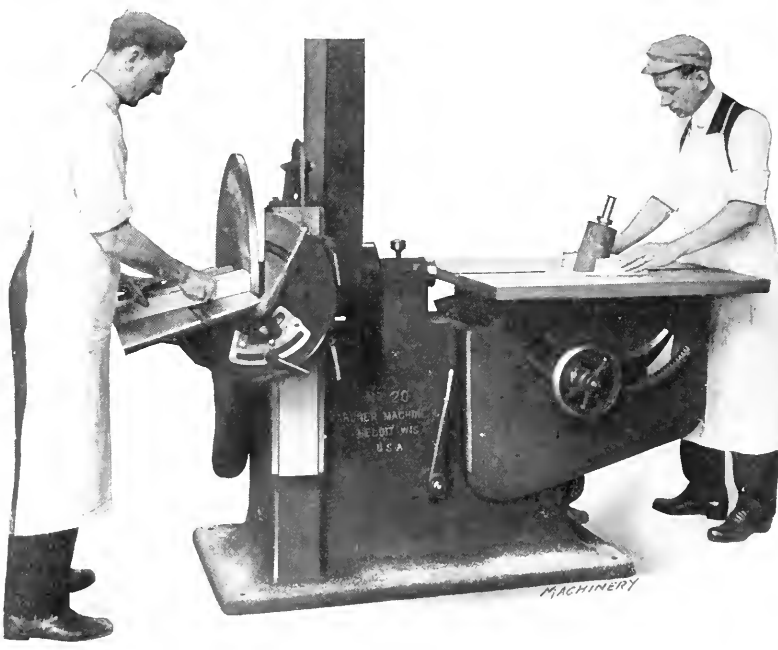

Fig. 2. Machine shown in Fig. 1 with Both Ends in Operation

in the work; this also increases the rapidity with which the roll cuts. The reciprocating motion is provided by having the roll spindle engage with a pivoted fork which works over a cam. The mechanism is positively driven by spiral gears and the entire weight of the spindle and roll is supported on a ball bearing. Another important feature of the roll end of this machine is that angular surfaces can be finished as readily as those which make an angle of 90 degrees with the table. For this purpose, the work spindle is set at the desired angle with the table rather than resorting to the alternative of setting the table at an angle with the roll spindle. The table at the roll end of the machine remains horizontal at all times. The angle to which the roll is set is accurately registered on a graduated segement which is lo-
accurately registered on a graduated segment which is located directly behind the locking handwheel. In shops where floor space is at a premium, this combination of two standard machines into a single unit effects a material saving in the room required for equipment.

If the main spindle which carries the disk wheel is in operation, the sanding roll can be started or stopped as frequently as necessary. The motion of the roll spindle is controlled by a clutch which is operated by a handle at the front of the machine. The disk wheel is provided with an efficient dust hood and the sanding roll throws but little dust into the air. When it is desired to make provision for removing the dust from the roll, the best plan is to suspend an exhaust pipe from the roll with an enlarged opening of suitable size. The driving spindle can be mounted in either babbitt lined bearings or ball bearings as required. The machine shown in the accompanying illustrations is provided with plain bearings. The machine is well adapted for direct connected motor drive and where this method of driving is employed, the motor is mounted on a bracket at the rear and connected to the main driving spindle by a silent chain. A few of the more important dimensions of the machine are as follows: The disk wheel table is 36 by 15 inches in size and the sanding roll table 31½ by 36 inches; the four sanding rolls provided for use on the machine are 2, 3, 4 and 6 inches in diameter by 7 inches in length; the speed variation of the roll spindle is from 2000 to 6000 R. P. M. and the disk spindle operates at 950 R. P. M. The power required to operate the machine at its full capacity is 5 horsepower and the operating space required is approximately 6 by 12 feet. The weight of the machine is about 3000 pounds. The regular equipment furnished with the Gardner No. 20 combination pattern-maker's machine includes a 30-inch disk wheel and four aluminum sanding rolls 2, 3, 4 and 6 inches in diameter by 7 inches high; a supply of "net bac" garnet paper disks and sanding strips; a supply of cement and grease; three work gages; a countershaft; and the necessary wrenches.

NUTTER & BARNES CUTTING-OFF MACHINE

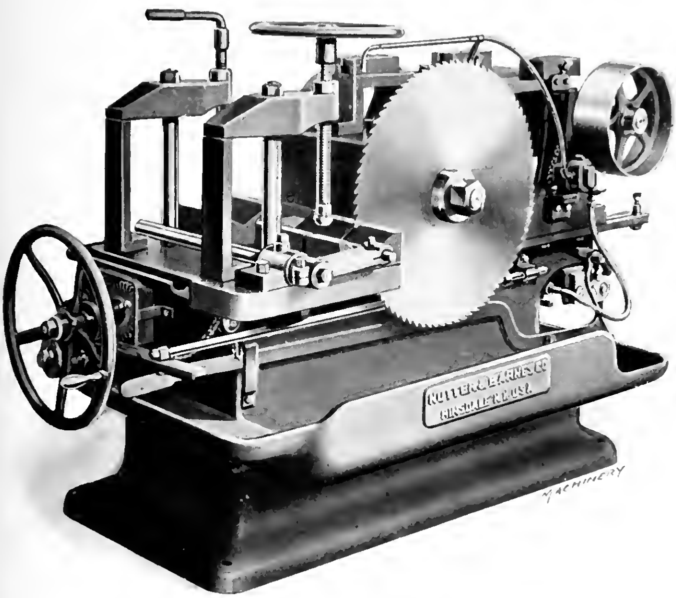

Fig. 1. Nutter & Barnes 10-inch Cutting-off Machine

The 10-inch cutting-off machine illustrated in Fig. 1 is a recent addition to the line of metal cutting saws built by the Nutter & Barnes Co., Hinsdale, N. H. This saw follows the general lines of design adopted in the construction of the other types of machines built by this company. The 10-inch machine differs from the smaller sizes, however, in that the saw carriage is automatically returned after completing the cutting stroke. Other features of this machine not found on the smaller sizes are the increased size of the work table, the double set of screw clamps for securing the work, and the heavier construction of the machine to adapt it for heavier work. Aside from these features, the machine is quite similar to the Nutter & Barnes 8-inch cutting-off machine which was illustrated and described in the December, 1910, number of MACHINERY.

The introduction of fast feeds and speeds in cutting metal has made it necessary to provide easy means for handling the stock to be cut, and for supplying a liberal quantity of lubricant to keep the saw and work cool. The cutting lubricant is stored in a reservoir in the base of the machine and delivered to the saw by a geared pump. An improvement has recently been made by attaching a combination saw guard and lubricator to the end of the piping. One of these combination guards is shown in Fig. 2, from which an idea of the construction will be obtained. The guard affords protection to the operator and also does away with the danger of breaking the saw when material is being placed on the work table. As it is possible to deliver a large volume of cutting lubricant at the exact point where it is most needed, this device is the means of enabling higher speeds and feeds to be employed with a corresponding increase in production. The combined guard and lubricator is quickly adjusted to suit different sizes of saws and can be raised to clear the saw when it is desired to remove it for sharpening. A special throttle is provided for changing the direction of lubricant

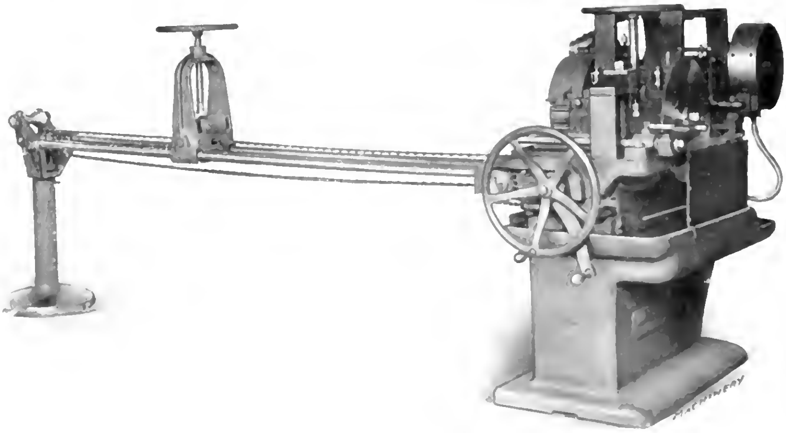

Fig. 2. Combination Guard and Lubricator for Nutter & Barnes Machines

as it is delivered to the cutting point, or for stopping the flow entirely while the machine is running.

In most cases, metal-cutting saws are employed to cut bar stock of various lengths, but the length of the work is usually great enough so that the use of an independent stock rest is necessary. The usual method of feeding the stock requires the operator to leave his machine and push or pull the bar along by hand, after each cut has been completed. Fig. 3 shows a stock feed attachment which has recently been brought out by the Nutter & Barnes Co. to provide for feeding the stock mechanically. This equipment is shown in connection with the 6-inch size cutting-off machine but may be applied to any of the machines built by this company. The device consists of a pedestal support containing an idler roll which supports the weight of the stock at the outer end. Two round bars connect this standard to the base of the machine; and the traveling stock rest or carriage in which the stock is clamped moves along these bars, the movement being controlled by a crank at the front of the machine. This crank is connected to a chain which, in turn, is attached to the stock carriage. The usual length in which this stock feed attachment is furnished is 6 feet, but the length may be easily increased by providing longer or shorter connecting bars and a chain of corresponding length. In operation, the

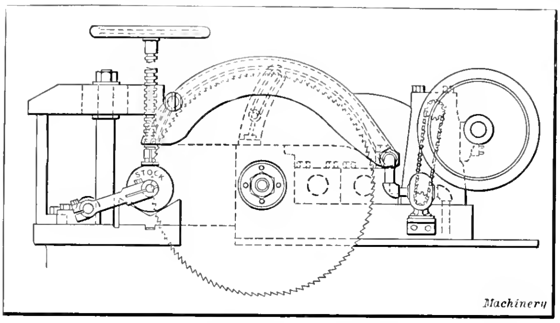

Fig. 3. Nutter & Barnes 6-inch Cutting-off Machine equipped with Stock Feed Attachment

stock clamp on the machine is released and the stock brought forward by turning the crank at the front of the machine, until the end of the bar has been brought into contact with the stock gage, which is set in accordance with the length of the piece that is required to be cut off. The clamp on the machine is again tightened and the saw started. This sequence of operations is repeated until the traveling clamp has reached the full length of its traverse, after which the clamp is released and moved back to the starting position at the opposite end of the connecting bars.

BECKER MILLING CUTTER

A high-power inserted tooth milling cutter which has recently been placed on the market by the Becker Milling Machine Co., Hyde Park, Mass., is shown in Fig. 1; and Fig. 2 presents details of the construction of this tool. The most important feature is the solid backrest for the cutter teeth, inserts being provided in the cutter body, against which the teeth have a solid bearing, as shown in the cross-sectional view *A–A*. The inserts which back up the teeth are prevented from moving in or out by means of screws, one of which is shown in the cross-section *B–B*. The section *C–C* shows one of the adjusting screws. These screws have 5/8 inch adjustment and provide for taking up wear on the cutter teeth as

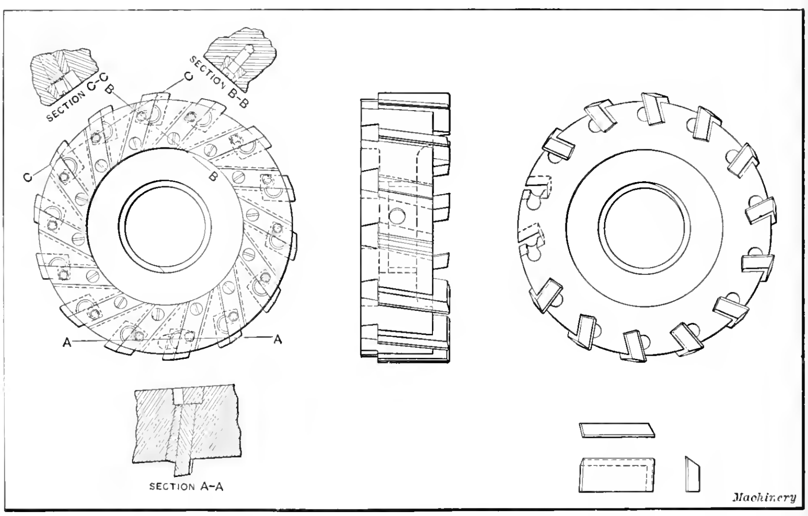

Fig. 2. Assembly and Cross-sectional Views of Becker Inserted-tooth Milling Cutter showing Construction

Fig. 1. Opposite Sides of the Becker Inserted-tooth Milling Cutter

they become smaller through repeated grinding. The teeth are held in the body by means of hardened tool steel pins.

The body of the cutter is made of nickel steel and the blades of "Novo Superior" steel. In assembling the cutter, it is important to observe that the blades must not drive so tight that the adjusting screws will not work them. The teeth are set back of the center line at an angle of 15 degrees and a rake of 10 degrees. In a recent test conducted with one of these cutters on a Becker high-power milling machine, the cutter was run at a peripheral speed of 115 feet per minute with a feed of 3/8 inch per revolution. Operating under these conditions, cast iron with 20 per cent steel was removed at the rate of 52 cubic inches per minute and the cutter showed no sign of chatter or vibration.

NORTON GRINDING WHEEL STAND

This machine is the result of the experience of the Norton Co., Worcester, Mass., in the use of grinding wheels on many types of floor stands; and the designers have endeavored to incorporate into it every feature that will help to obtain greater production, and to give longer life to the grinding wheels and the machine itself. While it is not a radical departure from the machines now common in the better equipped shops, it is evident that its designers have given careful attention to such features as rigidity, safety, convenience of operation, and means of lubrication and dust removal. Particular attention has also been paid to the general appearance of the machine as indicated by its freedom from sharp corners, recesses and uncovered bolts. While the foundation space occupied by the machine is small, its weight and rigidity permit of a very desirable overhang of the bearing-bed. This feature allows ample foot-room for the operator. Each bearing is divided into two parts and the large bearing surfaces help to insure long life. The diameter of the spindle in the bearings is made 1/16 inch

oversize, allowing sufficient stock for regrinding when this becomes necessary. The portion of the spindle outside the bearings is made sufficiently long to take taper wheels of $\frac{1}{2}$ or $\frac{3}{4}$ inch taper per foot, which have the same width of face as the maximum width of straight wheels. End play on the spindle is easily taken up. The inside flanges are fitted loose on the spindle and driven by a key, making their removal a simple matter. Taper flanges of any make may be used on these machines, if the hole is the right size, by cutting a spline in the hole of the inside flange to fit the square key in the spindle.

Oiling is accomplished by the splash system, insuring positive lubrication. The oil reservoir, which is located under and between the two parts of the bearing, holds a supply of oil sufficient for several months. The design allows ample space for the oil to drain back into the reservoir and be used over and over again. All lubricant can be easily and quickly removed from the reservoirs which are readily accessible for cleaning. Dustproof covers protect the bearings and oil chambers and an oil guard inside the bearing-chamber prevents the oil thrown up by the splasher from working out through the joints of the bearing-bed and bearing-cover. The under side of the overhanging bearing-bed is provided with a machined seat and T-slots; and the work-rest brackets, protection hoods and surface grinding attachments are secured by bolts placed in those T-slots, in which they may be attached or removed very quickly. All attachments

Fig. 1. The Norton Model D Grinding Wheel Stand

are independent and interchangeable. Whenever it is desired to grind large work that requires the removal of the work-rest, the work-rest bracket can also be removed. This permits the grinding of large pieces without interference of projecting brackets, even if the wheel in use is of minimum diameter. The top surface of the work-rest is chilled, insuring long life; and is of ample size to give adequate support for large and heavy work.

A substantial belt guard, which permits any belt angle from vertical to 45 degrees, extends two inches above the top line of the maximum size of wheels. This, besides affording protection to the operator, serves to protect the belt when long pieces are ground on the surface grinding attachment. A protection- and dust-hood, designed especially for the Model D floor stand shown in Fig. 1, is for the purpose of providing protection against injury in case of accident to the wheel; and also, when the hood is connected with some suitable dust removal system, against injury to health from inhalation of dust. The bracket which supports the hood serves also as a dust exhaust pipe. The closed hood consists essentially of a heavy band of boiler plate and two heads or side plates. The hood surrounds about five-sixths of the wheel, leaving a 60-degree opening, and a heavy steel slide provides adjustment for wheel wear. The slide travels in grooves, describing an arc around a center other than the spindle center so that, irrespective of the size of a wheel, 60 degrees of the periphery of the wheel is exposed for grinding purposes and protection is always afforded. This type of hood covers the end of the spindle, thus preventing accidents due to clothing becoming caught on the nut on the spindle. Through the employment of a special lock-nut the outer head or side plate is easily removed to permit making a change of wheels.

In addition to the Model D type of hood, the Norton Co. is also placing on the market a Model E hood which is designed along the lines of the former and adaptable to any make of floor stand conforming to the general contour of the Norton stands. In applying this hood, it is simply necessary to provide a suitable bracket to which may be attached the

Fig. 2. Protection- and Dust-hood of the Norton Model D Grinding Wheel Stand, shown Closed and Open

inner head, which, in turn, holds the entire structure. This hood is so designed that it is adjustable about the wheel, permitting the grinding to be done on top, at the front or at the bottom of the wheel. Instead of having the bracket by means of which the hood is fastened to the wheel, serve the additional purpose of a dust exhaust pipe, the inner head of the hood is solid and the exhaust pipe is located on the boiler-plate band. The exhaust pipe is mounted on a steel plate of the same radius as the band and is firmly bolted to the latter. Model E hoods are furnished with a full size band and the exhaust connection is not attached. The user can readily cut the opening at any desired point and attach the exhaust connection after the hood is located on the machine.

These machines are made in four standard sizes with spindles $1\frac{1}{4}$, $1\frac{1}{2}$, $1\frac{3}{4}$ and 2 inches in diameter, and a special machine can be built to order with a spindle $2\frac{1}{2}$ inches in diameter. The principal dimensions of the machine with a 2-inch spindle are as follows: Distance between wheels, 62 inches; height of spindle above the floor, $30\frac{1}{2}$ inches; length

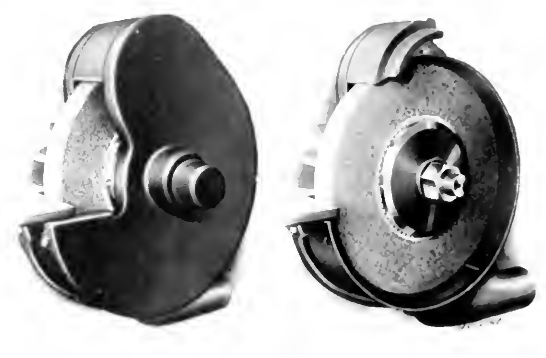

Fig. 3. Protection- and Dust-hood of the Norton Model E Grinding Wheel Stand shown Closed and Open

of bearings, $16\frac{1}{2}$ inches; diameter of spindle bearings, $2\frac{3}{16}$ inches; diameter of safety flanges, 12 inches; size of cone pulley steps, $9\frac{1}{4}$, $8\frac{9}{16}$ and $5\frac{3}{4}$ inches; foundation space required 27 by 42 inches; floor space occupied by machine, 27 by $88\frac{1}{4}$ inches; size of wheels used, 24 inches in diameter by 4 inches face width; net weight of machine and hoods, 1765 pounds.

FITCHBURG GRINDING MACHINES

The Fitchburg Grinder Co., Fitchburg, Mass., is the manufacturer of the 6 by 15 inch plain grinding machines shown

in the accompanying illustrations. Fig. 1 shows the front view of the style A machine and Fig. 5 shows the front view of the style B machine. Referring to these illustrations, it will be seen that a large pilot wheel has been substituted on the style B machine in place of the power table traverse employed on the style A grinder. By omitting the transverse gear box and automatic feed, it has been possible to build an efficient machine at a comparatively low price, for grinding short cylindrical pieces in large quantities. In other respects, the styles A and B machines are quite similar and the detailed description which follows is applicable to either type.

These machines are essentially manufacturing grinders for producing either straight or taper cylindrical work in quantities. The wheels used are 16 inches in diameter and 2 or 3 inches face width. The work may be supported on either dead or live centers. It has already been stated that the style A machine is fitted with power table traverse and work change gear boxes, each of which is independent of the other and provides suitable speeds and feeds for various classes of work which come within the range of this machine. A single lever provides for starting or stopping

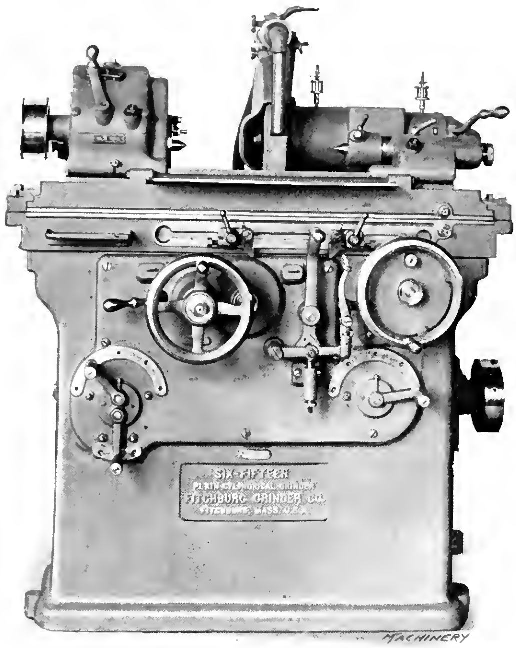

Fig. 1. Front View of Fitchburg Style A Plain Grinding Machine

the table travel at any point in its stroke and for simultaneously engaging or disengaging the traverse handwheel. The style A machine also has automatic cross feed and positive stops for use in the production of duplicate work. All shaft bearings in the machine are ground and fitted with removable bushings, and many of the bearings are self oiled.

The base of the machine is of massive proportions and internally braced to give the required rigidity. It is of compact design and the units are so located as to be easily accessible. Any unit may be removed from the machine without requiring the other units to be disturbed. Wide bearing surfaces of the V- and flat type are provided. An oil reservoir for automatically oiling the ways is located in the bed. A pan of liberal proportions is provided at the back of the machine to catch the water. The wheel spindle is made from a special alloy steel, and after hardening, is ground and lapped to the required size. Bearings are bushed with phosphor-bronze, and large self-feeding lubricators are provided to insure having a liberal supply of oil delivered to the boxes.

The wheel head is of massive proportions, and slides on long flat- and V-ways. It is held in place by gravity and is provided with a safety gib to guard against danger of lifting

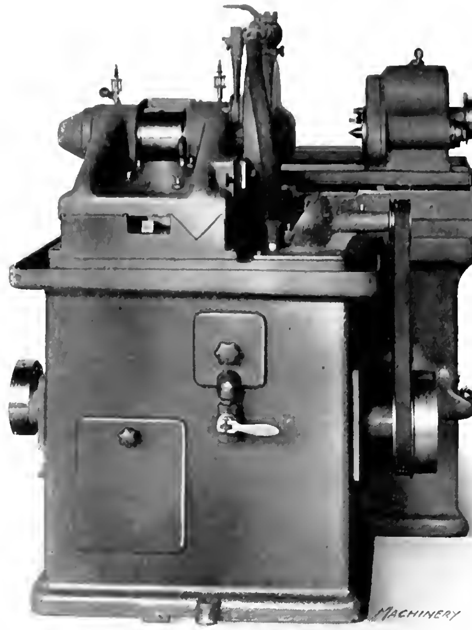

Fig. 2. Opposite Side of Machine shown in Fig. 1

under normal conditions. The table slide is unusually heavy and is powerfully ribbed to resist torsional strains. The swivel table has a liberal bearing on the table slide and pivots on a large central stud. This table provides for grinding tapers; it is graduated to read in degrees and tapers expressed in inches per foot.

The headstock slides on the ways of the table and is clamped in position by a hook bolt. It is of the geared type, the spindle being ground and fitted in removable bronze bushings which may be replaced when worn. The moving parts are lubricated by the splash system. The spindle is hardened and finished by grinding and lapping; it may be revolved for grinding parts which require a live spindle. The work is started and stopped by a lever mounted on the headstock. The footstock is secured to and preserves its alignment on the swivel table in the same manner as the head-

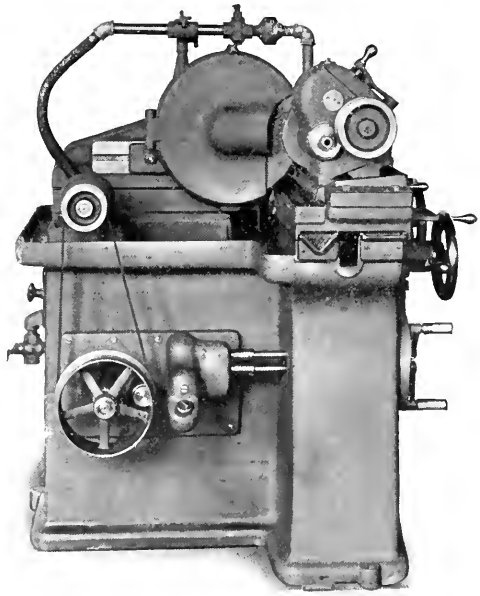

Fig. 3. End View of Fitchburg Style A Plain Grinding Machine

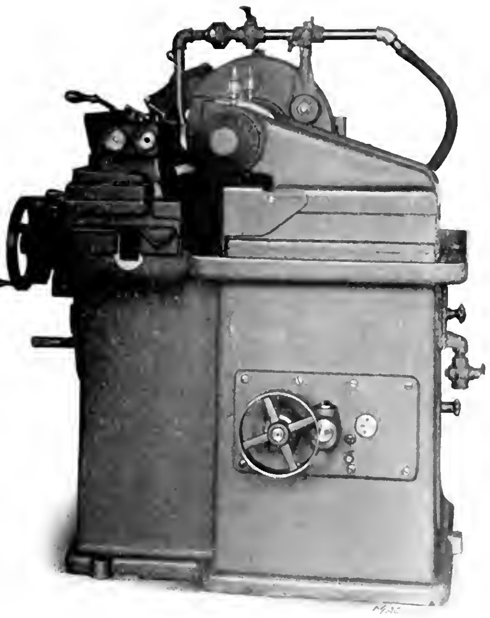

Fig. 4. Opposite End of Machine shown in Fig. 3

stock. The wheel side of the footstock base and the spindle are flattened, which reduces the movement of the wheel slide when truing the wheel. The diamond point for this purpose is mounted on the footstock spindle which may be rigidly clamped for supporting the center to the work.

The universal back-rests provided on this machine have both vertical and horizontal movement and very delicate adjustments can be made. The pump is of the fan type and revolves in a horizontal plane; it is kept immersed so that it is constantly primed and no packing is required. The water tank is of ample size and provided with settling pans which are easily accessible for cleaning. The self-contained countershaft provides three changes of speed for the grinding wheel and all rotating members run on Hyatt roller bearings. All overhead belt changes are operated from the front of the machine. The equipment of the grinder includes self-contained overhead works, a universal back-rest, a center grinding attachment, water guards, dogs, two grinding wheels and the necessary wrenches.

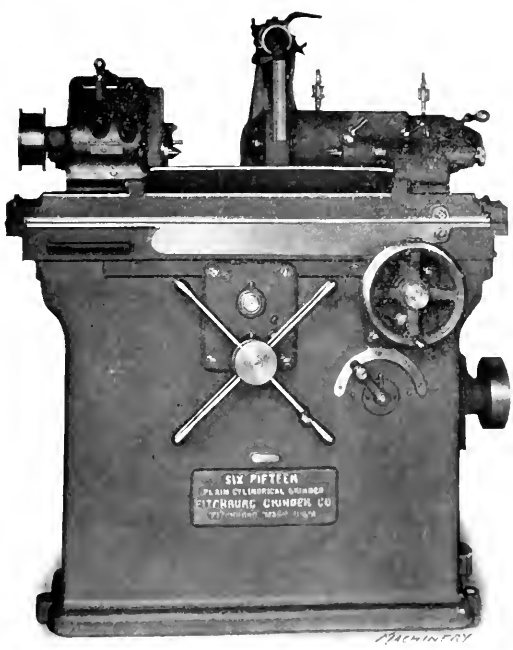

Fig. 5. Front View of Fitchburg Style B Plain Grinding Machine

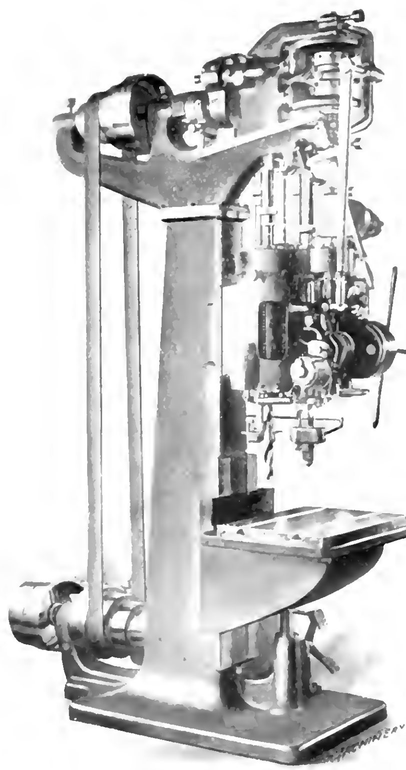
The principal dimensions of the style A machine are as follows: Swing over table, 6 inches; distance between centers, 15 inches; swivel table graduated to an angle of 13 degrees or to a taper of 5 inches per foot; number of work speeds, 10; range of work speeds, 30 to 345 R. P. M.; number of traverse table feeds, 10; range of traverse table feeds, 10 inches to 92 inches; number of grinding wheel speeds, 3. The power developed by the motor which drives the machine is 7 horsepower. The floor space occupied is 52 by 66 inches; and the net weight of the machine, 3600 pounds. Similar dimensions apply to the style B machine except that there are no power movements for the table, and the net weight of the machine is 3350 pounds.

TURNER AUTOMATIC TURRET DRILL

With the view of increasing production by having a series of tools available for performing successive operations on a piece of work without requiring it to be reset or the tools to be changed, the Turner Machine Co., Danbury, Conn., has brought out the Model F turret drill which is illustrated herewith. This machine is of heavier construction than the other types of turret drills built by this company, the present machine being intended for relatively heavy work. It frequently happens, however, that some small holes have to be machined in a piece in which it also is required to drill relatively large holes, and to enable these small holes to be drilled efficiently, the use of drill speeders is recommended. Each spindle in the turret carries a different tool which is successively and automatically registered in exactly the same position. The mechanism by which this automatic indexing is obtained is not complicated and the machine can be operated rapidly by an average workman and produce work of extreme accuracy. The accompanying illustration will give the reader an idea of the design.



Turner Model F Heavy-duty Turret Drilling Machine

The column and base are cast integral, the column being of rectangular section and tapering from 8 by 15 inches at the base to 5 by 11 inches at the top; it is internally ribbed and cross braced to provide the required rigidity. It will be seen that the turret is vertical; it rotates automatically and when the operator returns the spindle to its full height, the turret indexes to bring the next spindle into the operating position. The detents are adjustable for both wear and accuracy. They are made of a special chrome-vanadium steel which has a compressive strength exceeding 400,000 pounds per square inch when heat-treated according to the method used by this company. As the detents are located further from the center of the turret than the working tools or spindles, a high degree of accuracy is obtained. The spindles are of heat-treated nickel steel, the elastic limit of which is in excess of 90,000 pounds per square inch; the spindles are completely finished by grinding. The spindle driving gears are made of heat-treated chrome-nickel steel, and Feichtel & Sachs ball thrust bearings are mounted under the spindle gears on the top of the turret and also at the bottom of the spindle in order to support the thrust of the tools and increase the smoothness of drive.

The feed mechanism is driven from the vertical shaft which drives the spindle and the feed may be engaged or disengaged without stopping the machine. An automatic trip is provided to throw out the feed at any predetermined point in the spindle travel. The feed gears are enclosed in a dust-proof case and provide four changes of feed, the drive being direct on the coarser feeds. The feed gears, in connection with the two spindle speeds, provide a range of eight changes for the machine. The feed is actuated by helical gears which operate very smoothly. The feed gears are only running when the feed is in operation. Three sets of helical gears are used in the feed mechanism; the first two sets run at higher speeds and lower pressure than the final set. The thrust of the first two sets of gears is taken by a system of multiple washers and the thrust of the final set is carried by a ball thrust bearing. One gear of each pair is of chrome-nickel steel and the other is of a special grade of hard bronze.

The spindles may be fed by either hand or power. For the hand feed, either a handwheel or lever is used, the former being more sensitive and better adapted for profiling and other milling operations. The inactive spindles are positively locked in their extreme upper position and as each spindle is automatically swung into the working position, the positive lock is released. The spindle projects approximately 1½ inch under the sleeve and a ball thrust bearing is interposed between the nose of the spindle and the end of the sleeve. The bearing is packed with grease and surrounded by a dust-proof brass collar. The sleeve is 12 11/16 inches in length and the spindle has a 4-inch bearing within the sleeve at each end, with an oil chamber at the center. The upper end of the spindle is guided in the turret. This method of supporting the spindles close to the nose—together with the long bearings placed far apart—gives exceptionally rigid support.

A feature which makes the machine suitable for driving small and delicate tools, such as drills and taps, is that each tool has its own individual feed, which may be operated by hand if desired. This offsets the weight of the machine, which would otherwise be poorly adapted for driving delicate tools. It is not feasible to provide in a single machine the extreme range of speeds and feeds which are necessary for driving tools of widely divergent sizes. For example, a machine powerful enough to drive drills from 1 to 2 inches in diameter could scarcely be made suitable for driving small sized drills. Yet it is often desirable to have such operations follow each other on the same piece of work. As previously mentioned, the Turner turret drill is adapted for work of this character by using drill speeders to drive the smaller sized tools.

The back gears are operated by a friction clutch and may be rocked out of engagement when not in use, in the same way that the back gears of a lathe are disengaged. The gears which operate the reverse mechanism for tapping and threading operations, back out the tap or die at 1.6 times the forward speed. The tapping gears may be disengaged by means of an intermediate gear and friction clutch when the tapping mechanism is not required. Both the back gears and the tapping gears may be engaged or disengaged without requiring the machine to be stopped. The control levers for all members of the machine are within easy reach of the operator. All shaft bearings are bronze bushed so that they may be easily renewed when necessary. Wherever it is possible, lubrication is provided by grease cups. The table is adequately ribbed and has a working surface 18 by 23 inches in size. The oil groove is of ample proportions to prevent lubricant from overflowing, the lubricant being supplied by a gear-driven pump and delivered through a flexible supply pipe. The table is supported from the knee, on which it has a three-point bearing. In changing the machine over from one job to another, it is merely necessary to change the tools for the successive operations to be performed, and to locate the jig or fixture that is to be used on the table. Each tool is automatically brought to the same center until the sequence of operations has been completed.

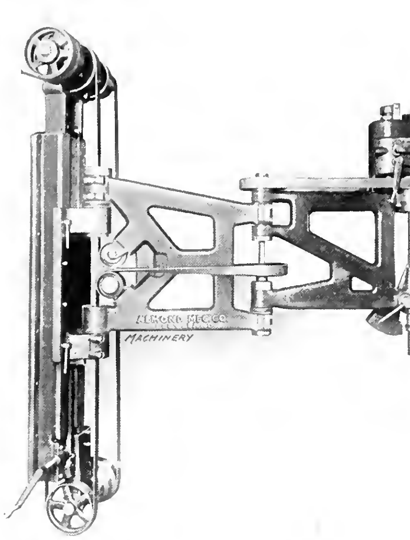


Fig. 1. Almond Post Type Radial Drill with Arm extended

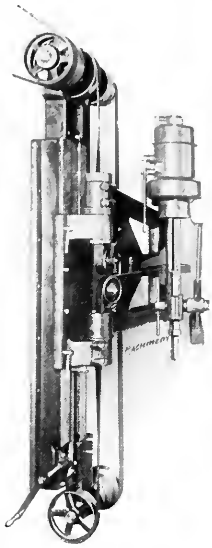

Fig. 2. Machine shown in Fig. 1 with Arm Closed

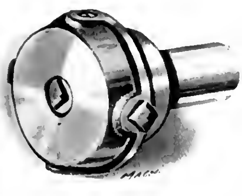
ALMOND POST TYPE RADIAL DRILL

A post type radial drill designed to be fastened to either a column or wall, and used for light drilling and tapping operations, is illustrated in Figs. 1 and 2. This machine has a drilling radius of 4 feet and will handle twist drills up to ⅞ inch and standard taps up to ¾ inch in diameter. The machine is entirely self-contained and may be driven direct from the lineshaft or by an individual constant-speed motor. Six changes of spindle speed are provided, these speeds being in geometrical progression and ranging from 175 to 1000 revolutions per minute. The machine is equipped with ball bearings throughout so that it is well suited for operation at high speed. The saddle that carries the swinging arm has a vertical adjustment of 2 feet, an elevating screw with the thrust supported by a ball bearing being provided for this purpose. The main driving belt passes through the trunnions on which the main frame swings, so that the belt tension and alignment are not affected by the swinging of the arms or by the vertical adjustment. Provision is made on the machine for maintaining the tension of the driving belts at the required point. The weight of the swinging frame is supported by ball thrust collars and provision is made for taking up any wear which may develop at the trunnions.

The geared tapping attachment is one of the features of this machine. When the spindle is run on either of the three open belt speeds which are obtained by the three steps on the cone pulley, the reversing gears are not running, these gears being automatically locked out of engagement when the machine is operating under these conditions. When the tapping attachment is thrown into operation, the spindle speed is reduced to 1/3 of the open belt speed and a quick reverse of approximately 2 to 1 is available. Owing to the fact that the belt speed is not reduced, this arrangement gives ample power as well as the proper speeds for large drilling, reaming, counterboring and stud set operations, in addition to tapping. The change from the drilling speed to the tapping speed is made while the machine is running by means of the operating levers shown on the side of the head. The hand feed lever has a ratchet adjustment and a counterweight is attached to it. This counterweight supports the weight of the spindle and tool, and provides for returning the lever into a convenient position for the operator. This machine is manufactured by the Almond Mfg. Co., Cleveland, Ohio.

SMILLIE TURRET LATHE DRILL CHUCK

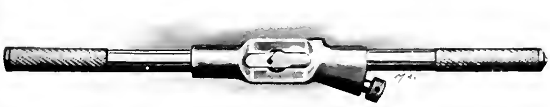
C. M. Smillie, 130 E. Larned St., Detroit, Mich., is the manufacturer of the turret lathe drill chuck illustrated herewith. This chuck is not self-centering. It is provided with means for setting the tool either way from the chuck center in order to line the tool up properly with the machine spindle. This adjustment is made by two cap-screws which move the jaws in a transverse slot in the body of the chuck. The chuck is set in the turret with the jaw slot either horizontal, vertical or at an angle, with the line of travel of the jaws crossing the axis of the machine spindle. The adjusting screws are then regulated to bring the tool into exactly the required alignment. If it is necessary to remove the tool for grinding, this is done by simply loosening one screw and after grinding the tool, replacing it in the chuck and tightening the screw up again. Where this method is followed, the alignment is not disturbed. The chuck can be quickly set up on the machine and it is of simple and substantial design so that ample wear is assured. The tool is made in three sizes which have respective capacities for drills from No. 42 to ½ inch, from ¼ inch to ¾ inch and from ½ to 1 inch in diameter.



Smillie Turret Lathe Drill Chuck

F. E. WELLS TAP WRENCH

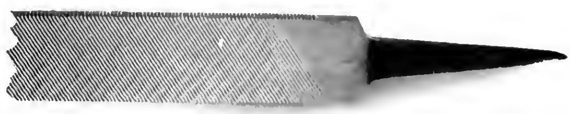
An adjustable tap wrench of simple design, which is a recent product of F. E. Wells & Son Co., Greenfield, Mass., is illustrated herewith. This wrench consists of four essential parts in addition to two connecting pins, and there is practically nothing to get out of order. The centers are drop-forged and the handles and jaws are in one piece. An independent screw is provided for tightening the movable jaw on the tap shank, the arrangement being such that the jaw cannot work loose. The jaws are milled flat to give the best possible grip on the shank; they are made of carbon steel, hardened and tempered. It will be seen that the center has a mottled or "gun metal" finish and that the handles are knurled to prevent the hands from slipping when they are covered with oil. This tap wrench is made in eight sizes and the range of the complete set is from 1/16 to 1½ inch.



F. E. Wells Tap Wrench of Simple Construction

AMERICAN SWISS FILE & TOOL CO.'S "WAVECUT" FILE

The American Swiss File & Tool Co., 24 John St., New York City, has added to its line a file known as the "wavecut." The cut consists of diagonal rows of cutting edges which give the file its wavy appearance, hence the name "wavecut." This new file removes metal in curly shavings rather than the granular filings produced by ordinary files. The new file operates at a high efficiency, and it is durable and of excellent appearance. Tests which have been made show that the "wavecut" file is equally serviceable in filing silver, brass, copper, nickel, cast iron and steel. At present, these files are only being made in the hand shape, and in 8-, 10-, 12- and 14-inch sizes, each size being made in coarse, medium and fine cuts.

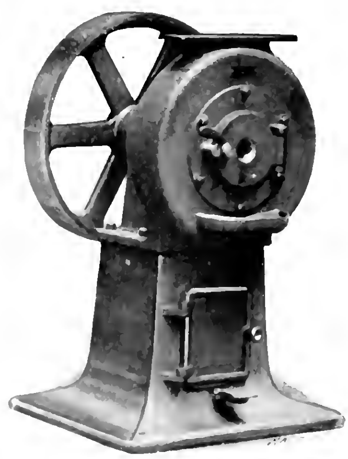


American Swiss File & Tool Co.'s New "Wavecut" File

Heretofore, the American Swiss File & Tool Co. has not made files exceeding 12 inches in length, but in response to an insistent demand, 14-inch files have been added and files of this size are now carried in stock. These files are made in the hand, round, square and mill shapes and three different cuts.

WATERBURY-FARREL SWAGING MACHINE

The demand for machines for pointing, reducing and shaping round stock and tubing by the cold process has led the Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., to build a line of standard rotary swaging machines which are made in several different sizes with capacities from ¼ to 1½ inch in diameter. These machines are largely used in rod and tube mills for pointing material preparatory to drawing it through dies on a "bull block," and they are extensively used in the manufacture of various staple articles in the metal trade such as hose nozzle, tapered shells and screw and bolt work.



Waterbury-Farrel Swaging Machine for reducing Round Bar Stock or Tubing

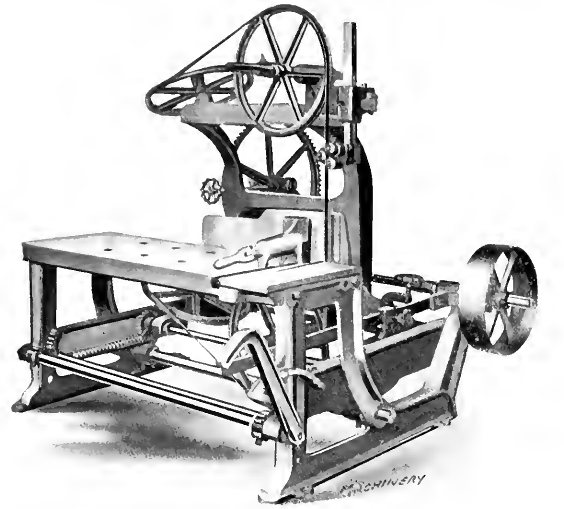
These swaging machines are extensively used by jewelry manufacturers for reducing a bar or ingot of pure or plated metal to a small size, which is suitable for drawing on individual blocks or continuous wire-drawing machines. They are of very simple construction and built exceptionally strong to enable them to stand up under various severe service conditions.

The design has been worked out in such a way that the dies and working parts of the mechanism are readily accessible. In the operation of this machine, a series of very rapid impressions is made in the rod or tube by a pair of die blocks which have a concentric or rotary motion around the work, thus effectually eliminating the possibility of developing a fin or burr.

SHINN METAL CUTTING BAND SAW

M. E. Shinn & Co., 1846 W. Lake St., Chicago, Ill., are now building the vertical, gravity-feed band saw which forms the subject of this article. This machine is designed for cutting metal into various lengths and at any required angle. It will be evident from the illustration that the design of the machine is such that there is nothing to interfere with the bar to be cut, no matter what its length may be. An easily adjusted swiveling table back, and a vise which operates in a groove on the table, enables the material to be cut at any angle, and to be rigidly held during the cutting operation. By loosening a single cap-screw, the saw may be adjusted to provide for ripping sheet metal lengthwise.

An important feature of this machine is the way in which the non-cutting part of the saw is returned, by passing over



Shinn Metal Cutting Band Saw equipped with Gravity Feed

idler wheels in such a way as to obviate the possibility of its interfering with the material that is being cut, and at the same time leaving the cutting edge of the saw perfectly vertical and free from twist. This arrangement enables the saw to run straight in the line of cut and insures accuracy and long life to the saw blade. The frame supporting the band saw wheels is mounted upon four ball bearing wheels, and provision is made for holding the frame in accurate alignment. The inclination of the track-way on which the wheels supporting the saw frame run is altered by means of the operating lever shown at the front of the machine at the right-hand end, the feed being regulated by setting the track-ways at an angle in this way. The cutting part of the saw maintains a vertical position during the entire length of cut and the gravity feed is constant although it can be increased or decreased by the lever referred to.

The action of the machine is entirely automatic and after the cut is completed, the saw is stopped by means of a dog operating a clutch attached to the driving pulley. This machine has a capacity for cutting metal up to 12 by 11 inches in size and leaves a smooth finished surface. The floor space occupied is 45 by 45 inches. The band saw used is 15 feet 6 inches long by ⅝ inch wide by 0.0312 inch thick. An idea of the capacity may be gained from the fact that the machine will cut a 2½-inch cold-rolled shaft in 3 minutes.

K. & E. SLIDE RULE INDICATOR

It frequently happens that after setting the indicator or "runner" on the Mannheim or duplex type of slide rules made by the Keuffel & Esser Co., Hoboken, N. J., it is impossible to read the result because certain important figures are hidden by the frame which holds the glass. Several figures are often obscured in this way, causing some inconvenience to the user of the rule. With the view of overcoming this difficulty, the frameless indicator shown in the accompanying illustration has been designed and patented by this company. It will be evident from the illustration that there is nothing to cover the scales on the rule, so that every figure is always visible. This improvement greatly increases the ease and rapidity with which a slide rule can be used and will doubtless be appreciated by the many engineers, draftsmen and others who have occasion to use these useful instruments in making rapid calculations. Hereafter, the K. & E. adjustable slide rules of the Mannheim and duplex types will be equipped with frameless indicators.

AMES BENCH FILING MACHINE

The Ames bench filing machine designed particularly for work on which it is desired to file surfaces perfectly straight and true to any required angle is shown in Fig. 1. This machine is adapted for filing dies, jigs, templets and for similar classes of service. The height from the bench to the table of the machine is 18 inches and the table is 9 inches in diameter. The length of stroke may be adjusted from 2 to 5 inches to meet the requirements of various classes of work. It will be seen that the machine is driven by a three-step cone pulley, and an idea of its size will be gained from the fact that the machine and countershaft weigh about 145 pounds.

This filing machine will not take regular stock files. Special parallel files are used which are supported at both ends, as in the case of a jig saw. These special files are 8 inches in length and are used in much the same way as a hack-saw blade; either saws or files can be used in the machine and accurate work is produced in both cases. The machine is particularly adapted for die work; and the dies are taken from the machine with straight, true surfaces of known clearance. This machine is a recent product of the B. C. Ames Co., Waltham, Mass.

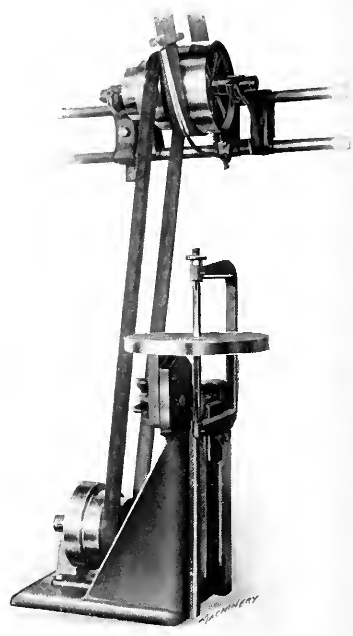


Fig. 1. B. C. Ames Bench Filing Machine

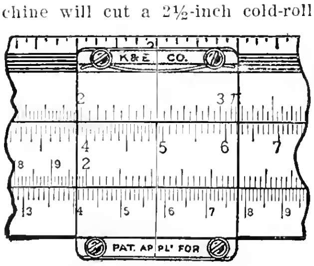

Frameless Indicator for K. & E. Slide Rules

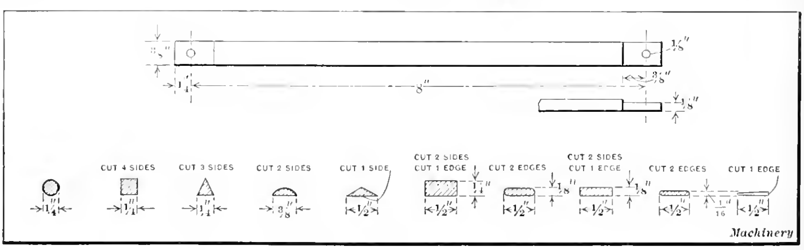

Fig. 2. Examples of Special Files for Machine shown in Fig. 1

EAMES ARBOR PRESSES

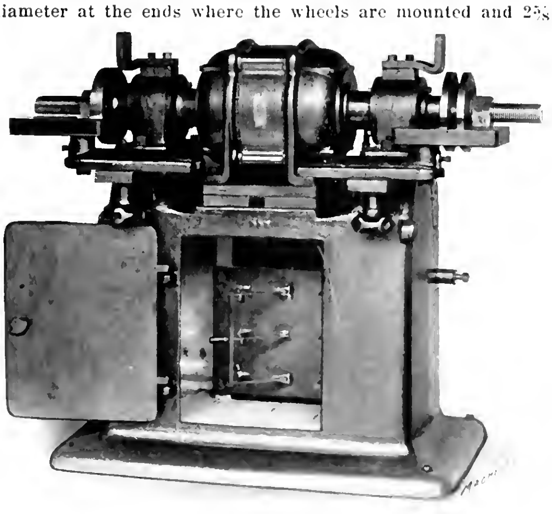
The G. T. Eames Co., Kalamazoo, Mich., has added to its line of arbor presses three small sizes known as the Nos. 0, 1 and 1½. These small machines were developed to meet the demand of shops where the work requires no great amount of power. The Nos. 0 and 1 machines are built with the ordinary vise type of handle, while the No. 1½ machine has a ratchet attachment so that the lever may be used in

Eames Nos. 0 and 1½ Arbor Presses

the most convenient position. The design and construction of these tools is in accordance with the most modern practice and is such as to enable them to stand up under hard service conditions.

RANSOM BALL BEARING GRINDER

The accompanying illustration shows a motor-driven dry grinding machine built by the Ransom Mfg. Co., Oshkosh, Wis. The motor is 5 horsepower and runs at 900 revolutions per minute; it is intended for use on a 60-cycle, 3-phase circuit. The motor is bolted to the main frame of the machine and is usually of the open type, although it can be enclosed if so desired. The rotor spindle is 2 inches in diameter at the ends where the wheels are mounted and 2⅝



Ransom Ball Bearing Motor-driven Grinder

inches in diameter between the bearings. It is made of high-carbon steel and supported on either side of the motor by S. K. F. ball bearings of the double row, self-aligning type. The ball races are exceptionally heavy. The grinder is equipped with two abrasive wheels 24 inches in diameter by 4 inches face width.

With the view of testing the durability of the bearings, one of these machines was recently kept in constant operation on heavy foundry grinding for a period of five months. Two operators were employed to have the machine running under full load at all times. At the end of this test a careful examination failed to show any appreciable wear in the bearings. The wheels are covered by steel guards provided with exhaust pipe connections. The guards have been removed from the machine shown in the illustration in order to illustrate the bearings to better advantage, but the supporting points for the guards are shown. Although the ball bearings cost more than babbitted bearings, they are the means of reducing friction and maintenance costs, preventing the rotor from hitting the starter due to play which may develop in plain bearings, and the ball bearings are easily replaced should they become worn. As previously mentioned, the machine shown in the illustration is equipped with wheels 24 inches in diameter by 4 inches face width, but grinders of this type are built in sizes for wheels from 16 inches in diameter up. They are made in both the belt- and motor-driven types.

ROCHESTER CASEHARDENING FURNACE

The Rochester Casehardening Co., Rochester, N. Y., has recently brought out the oil-fired furnace shown in Fig. 1, which was designed by G. L. Schuetz, the manager of this company. While the furnace can be supplied in several different sizes, the one in the illustration has a firebox 12 inches high by 24 inches wide by 48 inches long. For convenience

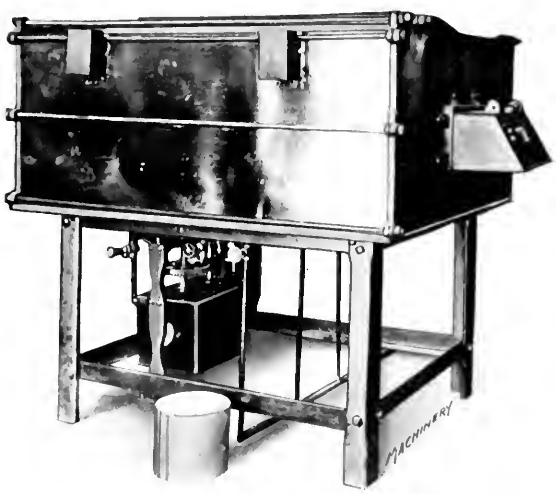


Fig. 1. Rochester Casehardening Furnace

in loading the furnace a door is placed at the rear end in addition to the one that is shown at the front.

This furnace is of the over-fired oil burning type, although it can also be equipped to burn gas. The oil burners are two in number and are located at opposite sides of the furnace near the top. The roof of the furnace is arched and the final combustion takes place in the upper part of the chamber, close to the roof. There is no vent in the roof of the furnace, it being claimed that the combustion is so complete that no objectionable products are given off. It is also said that because there is no vent, the opening of the furnace door does not create a draft.

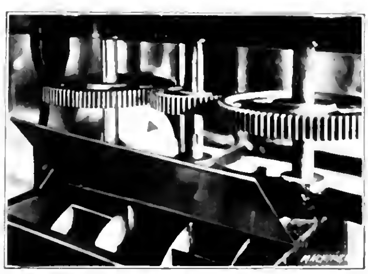

Fig. 2. Mechanism for revolving the Sections of the Furnace Floor

This furnace is fitted with revolving sections in the floor of the firebox so that work requiring very particular treat-

ment may be heated evenly. One of the floor sections is shown lying in front of the furnace. This is 9 inches thick and represents also the thickness of the walls at all sections—a feature that makes a great saving of fuel. The revolving sections of the furnace are rotated by the same air pressure that is supplied for atomizing the oil in the burners. The rotating mechanism is shown in detail in Fig. 2 and consists of a fan box having two bladed fans, against whose blades the air is directed. From the fan shaft, bevel gearing transmits motion to a central shaft, and from a spur gear on this shaft the shaft of the two revolving sections are turned by means of other spur gears. The amount of power required for turning the sections is extremely small, even when the furnace is filled with work. The fan travels at a rate of four hundred revolutions per minute and the revolving plate turns at a speed of 1.7 revolution per minute.

One of the principal advantages claimed for this furnace is that it can be operated on an extremely small amount of fuel. On average work the furnace shown in the illustration uses but two and one-half or three gallons of crude oil per hour. Therefore, at the present price of oil, the furnace can be run at a cost of from twelve to fifteen cents per hour.

KOKOMO HIGH-SPEED DRILL

Recognizing the need of more perfect lubrication of the high-speed parts of vertical drilling machines, the Superior Machine Tool Co., Kokomo, Ind., has added to its line a 21-inch machine in which the friction back-gears and spindle driving gears are completely encased in oil retaining housings. This is the means of avoiding damage due to failure on the part of the operator to pay the necessary attention to oiling his machine. In addition to serving as a means of lubrication, these housings completely enclose the gearing and protect the operator or those passing the machine from injury.

The back-gear case is cast integral with the yoke, with the exception of the gear case cover. It is completely machined as a unit ready to receive the removable bronze bushed bearings with which the machine is equipped throughout. The gear case cover is packed to form an oil-tight compartment in which the splash system of lubrication may be employed. One supply of lubricant will last for months and assure having the parts lubricated in a way which prevents undue wear. In addition, the gears and bearings are protected from dust and dirt and it is impossible for oil to be thrown on the floor or operator. In designing the machine, particular attention has been paid to the provision of means for rapid and constant production, together with a high degree of accuracy. All bearings are bronze bushed and the gears are cut from steel. The machine is equipped with friction back gears and a patented friction quick return.

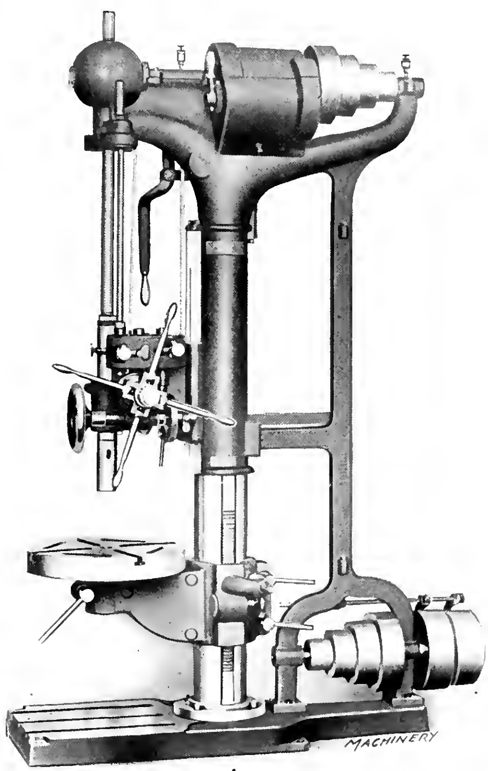

Fig. 1. Kokomo 21-inch Self-oiling Drill

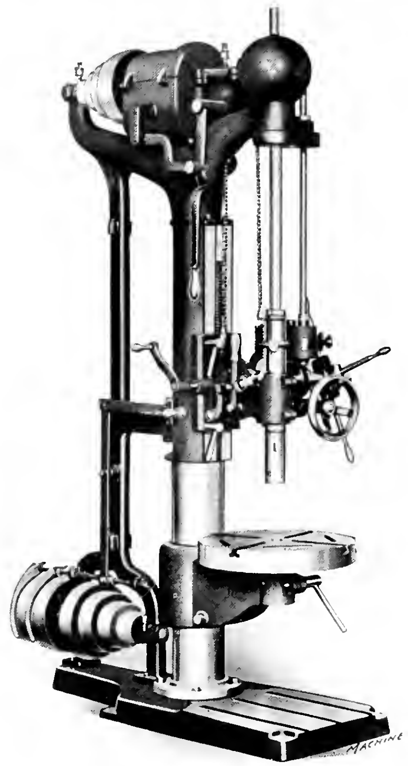

Fig. 2. Opposite Side of Machine shown in Fig. 1

INTERNATIONAL LATHE REVERSE MECHANISM

The International Machine Tool Co., Indianapolis, Ind., has recently designed a mechanical reverse mechanism for use in connection with the "Libby" heavy-duty turret lathe. This

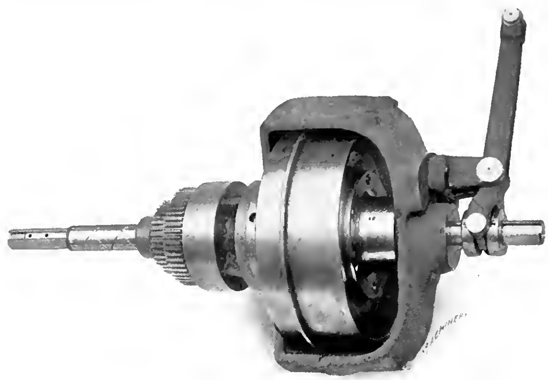

Fig. 1. Reverse Mechanism for Use on the "Libby" Turret Lathe

does away with the necessity for using a reversible countershaft or reversing motor in cases where the performance of tapping operations requires the lathe to be reversed at fre-

quent intervals. Fig. 1 shows the complete reverse mechanism and reference to this illustration will make it clear that this is a self-contained unit which can be easily applied in place of the standard driving pulley, thus making it feasible to add this equipment to any 18-inch "Libby" turret lathe which is now in service. Fig. 2 shows the reverse mechanism set up on a machine and the control at the front of the machine

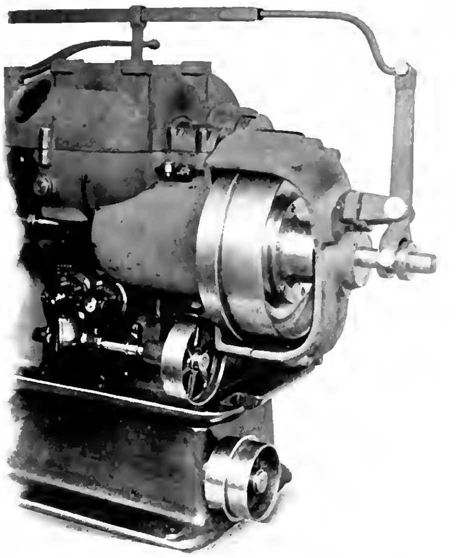

Fig. 2. Reverse Mechanism in Place on the Lathe

where all of the control levers are located. This reverse mechanism is of strong and compact design and is sufficiently durable to stand up under the most severe operating conditions which exist in the average machine shop. All gears are of steel and all bearings are bronze bushed. The gears are engaged by a band friction 7½ inches in diameter which is controlled from the front of the machine as previously mentioned.

NEW MACHINERY AND TOOLS NOTES

Truck Crane: General Vehicle Co., Long Island City, N. Y. An electrically-driven truck crane which can be run about the shop to enable heavy castings and other parts to be handled. The crane has a capacity for lifting work up to 2000 pounds in weight.

Autogenous Welding Outfit: Waterhouse Welding Co., Boston, Mass. A welding and cutting torch which may be used in connection with any type of pressure generator, although it is particularly adapted for use in connection with the safety storage type of acetylene cylinder and an oxygen tank.

Two Electric Tachometers: Electric Tachometer Co., Philadelphia, Pa. One of these instruments is a recording tachometer and the other is a combination recording tachometer and cut-meter, which enables surface speeds to be determined in feet per minute. The instrument can be placed at any desired distance from the shaft, the speed of which is to be determined.

Multiple Spindle Drilling Machine: Michigan Press Co., Ypsilanti, Mich. A machine especially designed for drilling gas burners, but which could also be applied to good advantage on a variety of similar classes of work. The capacity is for drilling from 50 to 100 holes simultaneously in pieces up to 10 inches in diameter. The drills are driven by a crank motion at one end of the spindles.

Cutter Grinder: Flint Specialty Co., 16 Waltham St., Boston, Mass. A grinder adapted for sharpening various types of cutters such as gear cutters and a variety of other formed cutters. No attachments are required except in handling such work as sharpening and backing off saw teeth. The capacity of the machine is for gear cutters up to 3 pitch and saws up to 8 inches in diameter.

Gear-cutting Attachment: Garrett Attachment Co., 14th Ave. and Clinton St., Nashville, Tenn. An attachment which enables milling, gear-cutting and drilling operations to be performed on the lathe. In addition to facilitating work of this nature, the attachment may be used on an upright drill for drilling holes in plates or shafts, where it is necessary to have the holes equally spaced.

Horizontal Milling Machine: Becker Milling Machine Co., Hyde Park, Mass. A high power machine equipped with single pulley drive. The spindle is belt driven, and the machine is double back geared. These millers are built in four sizes of plain and four sizes of universal machines, and the design is similar in many respects to the high power vertical miller of this company's manufacture.

Regenerator Furnace: W. S. Rockwell Co., 50 Church St., New York City. A furnace for use in the forge shop, in which a special economizer shield is provided over the working opening to prevent the loss of the large amount of heat which usually escapes at this point. A novel arrangement of blast acts as a barrier between the operator and the furnace, thus enabling him to work closer to the furnace than would otherwise be possible.

Tumbling Barrel: Warner Bros. Co., Bridgeport, Conn. A tilting tumbling barrel which is intended for cleaning and polishing small stampings, forgings or castings. The barrel may be used for wet or dry rolling of plated stampings, a method which is now finding application in place of hand burnishing. The machine is driven by a single pulley and friction clutch operated by a lever conveniently located for the operator.

Broaching Machine: Pawtucket Mfg. Co., Pawtucket, R. I. A machine designed to cover a wide range of broaching operations. It is operated by a rack and pinion, the pinion and pinion shaft being cut from a single steel forging; and the rack which operates the cutter bar is a steel casting. The work is held in position by means of a bushing through which the broach passes; consequently, it is unnecessary to fasten the work to the machine.

Pneumatic Hammer: Pennsylvania Pneumatic Co., Erie, Pa. A pneumatic hammer for use in the manufacture of die stamped parts from sheet metal. This hammer handles the classes of work which are ordinarily produced by a board drop hammer. The special object in designing this tool was to eliminate the board, friction rollers, gears, clutches, automatic trips and other parts of a somewhat complicated mechanism which are included in the design of many board drop hammers.

Cylinder Boring Machine: Barrett Machine Tool Co., Meadville, Pa. This machine is adapted for either belt or motor drive. The table is 71 by 66 inches in size and the tail pedestal can be adjusted on the bed from 0 up to 60 inches. The boring bar is 8 inches in diameter and has a continuous feed of 60 inches in either direction. Rapid power traverse in either direction is provided and the method of control is such that it may be handled with one hand when moving through short distances.

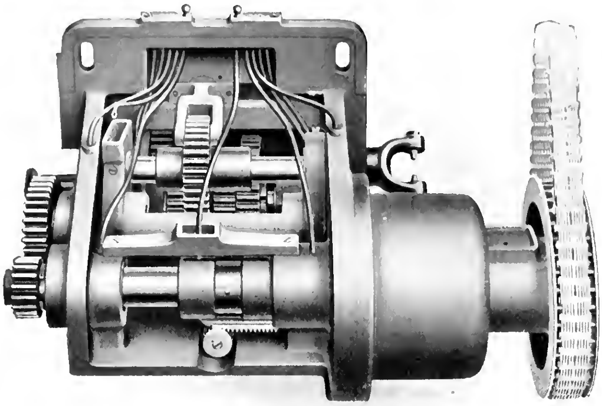
Spur Gear Testing Machine: Gleason Works, Rochester, N. Y. A machine equipped with power drive and a wood lined brake which may be adjusted for testing gears under various loads. The sliding heads of the machine are square gibbed and the spindle bearings are bronze bushed. The adjustment of the center distance is provided by a screw and handwheel graduated to 0.001 inch. The maximum distance between centers is 9 inches and the minimum distance 1¼ inch. The machine swings 16 inches.

Index Centers: Fred C. Dickow, 33 S. Desplaines St., Chicago, Ill. A set of universal index centers which swing 10 inches in diameter. The centers are made of tool steel, hardened and ground, and the spindle is equipped with a clamping device by means of which it can be locked during the cutting operation. This is the means of relieving the worm, wormwheel and index pin of all strain. The index plates provide for obtaining any number of divisions up to 50 and all even numbers from 50 to 100.

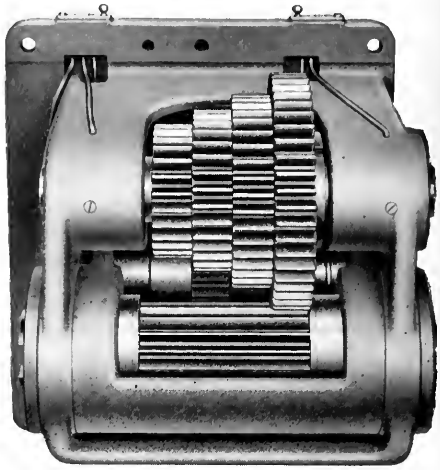
Nut Lock: O. K. Nut Lock Co., Providence, R. I. A nut lock consisting of a corrugated washer and a nut which is corrugated on the under side. The threaded section of the bolt has a slot in it which holds a split washer against turning. When the nut is screwed down, a lug on one end of the split washer engages with the corrugations in the washer, while a similar lug on the other end of the split washer engages the corrugations on the under side of the nut. In this way, the nut is prevented from turning.

Blueprint Machine: Revolute Machine Co., 417 E. 93rd St., New York City. A continuous blueprinting machine in which the light is obtained from two mercury vapor lamps. These lamps are contained in a revolving glass cylinder, and the blueprint paper passes between a belt and the tracing, the tracing being in contact with the glass cylinder. Printing is done while the paper revolves through three-fourths of a revolution of the cylinder. The machine is 32 inches wide and is designed for offices where the demand for blueprints is not large.

Length of Service is Determined



Interior of Feed Case



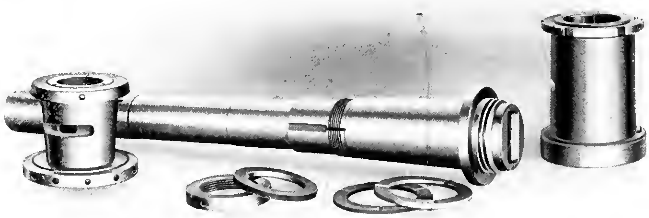
Interior of Speed Case

Bearings—the life of the Milling Machine—are easily overlooked in the general discussion of operating features and productive capacity when buying. Most of them are out of sight, yet their distribution, size and quality are the points which really determine length of service and the return on the investment.

The three cuts show examples of our attention to maintenance of accuracy in designing bearings. Note the heavy shafts mounted in massive housings in the feed and speed cases above. Each shaft is firmly supported close to the point of pressure.

Principal shafts are hardened and ground. All shafts run in long bronze boxes. The oiling system is simple and thoroughly efficient.

The spindle runs in long, heavy phosphor bronze boxes firmly mounted in thick walls. Simple and efficient means are provided to compensate for wear—front spindle bearing tapered, wear taken up by drawing spindle into taper—rear spindle bearing straight, wear taken up by clamping split box concentrically. End thrust taken by heavy hardened steel and babbitt washers.

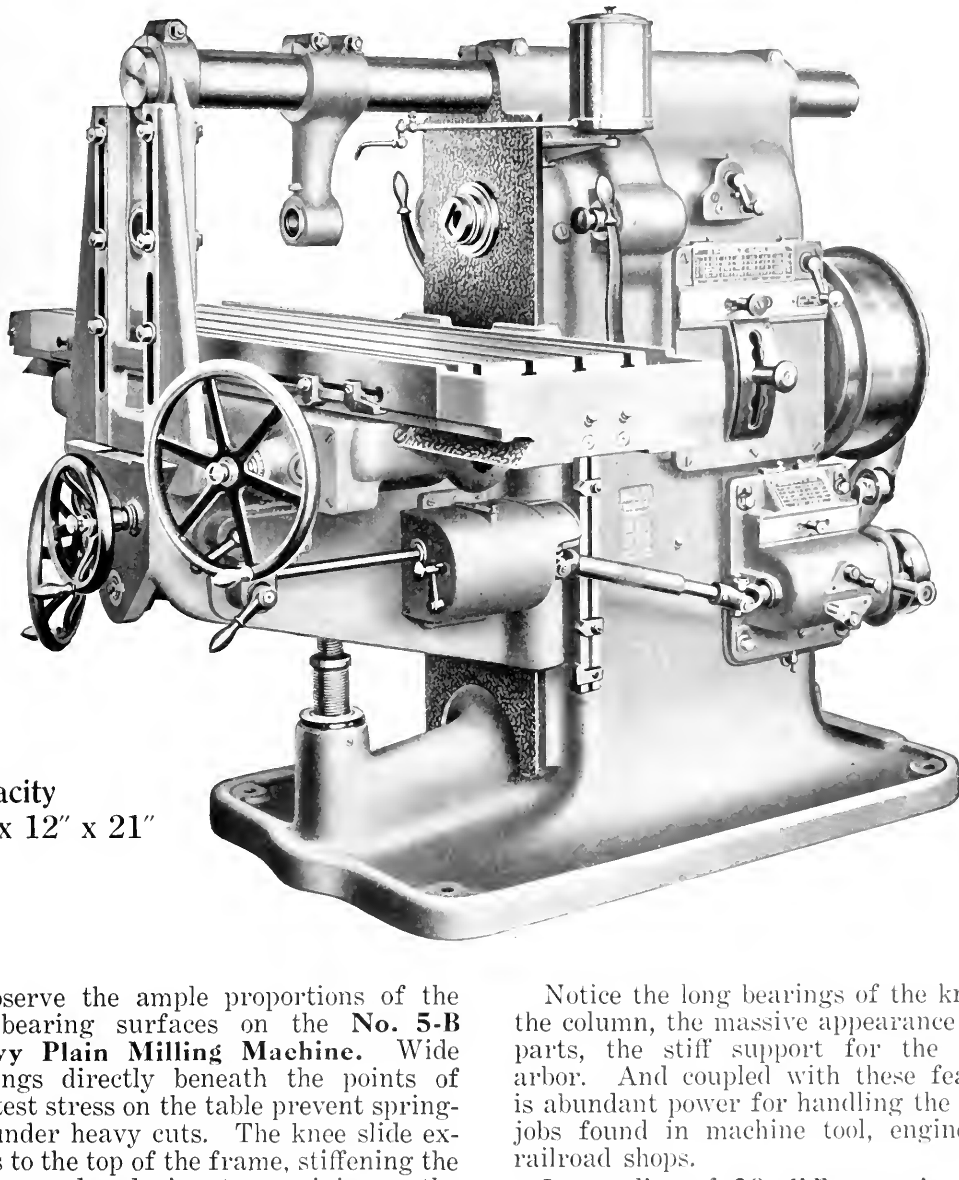


BROWN & SHARPE MFG. CO.

OFFICES: 20 Vesey St., New York, N. Y.; 654 The Bourse, Philadelphia, Pa.; 626 630 Washington Blvd., Chicago, Ill.; 305 Chamber of Commerce Bldg., Rochester, N. Y.; Room 419 University Block, Syracuse, N. Y.

Kinsey Co., Cincinnati, O., Indianapolis, Ind.; Pacific Tool & Supply Co., San Francisco, Cal.; Strong, Carlisle & Hammond Co., Cleveland, O., Detroit, Mich.; Colcord-Wright Machinery & Supply Co., St. Louis, Mo.; Perine Machinery Co., Seattle, Wash.; Portland Machinery Co., Portland, Ore.

y the Durability of Bearings



Capacity
50″ x 12″ x 21″

Observe the ample proportions of the flat bearing surfaces on the **No. 5-B Heavy Plain Milling Machine.** Wide bearings directly beneath the points of greatest stress on the table prevent springing under heavy cuts. The knee slide extends to the top of the frame, stiffening the column and reducing to a minimum the possibility of any spring in the spindle bearings.

Notice the long bearings of the knee on the column, the massive appearance of all parts, the stiff support for the cutter arbor. And coupled with these features is abundant power for handling the heavy jobs found in machine tool, engine and railroad shops.

In our line of **39 different sizes and styles** of Milling Machines there are just the right machines for your purpose.

Read page 67

Vertical Slotting and Milling Attachments: Rockford Milling Machine Co., Rockford, Ill. These attachments are driven by a geared connection at the back end of the spindle. When it is desired to use the milling machine for standard operations, the intermediate gear of the attachment is readily removed, thus disconnecting the drive. The distance from the face of the column to the center of the spindle of the vertical attachment is 7 inches and the maximum distance from the nose of the spindle to the top of the table, 19 inches. The slotting attachment has a stroke of 2½ and 3½ inches.

Electric Furnace Regulator: Thwing Instrument Co., 445 N. 5th St., Philadelphia, Pa. A special type of automatic temperature recorder and regulator for use on electric furnaces. This instrument is particularly adapted for use in connection with furnaces employed for the heat-treatment of small tools, springs and similar parts. It can also be used in connection with an oil or gas fired furnace. A furnace equipped with this regulator enables the temperature to be held within close limits, thus providing for treating the work at exactly the right temperature and having all of the parts of uniform hardness.

Barrel Welding Machine: Davis-Bournonville Co., Jersey City, N. J. A machine for welding the side seam of barrel bodies made of steel plates 3/32 inch in thickness. The edges to be welded are brought together without lap and no metal is added in making the weld. Two torches are employed, one of which acts outside and one inside the barrel as they are fed over the work. A duplex work arm is provided which enables one barrel to be in the working position, and while this barrel is being welded a second barrel may be mounted in the clamps on the other arm, so that there is practically no loss of time between successive operations.

Electric Buffing Machine: United States Electrical Tool Co., 6th Ave. and Mt. Hope St., Cincinnati, Ohio. In the May, 1913, number of MACHINERY, two sizes of motor-driven grinding machines built by the United States Electrical Tool Co., Cincinnati, Ohio, were illustrated and described. Since that time this company has brought out a line of six sizes of buffing machines, which are of similar design except for the fact that the length of the spindles has been extended to provide the necessary clearance for buffing, and that the speed is increased to the required figure. These machines are made in ¼, ½, 1, 2, 3 and 5 horsepower sizes. Motors may be provided for use on 220-440 volt, 60-cycle, two or three phase alternating current, or for 110-220 volt, direct current.

Screw Plates: Russell Mfg. Co., Greenfield, Mass. To meet the demand for a simple, quick opening die for threading bolts by hand, this company has brought out a quick opening die screw plate. It is similar to the Russell Style B screw plate, except that it may be quickly opened by means of a small lever, thus disengaging the die from the work. This means a considerable saving of time, as when the thread has been cut to the required length the die is opened and lifted off the work. Another recent product of the Russell Mfg. Co. consists of a full mounted screw plate. This plate is evolved from the original adjustable die which was invented in 1871. The die may be adjusted to compensate for wear, or to make a tight or loose fit for the bolt and nut, by first loosening two outside binding screws and then adjusting two taper headed screws which control the position of the cutters. After the adjustment has been made, the binding screws are again tightened and the tool is ready for use. The dies in this plate and in all other Russell plates are made double, so that they will cut from either face.

Manufacturing Milling Machine: Potter & Johnston, Pawtucket, R. I. One of the most striking features of this machine consists of two parallel work tables. One of these tables is located under the cutter arbor while the other is out at the front of the machine. By this arrangement the cutter may be operating on the work on one table, and while this operation is in progress the mechanic may be setting up work on the other table. In this way, the time between operations is cut down to a trifle more than the time required to index the table. The work tables are mounted on a circular turntable which brings them alternately into the loading and cutting positions, and locates them accurately. The machine spindle is carried on a vertical slide on the column upon which its position may be adjusted. The column, in turn, is carried on a horizontal slide. A rigid arbor support is provided. There are twelve spindle speeds and sixteen independent feeds. The available spindle speeds are 20, 25, 30, 37, 44, 54, 66, 80, 99, 121, 147 and 180 revolutions per minute. The feeds which are available are 3/4, 7/8, 1 1/16, 1 5/16, 1 11/16, 2 1/16, 2 7/16, 2 15/16, 3 3/8, 4 1/8, 4 15/16, 5 15/16, 7 1/16, 8 9/16, 10 1/4, 12 1/4 inches per minute. The feed changes are independent of the changes of spindle speed.

PERSONALS

Otto Abrahamsen, treasurer of Beaudry & Co., Inc., Boston, Mass., has gone to Europe on a three months' trip.

R. C. Cole has joined the staff of the pneumatic tool department of the Ingersoll-Rand Co., and has been stationed at the Chicago office.

Ralph E. Flanders, general manager of the Jones & Lamson Machine Co., Springfield, Vt., sailed May 9 on the *Olympic* for a short business trip in Europe.

M. E. Towner has been appointed special representative of the Whitman & Barnes Mfg. Co., Akron, Ohio, with office at 113 N. Second St., St. Louis, Mo.

W. S. Dickson, representing the Cincinnati Planer Co., and the Acme Machine Tool Co., both of Cincinnati, Ohio, sailed for Europe the latter part of May for a business trip.

R. E. Ellis, formerly with the Chicago office of Manning, Maxwell & Moore, Inc., is now sales manager for the Steinle Turret Machine Co., Madison, Wis.

H. M. Waite, manager of the city of Dayton, Ohio, addressed the Engineers' Club of Cincinnati and the Cincinnati section of the American Society of Mechanical Engineers, Thursday evening, May 21, on "Municipal Government under the City Manager Plan."

A. H. Boyd, who has been with the Fort Wayne Electric Works of the General Electric Co. since 1898 and for the last four years has been acting as manager of the company's Philadelphia office, has resigned to become general manager and treasurer of the Santo Mfg. Co., Philadelphia, Pa.

OBITUARIES

W. G. Kirkaldy, a well-known British expert on the testing of engineering materials, died April 10, aged fifty-one years. He had contributed a number of papers to engineering societies recording the results of his investigations. He was a member of the firm of David Kirkaldy & Son, London.

* * *

The Baldwin Locomotive Works has built a new type of articulated locomotive for the Erie R. R. which is known as the "triplex compound." It is a development of the Mallet articulated type in which the weight of the tender is made available for tractive purposes, a third engine being under the tender. The total weight of the unit is 853,000 pounds, and the tractive power is 160,000 pounds. It has twelve driving wheels on each side arranged in three groups of four wheels each. A pony truck in front and at the rear makes the total number of wheels supporting the unit twenty-eight. The design, originated by G. R. Henderson, consulting engineer of the Baldwin Locomotive Works, makes 89 per cent of the total weight of engine and tender available for traction effort. High pressure, superheated steam is supplied to the high-pressure cylinders of the center unit. One of these cylinders exhausts to the pair of low-pressure cylinders in the rear and the other high-pressure cylinder exhausts to the pair of low-pressure cylinders in front. The firebox is nine by ten feet, the grate surface being 90 square feet. The tube heating surface is 6418 square feet and the total equivalent heating surface including tubes, firebox, combustion chamber and superheater is 9262 square feet.

* * *

The liner *Laconia*, of the Cunard Line, which was built three years ago, was provided with Frahm's anti-rolling tanks, and it has been shown beyond doubt that in the case of this 18,000-ton steamer the rolling of the vessel has been reduced, on an average, 60 per cent. The success with the *Laconia* in this respect has induced the Cunard Co. to provide the 50,000-ton *Aquitania*, just being completed, with anti-rolling tanks.

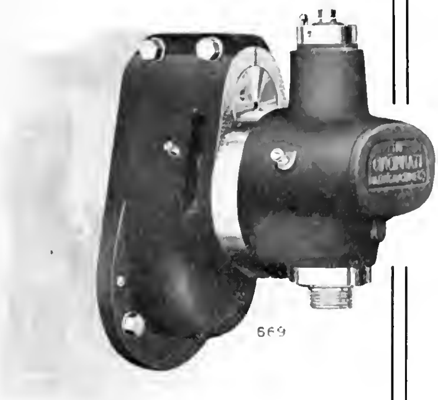
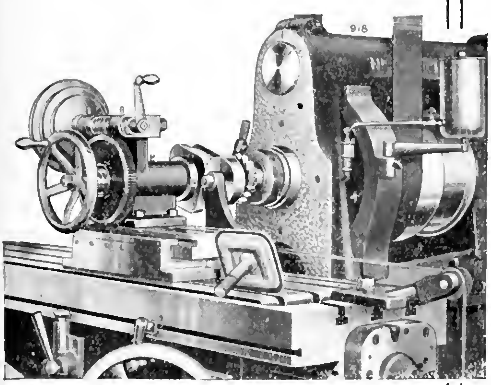
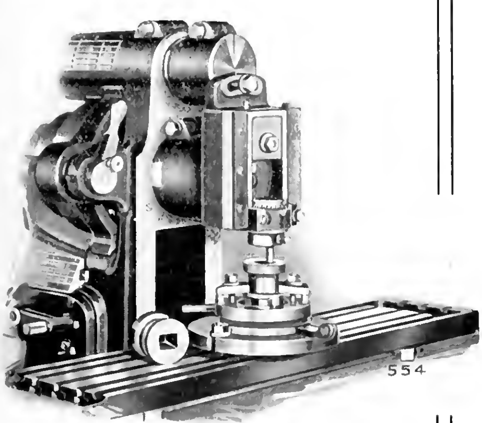
HARRY B. HEALEY,
Notary Public No. 84, Kings County,
Certificate filed in New York County No. 74.

(SEAL) (My commission expires March 30, 1916.)







A Small Machine Shop

equipped with a

CINCINNATI UNIVERSAL Milling Machine

These three attachments and a sensitive drill can do every variety of milling—end, side and surface—a general line of die sinking, profiling and engraving, broaching, shaping, slotting, mill cams of every description, cut spur, bevel and spiral gears; in short, handle nearly everything within the range of the machine—rapidly and accurately.

Instead of tying up money in a lot of miscellaneous tools, the proprietor of a small shop should first buy a *Universal Milling Machine.*

No matter whether your shop is small or large, let us tell you how and why the prominent firms in America and Europe use Cincinnati Millers.

SEND FOR OUR NEW CATALOG

The Cincinnati Milling Machine Company

CINCINNATI OHIO, U. S. A.

COMING EVENTS

June 4.—Joint meeting of the Engineers' Club of Cincinnati, and the Cincinnati section of the A. S. M. E in McMicken Hall, University of Cincinnati, Cincinnati, Ohio, addressed by a representative of the National Tube Co. on the "Manufacture of Steel Tubes."

June 9-12.—Second convention of the National Association of Corporation Schools at Philadelphia, Pa. Arthur Williams, President, Irving Place and 15th St., New York City.

June 10-12.—Annual convention of the Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill

June 15-17.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Karpen Bldg., Chicago, Ill.

June 15-17.—Annual convention of the American Supply & Machinery Manufacturers' Association at White Sulphur Springs, West Virginia; New Green Brier Hotel, headquarters. General offices of the association, Woolworth Bldg., New York City.

June 16-19.—Spring meeting of the American Society of Mechanical Engineers, Minneapolis and St. Paul, Minn. Calvin W. Rice, secretary, 29 W. 39th St., New York City.

June 30-July 4.—Annual meeting of the American Society for Testing Materials, Atlantic City, N. J. Hotel Traymore, headquarters. Edgar Warburg, secretary, University of Pennsylvania, Philadelphia, Pa.

July 15-22.—Second International Congress of Consulting Engineers, to be held in Berne, Switzerland.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

SOCIETIES, SCHOOLS AND COLLEGES

University of South Carolina, Columbia, S. C. Catalogue 1913-1914.

Hebrew Technical Institute, 34 and 36 Stuyvesant St., New York City. Catalogue for 1914.

University of Nevada, Reno, Nev. Proceedings of the First Annual Industrial Safety Conference, held at the University of Nevada, January 26-27, 1914.

Columbia University, New York City. The summer session of the university extends from July 6 to August 14, not from June 3 to September 23, as erroneously stated in the May number of MACHINERY.

Technical League of America, 74 Cortlandt St., New York City, has issued a manifesto to the salaried members of the engineering profession which entreats them to unite to obtain that economic and social standing to which they are entitled by the services they render. The manifesto will strike a responsive chord in the hearts of every designer, draftsman and engineer who appreciates what their professions are doing for the world at large.

University of Wisconsin, Madison, Wis. Bulletin of the summer school extending from June 22 to July 31. The law course and certain courses in the College of Agriculture last until August 28. Courses of instruction and laboratory practice are offered in electrical, hydraulic, steam and gas engineering, mechanical drawing, applied mechanics, testing of materials, machine design, shop work and surveying. Copies of the bulletin can be obtained from F. E. Turneaure, University of Wisconsin, Madison, Wis.

National Association of Corporation Schools, 124 W. 42nd St., New York City. Bulletins 1 and 2, containing "Report of Sub-Committee on Manufacturing and Transportation," by Mark B. Hughes; "Engineering Schools of Electrical Manufacturing Companies," by Dr. Charles P. Steinmetz; "Methods of Selecting Men in Business," by F. C. Henderschott; the president's address delivered at the banquet of the organizing convention, by Arthur Williams; "National Cash Register Schools for Salesmen," by R. H. Grant; and "Reasons for the Shortage of Skilled Mechanics," by A. F. Bardwell.

NEW BOOKS AND PAMPHLETS

American Water Works Association Proceedings, 1913. 749 pages, 6 by 9 inches. Published by the Association, John M. Diven, secretary, Troy, N. Y.

Testing the Hardness and Durability of Metals. Second edition. 40 pages, 6 by 9 inches. 19 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

Safety and Sanitation. By Magnus W. Alexander, an address delivered at the seventeenth annual convention of the National Founders' Association, New York City, November, 1913.

Official Record of the First American National Fire Prevention Convention, held at Philadelphia, Pa., October 13-18. Compiled by Powell Evans, Philadelphia, Pa. 541 pages, 6 by 9 inches.

Critical Ranges A2 and A3 of Pure Iron. By G. K. Burgess and J. J. Crowe. 100 pages, 7 by 10 inches. Published by the Department of Commerce, Washington, D. C., as Reprint 213 of the Bureau of Standards, Vol. 10.

Electric Switches for Use in Gaseous Mines. By H. H. Clark and R. W. Crocker. 36 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 68.

The Use of Iowa Gravel for Concrete. By T. R. Agg and C. S. Nichols. 31 pages, 6 by 9 inches. 9 illustrations. Published by the Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa, as Bulletin 34 of the Engineering Experiment Station, Good Roads Section.

The Sampling and Examination of Mine Gases and Natural Gas. By George A. Burrell and Frank M. Seibert. 116 pages, 5¾ by 9 inches. Illustrated. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 42.

The Utilization of Petroleum and Natural Gas in Wyoming. A preliminary report by W. R. Calvert. With a discussion of "The Suitability of Natural Gas for Making Gasoline," by George A. Burrell. 23 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical paper 57.

Caspar's Technical Dictionary of the English and German Languages. 272 pages, 4½ by 6 inches. Published by C. N. Caspar Co., Milwaukee, Wis. Price, $1 net.

This dictionary comprises the most important words and terms employed in technology, engineering, machinery, chemistry, navigation, shipbuilding, electro technics, "automobilism," aviation, etc. It is in two sections—English-German and German-English. The important technical words and phrases which have come into general use during the last decades are included.

Harper's Gasoline Engine Book. By A. Hyatt Verrill. 292 pages, 5¼ by 7¾ inches. Illustrated. Published by Harper & Brothers, New York City. Price, $1.

The extensive and growing use of the internal combustion motor has made it an object of general interest. This work, intended for boys and young people generally, treats of the gas engine, motor anatomy, marine and stationary motors, vehicle motors, troubles and repairs. It deals with both the two-stroke cycle and four-stroke cycle types and takes up construction features in detail.

Electric Furnaces for Making Iron and Steel. By Dorsey A. Lyon and Robert M. Keeney. 142 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of Interior, Washington, D. C., as Bulletin 67.

The bulletin is divided into two parts, the first treating of the electric furnace in pig-iron manufacture and the second on the electric furnace in steel manufacture. The growing importance of the electric furnace in iron and steel production should make this bulletin of unusual interest and value to iron and steel makers.

Harper's Aircraft Book. By A. Hyatt Verrill. 245 pages, 5¼ by 7¾ inches. Illustrated. Published by Harper & Brothers, New York City. Price, $1.

This work, intended for boys and others interested in making model aeroplanes, tells why aeroplanes fly, how to make models, and other interesting facts regarding heavier-than-air machines. It treats of motor-propelled and gliders, or non-propelled aeroplanes, hydro-aeroplanes and flying boats, the uses of the aeroplane, etc. Being profusely illustrated, the text should be readily understood by those who wish to follow the directions for making models.

Where and Why Public Ownership Has Failed. By Yves Guyot. Translated from the French by H. F. Baker. 459 pages, 5 by 7½ inches. Published by the MacMillan Co., New York City.

The work is divided into four parts as follows: Public and Private Trading Operations; Financial Results of Government and Municipal Ownership; Administrative Results; Political and Social Consequences of Public Operation. The author discusses the conditions of municipal activity in the United Kingdom, the United States, Germany, Russia, France, Austria-Hungary, Italy, Denmark, Switzerland, Netherlands, Belgium and Sweden.

Metal Coloring and Finishing. 39 pages, 6 by 9 inches. 14 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This is No. 123 of MACHINERY'S Reference Books, and deals with the methods of producing colors on iron, steel, copper, bronze, brass and aluminum, together with chapters on burnishing metals, including both lathe burnishing and ball-burnishing processes. The book deals with a subject on which no information is generally available except in large volumes containing formulas and recipes for all kinds of purposes. It gives descriptions of many processes for obtaining colors on metals and will be found valuable by those who are interested in this class of work.

Telephone Construction, Installation, Wiring, Operation and Maintenance. By W. H. Radcliffe and H. C. Cushing, Jr. 223 pages, 4 by 6½ inches. 132 illustrations. Published by Norman W. Henley & Son, New York City. Price, $1.

The first edition of this work was published in 1908. Considerable new matter has been added to the second revised edition to bring the work up to date. The work begins with the first principles, the assumption being that the reader knows nothing of telephony. It deals with the subject so thoroughly, however, that not only the amateur, but the wireman, the engineer and the contractor will find it useful. It treats of the construction, operation and installation of telephone instruments, inspection and maintenance of telephone instruments, testing telephone line wires and cables, wiring and operations of special telephone systems, etc.

Cold-heading. By Chester L. Lucas. 44 pages, 6 by 9 inches. 47 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

This is No. 119 of MACHINERY'S Reference Books. It deals with the machines, methods and tools used for the cold-heading of screws, rivets and similar machine parts. The contents of the book are divided into three distinct parts: the first deals with principles of cold-heading, describing and illustrating the general methods employed; the second with cold-heading machines and operations, illustrating and describing the typical cold-heading machines manufactured and used in this country; and the third with cold-heading dies and tools, showing their construction and illustrating the methods used in making them. Mechanics will be particularly interested in this book, as it is the only one that has ever been published on the subject.

Machining Tapered and Spherical Surfaces. By Albert A. Dowd. 43 pages, 6 by 9 inches. 35 illustrations. Published by the Industrial Press, New York City. Price, 25 cents.

During the past year MACHINERY has published a number of valuable articles by the author of this book, relating to tools and devices used for machining operations. Two of these, describing taper boring and turning attachments and the machining of convex and concave surfaces, have been given permanent form in this book, which is No. 121 in MACHINERY'S Reference Books. The book shows a great number of devices illustrated by carefully made line-engravings and accompanied by concise descriptive text. All of the devices shown are taken from actual practice and have been designed for commercial purposes. The range covered is very extensive, passing from the simple to the complex devices used for the purposes mentioned. Tool designers, shop foremen, and those responsible for production in general will find much valuable material in this book.

National Association of Corporation Schools. Report of First Annual Convention including papers and discussions presented at Dayton, Ohio, September 16-19, 1913. Executive office, Irving Place and 15th St., New York City.

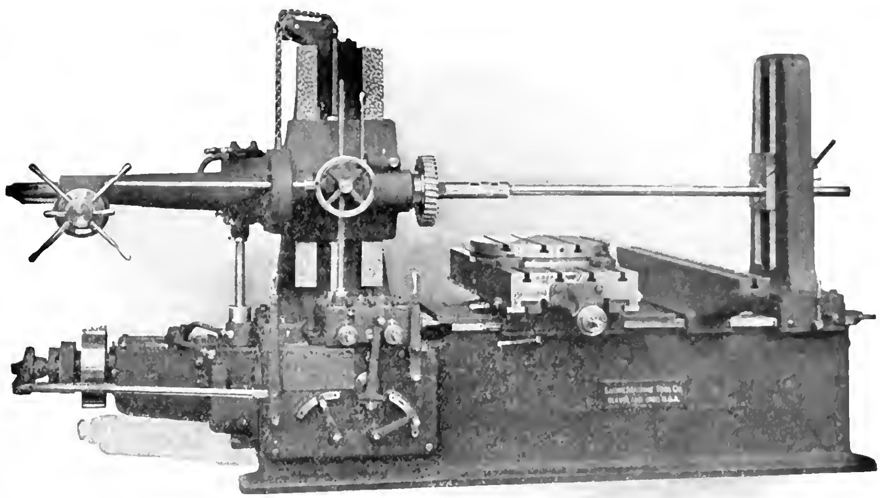
The National Association of Corporation Schools movement differs from any other in that it aims to carry specialized and general training to young men and women after they have actually entered upon their business or industrial careers. The work of the association does not enter into any of the established continuation schools, but is confined primarily to the establishment of what is practically a continuation school in industry, endeavoring through specialized training to replace the former, and now practically obsolete, apprenticeship training; and to bring as much as possible of a more general training and education to the industrial workers of our country. The membership of the association now includes nearly 150 in all classes, including thirty-two industries employing in the neighborhood of a million men and women.

Business Administration. By Edward D. Jones. 275 pages, 5 by 7¼ inches. Published by Engineering Magazine Co., New York City. Price, $2.

The Engineering Magazine Co. has published a number of well-known books on works management and this work is the latest addition to the list. Prof. Jones assumes that success in dealing with men and affairs depends upon certain laws which can be discovered in the work of successful administrators, but that the rules and methods followed by masters of business and finance are usually not open to investigation. The leaders in statecraft, war and science, however, are figures whose careers and practice are fully recorded and open to analysis. In the study of history and the biography of warriors, diplomats and scientists, he has found what he considers to be the elementary rules of success. In short, Prof. Jones derives the principles, motives and actions of successful business men by studying the careers of successful public men. The contents are as follows: The Rise of a New Profession; The Utility of the Study of History; Military History; Administrative Principles; The Pioneers of Science; System-makers of Science; The Application of Science; The Principles of Mental Efficiency; History of the Gentleman Administrator; Methods of the Gentleman Administrator; Ideals of the Gentleman Administrator.

Compressed Air. By Theodore Simons. 173 pages, 6 by 9 inches. Illustrated. Published by the McGraw-Hill Book Co., New York City. Price, $1.50.

This treatise on the production, transmission and use of compressed air treats of the natural laws and physical principles concerned. The endeavor has been made to produce a work suitable for the average technical student who has a sound knowledge of the elements of algebra, physics and mechanics. The contents comprise Production of Compressed Air; The Behavior of Air Undergoing Compression and Under the Application of Heat; The Compression of Air in Air Compressors; Theory of Air Compression; Clearance, Volumetric Efficiency, Capacity, Speed, Mechanical Efficiency of Compressors; Two-stage and Multi-stage Compressions or Compound Compression; Effect of Altitude on Air Compression; The Compressed Air Indicator Card; Cooling Water Required in Compression—Efficiency of Compressor Plant—Air Compressor Ex-



plosions; The Transmission of Compressed Air; Dimensions of Pipe Lines for Conveying Compressed Air; The Use of Compressed Air; Theory of Air Engines; Effective Heat Losses; Internal or Intrinsic Energy of Air; The Efficiency of a Compressed Air System; Reheating of Compressed Air; Air Compressors and Accessories; Examples of Modern Air Compressors of the Reciprocating Type; Important Mechanical Features of Air Compressors; Compressor Accessories.

Steam Turbines. By James A. Moyer. 376 pages, 6 by 9 inches. 225 illustrations. Published by John Wiley & Sons, New York City. Price, $3.50.

The first edition of Prof. Moyer's work was published in 1908. The additions made in the 1914 edition of this favorably known work on steam turbines have been mainly in the line of new applications. The chapter on low pressure turbines has been rewritten to include the latest developments and applications. The real important developments of the last few years have been in the construction of increasingly large sizes of steam turbines. The author mentions that the largest turbine generator now ready for installation is rated at 35,000 kilowatts, which is to be compared with a maximum size of 14,000 kilowatts of only three years ago. The contents by chapter heads are: The Elementary Theory of Heat; Nozzle Design; Steam Turbine Types and Blade Design; Mechanical Losses in Turbines; Method for Correcting Steam Turbine Tests; Commercial Types of Turbines, including De Laval, Parsons, Westinghouse, Allis-Chalmers, Curtis, Rateau, Wilkinson, Zoelly, Sturtevant, Riedler-Stumpf, Kerr, Terry Dake, etc.; Governing Steam Turbines; Low-pressure (Exhaust) Turbines; Mixed Pressure Turbines; Bleeder or Extraction Turbines; Marine Turbines; Tests of Turbines; Steam Turbine Economics; Stresses in Rings, Drums and Disks; Gas Turbines; Electric Generators for Turbines.

NEW CATALOGUES AND CIRCULARS

George P. Clark Co., Windsor Locks, Conn. Bulletin AC giving dimensions, prices, etc., of wheels and casters.

H. Bickford & Co., Lakeport, N. H. Leaflets illustrating boring and turning mills with motor drive and rapid power traverse, respectively.

Percy Pitman, 3 Willcott Road, Acton, London, W., England. Circular of the Pitman hydraulic governor for controlling the speed of water turbines, impulse wheels, etc.

Lutz-Webster Engineering Co., Philadelphia, Pa. Leaflet giving prices of the various sizes of compression wrenches, ratchets and bolt and nut sockets made by this company.

Sprague Electric Works of the General Electric Co., 531 W. 34th St., New York City. Circular 905 on Sprague electric hoists, illustrating a large number of designs suited to all kinds of hoisting service.

Millers Falls Co., Millers Falls, Mass. Pamphlet describing the Nos. 99, 99A, 100, 199, 199A, 200, 2100 and 2200 breast drills of this company's manufacture. Each style of drill is illustrated and its features briefly described.

David Maydole Hammer Co., Norwich, N. Y. Catalogue on the Maydole hammers, which are forged from solid crucible cast steel. The specifications for these hammers are printed in English, French, German and Spanish.

C. M. Smillie, 130 E. Larned St., Detroit, Mich. Circular of Smillie compensating turret chuck or drill holder for Fox lathes, turret lathes and screw machines. The chuck is made in three sizes, taking drills from No. 42 to 1 inch.

Laidlaw-Dunn-Gordon Co. (International Steam Pump Co., successor), Cincinnati, Ohio. Bulletin L-523-A, treating of the Cincinnati gear duplex Corliss steam driven air compressors, classes WA and XA. 24 pages, 6 by 9 inches.

Fred C. Dickow, 33 S. Desplaines St., Chicago, Ill. Leaflets illustrating double friction clutch countershaft and 10-inch universal index centers. The countershaft is provided with hollow set-screws which should commend it to those interested in "Safety First."

Ph. Bonvillain & E. Ronceray, 9-11 Rue des Envierges, Paris, France. Catalogue 6 in French on molding machinery, 104 pages, 8½ by 10¾ inches, containing descriptions of the line of up-to-date molding machines and accessories manufactured by this company.

Carroll-Jamieson Machine Tool Co., 257 Davis St., Batavia, Ohio. Bulletin on the Carroll-Jamieson "selective" sliding gear, single-belt drive 14-inch tool-room manufacturing lathe, illustrated. This lathe has a headstock designed to meet the demand for rapid production.

Lumen Bearing Co., Buffalo, N. Y. Booklet entitled "Bronze Alloys and Babbitts." The data given for each alloy is classified separately for a test bar cast in a chill and for a bar cast in sand; it includes tensile strength, elongation, Brinell hardness and specific gravity.

Diamond Clamp & Flask Co., Richmond, Ind. Circular of an "air spreader" or fan for use in machine shops, factories, etc. The fan is mounted in a bracket that is secured to the ceiling, and is driven by a belt from the lineshaft. A clutch is provided for throwing it in or out of action.

Baker Bros., Toledo, Ohio. Catalogue on Baker heavy pattern high-speed drills built in 5-inch, 4-inch, 3-inch and 2½ inch capacities. Illustrations of these machines with their various attachments are shown. The 1-inch by 6-inch automatic drill built by the Baker Bros. is also illustrated.

Consolidated Expanded Metal Companies, Architects Bldg., New York City. Pamphlet illustrating the use of "Steelcrete" guards for machine tools, lineshafts, chain drives, punch presses, stairways, etc. Expanded metal is well suited for machine guards, being light, strong and durable.

Monarch Mfg. Co., Dayton, Ohio. Circular of the Dayton welding and decarbonizing plants for use in repair shops, garages, etc. The company furnishes a welding outfit for $75 and a decarbonizing, welding and cutting outfit for $115. Directions are given for building acetylene generators at small cost.

Mesta Machine Co., Pittsburg, Pa. Catalogue O, giving the advantages of rope drives, among which may be mentioned smooth continuous action, low cost and high efficiency, noiselessness, freedom from shocks, etc. The catalogue also contains charts showing the length of life and horsepower transmitted by manilla ropes.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue D 1914, treating of "Brownhoist" tramrail systems, trolleys and electric hoists. A number of interesting installations of Brown hoists are shown, and the specifications are conveniently arranged in tabular form, capacity, dimensions, prices, etc., being given.

American Swiss File & Tool Co., 24 John St., New York City. Circular of a fourteen-inch file with a new cut called "Wavecut." This file removes metal in curled shavings instead of the ordinary granular filings. It has diagonal rows of cutting edges which give the file a wavy appearance that suggested the trade name, "Wavecut."

Sleeper & Hartley, Worcester, Mass. Bulletins 277 and 280 on spring hooking machines and spring coiling machines, respectively. The spring hooking machines produce any desired form of hook or loop on either right- or left-hand springs without waste of stock. The spring coiling machines produce either extension or compression springs.

Ransom Mfg. Co., Oshkosh, Wis. Bulletin SD1, showing the application of Ransom safety devices to abrasive wheels. These devices include steel and cast-iron wheel guards of the open and enclosed types, safety flanges, safety nuts, and the Ransom patent speed controller which obviates the possibility of over-speeding the wheel.

Hoggson & Pettis Mfg. Co., New Haven, Conn. Catalogue and price list 10 C of "Sweetland" lathe chucks, comprising combination chucks, universal chucks, car-wheel chucks, independent chucks, geared scroll chucks, planer chucks, drill chucks, etc. Information is also contained on the mounting and care of chucks, repairs and special chucks.

C. & E. Mfg. Co., Marshalltown, Iowa. Leaflet entitled "How do you do without the Marshalltown?", setting forth the advantages of the "Marshalltown" wrench—a ratchet wrench with only three working parts. Four detachable jaws are furnished for use on ⅜, 7/16, ½ and 9/16 inch nuts, and in addition there is one alligator jaw in the handle.

Munning-Loeb Co., Matawan, N. J. Bulletin 500 of plating and industrial brushes, comprising circular brushes, horse hair brushes, camel hair brushes, metal wire and cotton brushes, crinkled brass or steel wire brushes, hand polishing and scratch brushes, scouring brushes, etc. This line of brushes is made for electroplaters, buffers and other manufacturers of finished metal goods.

Independent Pneumatic Tool Co., Thor Bldg., Chicago, Ill. Circular E-1 of the new "Thor" electric drill equipped with universal motor for alternating and direct current, made in four sizes, the small size having capacity from 0 to ¼ inch; the second, 0 to 5/16 inch; the third, 0 to ⅜ inch and the fourth, ⅛ to 9/16 inch. These drills are equipped throughout with ball and roller bearings.

Betts Machine Co., Wilmington, Del. Catalogue 2614 on horizontal boring and drilling machines and attachments. 20 pages, 6¾ by 9¾ inches. The attachments that can be furnished for these machines at the desire of the purchaser are: additional circular table, extra facing head to facilitate machining both ends of a casting at the same time, threading attachment, power feeds to tables and electric drives.

Shepard Electric Crane & Hoist Co., Montour Falls, N. Y. Bulletin No. 61 on electric traveling cranes. 39 pages, 8½ by 11 inches. This book gives a complete description of the Shepard electric cranes and their various parts. Some of the basic features are: the balanced drive, complete enclosure of high-speed gearing, system of load brakes, and lubrication. A large number of installations of Shepard electric cranes are shown.

Van Dorn & Dutton Co., gear specialists, Cleveland, Ohio. Booklet treating of "V. D. & D." railway and mill motor gears and pinions. The gears are made from open-hearth steel castings in both solid and split types, with the exception of the forged or rolled gears which are furnished in the solid type only. Extreme care is taken both in the selection of material and in the manufacture of these gears.

Fitchburg Grinder Co., Fitchburg, Mass. Circular of the Fitchburg "Six-Fifteen" cylindrical grinding machine, styles A and B. The machine is of heavy proportions, being of 2- by 16-inch wheel capacity. It was designed especially to meet the demands for a simple machine suitable for grinding short cylindrical pieces in large quantities. Style A has an automatic traverse while style B is provided with hand traverse only.

Nazel Engineering & Machine Works, 4043 N. 5th St., Philadelphia, Pa., is issuing the "Nazel Hammer Book," which contains complete information concerning the Beche and Nazel hammers. These hammers are built in six sizes for either belt or motor drive. The Nazel-Beche hammer works on the same principle as the Beche hammer, but has a larger capacity and greater die area. The line of speed hammers produced by this company is also illustrated.

Oster Mfg. Co., 2107 E. 61st St., Cleveland, Ohio. Booklet entitled "Actual Pipe-Threading Experiences—II" containing information on average working times of Oster pipe-threading machines and showing installations of these machines in various parts of the country. All parts of Oster pipe-threading machines are standardized and interchangeable. The "facts and figures from the day's work" will be of much interest to those employing this class of machinery.

Gleason Works, Rochester, N. Y. Gear planer catalogue, 48 pages, 6 by 9 inches. This book includes descriptions and specifications of generating bevel gear planers(fully automatic), forming bevel gear planers (fully automatic), combination bevel and spur gear planer (semi-automatic), sixteen-foot bevel gear planer, bevel gear tempering machine and bevel gear testing machine. Each of these types of machines is illustrated by excellent half-tone engravings. The last section of the book illustrates mandrels for use on these machines.

National Machinery Co., Tiffin, Ohio, is issuing a series of folders entitled "National Forging Machine Talks." No. 2 takes up the bed frame as a potent factor in the efficiency of the forging machine, pointing out the necessity of providing stiffness and rigidity in this part of the machine. The halftone and line drawings illustrate the steel bed frame casting of the National heavy-pattern forging machine, showing the heavy under-ribbing and the improved form of gap which extends but one-third the depth of the bed.

Harrington Machine Co., Erie, Pa. Folder descriptive of "under" milling machines A and B. These machines derive their name from the fact that the cutter is mounted so as to be underneath the work, thus leaving the lines on the work always in plain view, the table being entirely unobstructed by spindle or housings. Type A is especially designed for milling trimming dies used in drop-forges and for all irregular open work. Type B is similar to A, but is much heavier and is not equipped with a tilting table.

Herman Bacharach, 14 Wood St., Pittsburg, Pa. Catalogue B descriptive of "Hydro" volume and pressure recorders, for measuring and recording the volume and pressure of gases. 16 pages, 6 by 9 inches. The velocity charts included will be found of value in determining the velocity of gases of any specific gravity. Some interesting curves obtained from "Hydro" volume meters are shown. These record the gas consumption of by-product coke ovens, the amount of blast furnace gas used for heating stoves and the amount of coke oven gas consumed in a steel mill.

Cullman Wheel Co., 1339 Greenwood Terrace, Chicago, Ill. Catalogue 9, 24 pages, 5¾ by 8¾ inches, giving price lists of sprockets for use with Coventry and Whitney noiseless chain. Noiseless chains and wheels are now being made in 8 and 10 millimeter pitches, to provide a light, compact and efficient drive. Tables of specifications giving dimensions, weight, strength, price, etc., of Coventry and Whitney noiseless chains of different pitches are among the material that will be of value to automobile manufacturers and others interested in this form of transmission.

Heald Machine Co., 20 New Bond St., Worcester, Mass. Catalogue illustrating the Heald line of internal cylinder, ring, and drill grinding machines and magnetic chucks. This catalogue was produced as a souvenir for the National Machine Tool Builders and National Metal Trades Associations' conventions, which probably accounts for the decided departure from the stereotyped style of machinery catalogue that it presents. The cover is light grey with silver lettering and deckled edges. The artistic touch is also shown in the arrangement of the type and cuts, the latter being printed on a fine grade of paper and pasted along the top edge to the japan stock used for the body of the book.

Crescent Machine Co., Leetonia, Ohio. New catalogue on Crescent wood-working machinery. 143 pages, 4 by 6 inches. This catalogue describes the Crescent bandsaws, special equipment, bandsaw blades, saw-tables, shapers, planers, matchers, surfacers, cut-off saws, disk grinders, wood-workers, etc. Special attention is called to the No. 101 to 112 "Universal" wood-worker illustrated and described on pages 108 to 125. This machine consists of a bandsaw, a jointer, saw-table, borer and shaper. Additional attachments may also be provided, adapting the machine for mortising, tenoning, making moldings, grinding tools, and sanding. Other new features include the remodeling of the 26 by 8 inch surfacer, which has now been equipped with variable friction feed, and improved fenders on bandsaws.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Catalogue 3002-A, Section 3082 on motor-driven pumps, describing pumps of various kinds driven by electric motors. A number of installations of these pumps are shown. Tables are also included giving the frictional heat in wrought-iron pipe, horsepower for pumping, standard dimensions for pipe, and atmospheric pressures, equivalent heads and suction lifts. Leaflet 2364-A treats of Westinghouse electric direct-current Type K crane

JULY, 1914

MANUFACTURE OF SAVAGE 0.22 CALIBER HIGH-POWER RIFLE*—1

EFFECTIVENESS OF A HIGH-POWER SMALL CALIBER RIFLE—MANUFACTURING AND TESTING METHODS AT THE FACTORY OF THE SAVAGE ARMS CO.

BY FRANKLIN D. JONES†

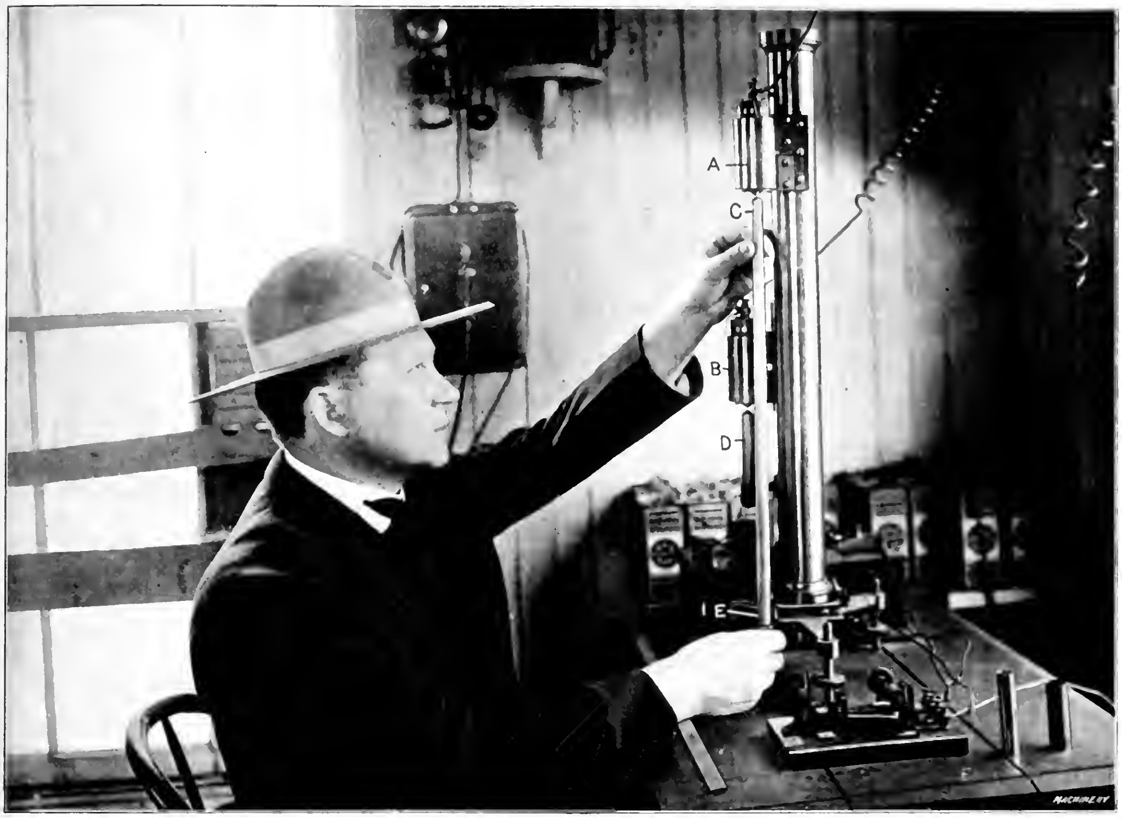

Fig. 1. The Chronograph, used to determine the Initial or Muzzle Velocity of a Rifle Bullet—The Instrument is being adjusted preparatory to making a Test

NOT many years ago the average sportsman prided himself on owning a rifle of large caliber, the idea being that a bullet must be large to be deadly. Modern gunmakers, however, have demonstrated that a small bullet may be much more effective and destructive than a large one, if it has the power behind it and is correctly shaped so that the average velocity during flight will be as high as possible, thus flattening the trajectory and increasing the accuracy as well as the striking energy of the bullet. The result has been that large calibers have been quite generally superseded by smaller ones, such as the 30-30 and other comparatively small bores, as those interested in firearms know.

One of the most wonderful developments of the small caliber high-power rifle has been made by the Savage Arms Co. of Utica, N. Y. We refer to the 0.22 caliber high-power rifle placed on the market by this company about a year ago. In many respects, this is the most remarkable firearm ever designed and manufactured, owing to the inverse relation between the size of the bullet and its destructive power. It is a hammerless repeater and is similar to the '99 model so far as the action is concerned. This rifle was originally intended for shooting wolves, coyotes, foxes, etc., but actual hunting experience has shown it to be powerful enough for deer, moose, caribou, mountain sheep, and even for such large game as Alaskan brown bear and American black bear.

Here are some figures which will show, in a general way, the performance of this rifle. The initial or muzzle velocity is 2800 feet per second and the theoretical striking energy over 1200 foot-pounds. The velocity is higher than that of any other firearm manufactured in this country and is 100 feet per second higher than that of the new Springfield United States Army rifle. Owing to this extreme velocity, the trajectory (or path followed by the bullet in its flight) is very flat, which increases the accuracy, especially at long ranges. The mid-range height of the trajectory for a range of 200 yards is only 2.99 inches and the rifle can be used for distances up to 350 yards without changing the point-blank adjustment of the sights. Under favorable weather conditions, this rifle (which only weighs $6\frac{1}{4}$ pounds) has done excellent work on a military target at 1000 yards range. It has scored twenty-five consecutive "bulls" on the 500-yard military target (20-inch bullseye), and has placed ten consecutive shots within a 10-inch circle at 500 yards. To those familiar with rifle shooting, these figures speak for themselves.

* For information on rifle manufacture previously published in MACHINERY see the series on "The Ross Rifle and Its Manufacture" in the October, November and December, 1911, and January, 1912, numbers of MACHINERY. See also articles referred to in connection with the first installment.

† Associate Editor of MACHINERY.

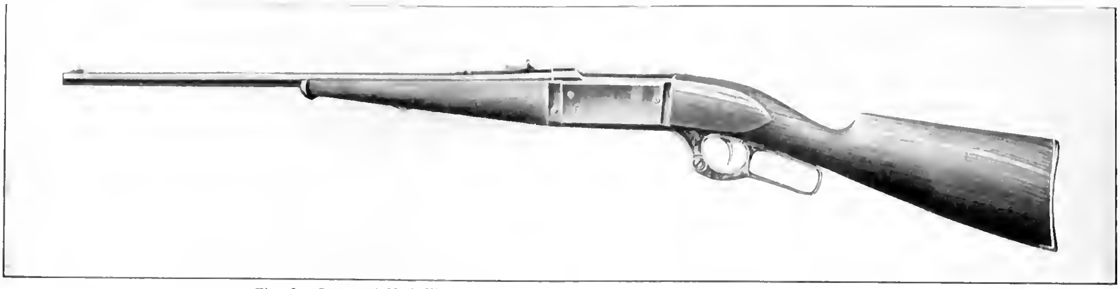

Fig. 2. Savage 0.22 Caliber High-power Rifle—Initial Velocity 2800 Feet per Second

The following data may also be of interest: The weight of the bullet is 70 grains; the diameter of the bullet, 0.228 inch; the diameter of the barrel from groove to groove, 0.2275 inch; the number of grooves, six; the lead of the rifling or the distance the bullet travels to complete one revolution, 12 inches. The pressure back of the bullet at the instant of discharge is 48,000 pounds per square inch. Incidentally, the pressure in a 14-inch gun, which is the largest now used in the United States Navy, is 35,000 pounds per square inch. These comparative figures are interesting, especially when we consider that the rifle can safely withstand this enormous pressure, although its weight is only 6¼ pounds. The bullet will penetrate a pine block in an endwise direction a distance of 7¾ inches, and it will pass through ½-inch chilled steel boiler plate.

The performance of this rifle at ranges varying from 100 to 1000 yards is given in the accompanying table, which was compiled by the ballistic department of the Savage Arms Co. The first horizontal column gives the ranges, and the second, the velocity in feet per second. As will be seen, the velocity at a distance of 700 yards is over 1000 feet per second. The mid-range trajectory or the vertical height of the path described by the bullet at a point midway between the rifle and target varies from 0.506 inch at a range of 100 yards to 248.5 inches at 1000 yards. The angle of departure represents the angle at which the rifle barrel must be elevated for a given range, to cause the bullet to strike at a point in the same horizontal plane as the muzzle of the rifle. By referring to the table, it will be seen that for 100 yards this angle is only 2 minutes 5 seconds, and for a long range of 500 yards, it is only 18 minutes 32 seconds, or less than one-third degree.

At the plant of the Savage Arms Co. new rifles are designed in the ballistic and experimental department. To develop a high-grade firearm not only requires a thorough knowledge of ballistics but a broad mechanical knowledge as well, in order to obtain a design that is not only accurate and effective, but mechanically perfect so that it can be manufactured on an economical basis. The designer begins with the cartridge and largely builds the rifle around it. He is confronted with many problems, all of which must be considered—and the problems are not solved in a day, but as the result of numerous experiments backed up by wide experience. The rifle designer has an interesting but difficult task; in fact, so difficult that no intelligent conception of the methods of procedure could be given here even though we were familiar with this science. So we shall leave the ballistic department and consider some of the methods and tools employed by the Savage Arms Co. in the manufacture of rifles, dealing particularly with the 0.22 caliber high-power design previously referred to.

Action of the Savage High-power Rifle

The action of the 0.22 caliber high-power rifle will be described first so that references in this and succeeding articles to specific parts will be intelligible. This action, which is the same as that used in the '99 model, is illustrated in Fig. 3. The upper view shows the action closed and the lower view shows it open. These two views illustrate a "cut-open action," the receiver having been cut away in several places to expose the interior parts. The operation of the mechanism for loading, firing, and reloading is as follows: When finger lever *A* is thrown down to the position illustrated in the lower view, it withdraws the breech-bolt *B*. A cartridge in the rotary magazine carrier *C* then jumps up in front of the breech-bolt and is held in position by a three-point contact between the carrier, the cartridge guide on the right side of the receiver, and the ejector or automatic cut-off *D* which is now forced out over the cartridge by a spring.

As lever *A* is pulled back to close the action, breech-bolt *B* moves forward, pressing ejector *D* back into its seat and pushing the cartridge forward into the barrel. When lever *A* is pulled back about half way, lug *E* on the hammer strikes against the sear *F* and the hammer is held back. As the forward movement of the breech-bolt is continued, the hammer spring is compressed, and when the breech-bolt is forced upward to its seat, the rifle is ready to fire, the action being in the position shown by the upper view, Fig. 3. When the trigger is pulled it turns sear *F* downward until the hammer is released; the hammer then flies forward and strikes the firing pin.

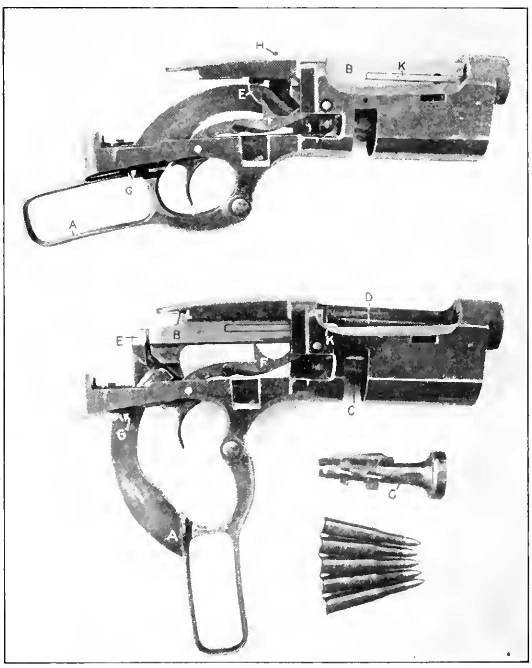

Fig. 3. Action used on 0.22 Caliber High-power Rifle—Sections of the Receiver are cut away to expose Mechanism

When lever *A* is again pushed forward, the extractor *K* (which is a latch shaped part at the end of the breech-bolt that hooks over the rim of the cartridge) withdraws the cartridge shell from the barrel. When the shell is back far enough to clear the forward end of the receiver, it strikes a small projection on the ejector *D* and is whirled around and out of the receiver. As the shell is thrown out, the ejector moves out over the next cartridge which is now in front of the bolt and in position for loading. The cycle of movements just described is repeated each time the rifle is fired.

The entire mechanism is very simple and positive in its movements. When the action is closed, the breech-bolt is forced upward to its seat by a cam surface on the inner end of lever *A*. The lower side of this inner end also bears on a

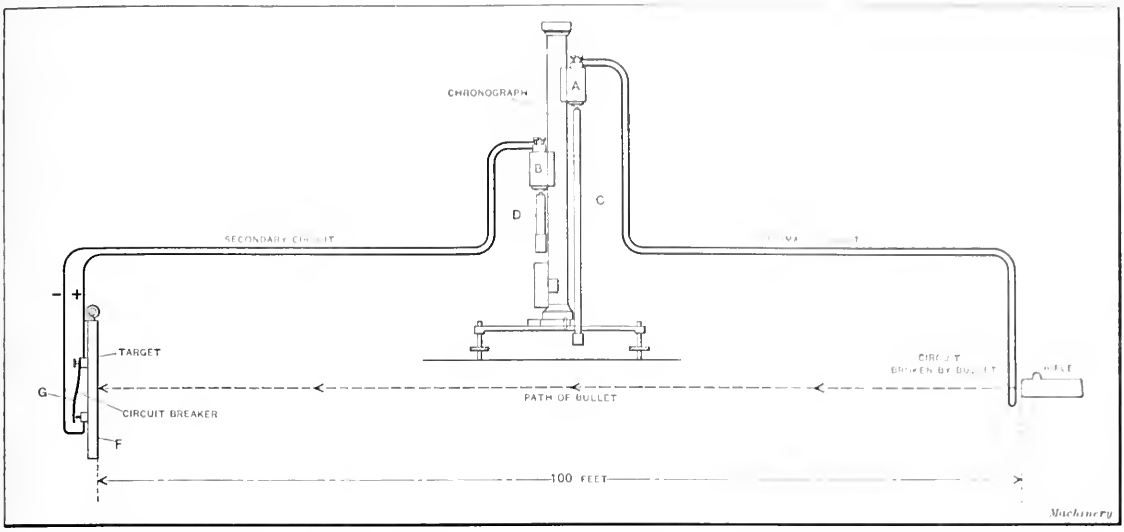

Fig. 4. Diagram showing how Primary and Secondary Circuits of the Chronograph are broken at Muzzle of Rifle and at Target by Bullet

projection on the bottom of the receiver, so that the breech-bolt is not only supported by the solid receiver frame at the rear, but has a positive support against downward thrust as well. In designing this action, particular attention was given to the matter of safety. By pushing the small slide *G* forward, the lever as well as the trigger is positively locked to prevent accidental discharge. The position of the hammer, that is whether cocked or uncocked, is shown by a small pin *H* which projects when the hammer is cocked.

As previously mentioned, the cartridges, when in the rifle, lie side by side around the circular, revolvable magazine carrier *C*. This arrangement prevents the bullet of one cartridge from bearing against the primer of another, thus making it impossible to discharge a cartridge while in the magazine by endwise shock. The forward end of the magazine carrier is in the form of a circular disk (see detail view) and is numbered from 0 to 5. These numbers are visible through a small aperture on the left side of the receiver and show the number of cartridges in the magazine.

General Process of Manufacture and Factory System

In this particular article, the manufacturing operations, as well as the inspection system, will be referred to in a general way, the idea being to present specific operations of interest in succeeding articles where the space will permit of detailed descriptions. Rifle manufacture is quite different from other lines of manufacture involving the use of metal-working tools. This is partly due to the irregular and intricate shapes of many of the parts, which makes it necessary to use many special tools and fixtures. The irregular shapes which must be machined, often with a considerable degree of accuracy, also greatly increase the number of operations required. For example, a receiver for the action illustrated in Fig. 3 requires 128 separate operations and the finger lever, 51. Most of these are machining operations. While in some cases there is a great deal of work on one part, this part is carefully designed to serve many purposes in a simple way.

The manufacturing operations may be divided into the following general classes: Turning, drilling, reaming and rifling the barrel; machining the receiver and its attached parts which form the action or breech mechanism; turning, inletting and mortising the stock; polishing and finishing the various parts; assembling; inspecting. The inspection is referred to last, but this does not mean that there is but one final inspection. In fact, this system has been very carefully developed and will be explained later.

The barrel is made from alloy steel of special composition and of the same analysis as the steel used in the barrels of the new Springfield United States Army rifle. After the outside is rough-turned close to the finished size, the hole is drilled. The drilling, reaming and rifling is done in the well-known Pratt & Whitney machines which will be described in the second installment of this series. The work on the breech mechanism is done largely on Lincoln type milling machines or "power mills," profiling machines, hand milling machines, and drilling machines. Multiple-spindle, semi-automatic, combination drilling, reaming, and milling machines of special design are also used for machining the receivers. While many of the operations on the different rifle parts are common to those familiar with manufacturing methods, the Savage factory contains a great variety of special tools and fixtures, many of which are very ingenious and enable the work to

Fig. 5. General View of Lincoln or Power Milling Machine Department at Savage Arms Co.

be done rapidly and accurately. Some of the small parts of the action, especially for the lighter class of rifles, are blanked out and formed in dies.

Many thousands of parts are being machined continually in the factory of the Savage Arms Co., and in order to account for these parts without confusion and excessive waste of time, a very simple but effective system has been adopted which is utilized by the cost, inspection and manufacturing departments. The most important feature of this system is a card, such as the sample shown in Fig. 6, which accompanies each lot of parts that is to be machined and makes it possible to determine quickly the exact quantity of completed parts that is in stock. This card also serves other important purposes in connection with inspection, etc. When

Fig. 6. Card used at Savage Factory in connection with Manufacturing and Inspection Systems

a certain lot of parts is to be machined the tray containing them is accompanied by one of these cards. As will be seen, it gives the model of the rifle, the name of the part and the lot number. All operations are numbered, and the vertical column to the left contains the operation numbers for this particular part. In the next column is recorded the number of parts which are sent to each operator and also the number of good parts he returns. In this particular case, the card shows that 500 parts were sent out for the first operation and 500 were returned. For the second operation, 500 parts were sent out but only 498 were returned, two being lost; hence 498 are credited on the card and the operator is paid for the actual number returned. On the third operation three parts were spoiled and did not pass the inspector so that the number is now reduced to 495, and the final number after the fifth operation is 494, because, in this case, one part was "skipped" and came to the inspection department without being machined. When all the operations are finished and the parts are found to be up to the required standard of accuracy, the final number of completed parts, as shown by the card, is transferred to a card index so that the quantity on hand can be determined at any time. The card also gives the name of the operator, the department in which the work was done, the date upon which each operation was completed, the rate of pay for each operator, and the names of the inspectors.

System of Inspection

Each machine department has one or two inspectors who make frequent inspections while the work is being done, so that in case a machine is out of adjustment slightly or a cutter has worn excessively, the error will be detected before a large quantity of work is finished. From this it will be seen that the inspection is not only to detect inaccuracies but to prevent them. For instance, if the "outside" or department inspector finds that the cutter of a profiler is a little too high, the parts which were milled while the cutter spindle was incorrectly adjusted are run through again. These outside inspectors are constantly on the lookout for trouble and greatly reduce the number of parts rejected by the final inspection which is made in a centrally located inspection department.

The method of handling the various parts, while they are being transferred from one department to another, is worthy of note. Small pieces, such as triggers, sears, hammers, etc., are kept in plain metal trays, and the larger parts, such as rifle receivers or pistol frames, are placed in special trays in an orderly, convenient way. A number of these trays may be seen in the illustration Fig. 1. When the parts in one tray have been machined and are returned to the inspection department, another tray of rough parts is ready, so that there is no delay.

In addition to the careful inspection of the individual parts during the process of manufacture, the action of the rifle is thoroughly tested in the assembling department, and, finally, the operation and accuracy of the rifle by actual use. In connection with this final test, which is made by expert marksmen, the sights are carefully adjusted.

Determining Initial Velocity of Bullet with Chronograph

One of the most interesting instruments used in connection with rifle testing is the chronograph. By means of this instrument, which is illustrated in Fig. 1, the initial or muzzle velocity of a bullet is determined. The chronograph has two magnets, *A* and *B*, which have sufficient power to hold the bars *C* and *D* when the circuits are closed. Magnet *A* is fixed to the vertical column of the chronograph, whereas magnet *B* is adjustable vertically. (The purpose of this vertical adjustment will be referred to later.) Magnet *A* is energized by a primary circuit, and magnet *B* by a secondary circuit. The primary wire crosses the muzzle of the rifle and the secondary circuit connects with the target. When the rifle is fired the bullet cuts the primary circuit and the long bar *C* drops. Now when the bullet hits the target, which is located 100 feet from the rifle, the secondary circuit is momentarily broken, thus demagnetizing magnet *B*. The short bar *D* then drops and falls through a tube located just beneath it and onto a trip which releases a spring-actuated marking plunger at *E*, which is forced outward and instantaneously makes a mark on the long bar *C* as it drops. The distance from this mark to a standard datum line on bar *C* indicates the initial velocity of the bullet. That this dis-

tance will enable the velocity to be determined will be more apparent when we consider the fact that if both circuits were broken at the same instant, the mark made on bar C as it fell would exactly coincide with the datum line, provided magnet B were adjusted to the proper vertical height; but there is an interval between the breaking of the circuits which is equal to the time required for the bullet to travel from the rifle to the target, or 100 feet. Therefore, when the primary circuit is first broken by the bullet as it leaves the rifle, bar C begins to fall and when the secondary circuit is broken by the bullet as it hits the target, the mark made on bar C does not coincide with the datum line but is some distance from it, this distance determining the velocity of the bullet. The velocity is ascertained by measuring the distance between the lines with a special instrument which resembles an ordinary vernier caliper, except that it is longer and is graduated to give direct velocity readings in feet per second.

Before using the chronograph it must be "leveled," which means that the adjustable magnet B for holding the short bar must be moved vertically until the marker strikes the long bar exactly on the datum line when both primary and secondary circuits are broken at the same instant. The distance from the marker to the datum line on the bar is standard and if the instrument is properly adjusted, the marker should strike this line when both magnetic circuits are broken at the same time. The point, however, at which the mark is made when the circuits are broken simultaneously varies with the altitude and also because of different atmospheric conditions; hence, it is necessary to make this vertical adjustment of magnet B each time the chronograph is used, and on some days considerable time is required to get the adjustment exactly right. The holding power of the magnets must also be within certain standard limits. The energizing current is regulated by a rheostat until the magnet will hold the bar but will not hold it when a standard auxiliary weight is attached. These weights are in the form of tubes which are placed over the bars and are supported by shoulders at the lower end. The tubes are shown in the lower right-hand corner of Fig. 1. The method of breaking the circuit at the target the instant the bullet strikes is very simple but ingenious. The diagram Fig. 4 illustrates the principle. When the bullet strikes the steel target plate F, the impact causes the thin, flat spring G to jump off the binding post which momentarily breaks the secondary circuit and causes the short bar of the chronograph to fall and release the marker, as previously described. This diagram also shows how the primary circuit is broken by the bullet as it leaves the rifle. Of course it will be understood that the position of the chronograph relative to the rifle and target is immaterial.

In the next installment of this article some interesting machining operations on various rifle parts will be described in detail.

* * *

The following story is told about the early experiences of one of the leading men in the machine tool building field in America today. Some twenty-five years ago, when he arrived in the United States from across the sea, his knowledge of the English language was not all that might have been desired, and when he was first employed in a railway shop the foreman, for that reason, proportioned his compensation accordingly. This man, however, was a good mechanic and he soon satisfied himself that he was giving as much in return for his small wage as the native journeymen. He therefore promptly applied to the foreman for a raise, which was refused with the explanation that as the young man could not talk English very well, it was not possible to pay him any more. This explanation was quite unsatisfactory to the applicant, who quickly replied: "——— ——— it. I want to know whether you are keeping me here to talk or to work." He got the raise.

* * *

A light weight metal alloy known as "metal cork," considered superior to aluminum, is made from about 90 per cent magnesium, the remainder being zinc, sodium, aluminum and iron. The specific gravity of this alloy is said to be 1.76.

THE SYSTEMATIZER AND HIS SYSTEM

Perkins was an efficiency expert and systematizer. He had equipped the offices with innumerable card systems and blanks and report forms, and to save work and time in the writing and reading of long and cumbersome names, the men in the shop were all numbered. He installed various accounting machines and also a Hollerith tabulating machine, such as is used by the census office.

He was also a worker, and so it happened that one Thanksgiving day, in the afternoon, when everybody else was digesting turkey, he went down to the shop to plan some more systems and devise a few more blanks to be filled out when a stripped 3/8-inch nut had to be replaced with a new one on the machine known as "B-No. 36." It happened that a little later in the afternoon he found that he wanted to run the tabulating machine, but as the engine in the shop was not running and as he did not know that there was an emergency connection with the city supply, he was at a loss how to get current for the 1/4-horsepower motor of the machine; but as a great systematizer is never at a loss for long, he wandered down into the engine room, only to find that the engineer was properly celebrating Thanksgiving with his family, as every engineer ought to be given a chance to do. In the boiler room, however, he found a fireman, and he promptly ordered him to start the 200-horsepower high-speed engine that was direct-connected to the dynamo, in order that current might be produced for the 1/4-horsepower motor upstairs. The fireman, however, knew nothing about engines, nor about dynamos, and what is more—he knew that he did not know anything about them, and he said so. The systematizer went upstairs again and thought the matter over, and the more he thought about it the more thoroughly it was impressed on his mind that a fireman was inefficient if he did not know how to run an engine in an emergency case, and he went down again and told the fireman that it was up to him to start that engine or lose his job. Now, the fireman was used to doing the firing himself, and being fired by somebody else did not appeal to him, particularly as he had a wife and children depending upon him; so he took a chance, and after he had tried a number of handwheels on various valves, he got the big engine started.

Then there was another difficulty—the fireman did not know which switch to throw to connect with the 1/4-horsepower motor upstairs. The efficiency expert, however, quickly found a way out of this difficulty. He told the fireman to throw in one switch at a time, he himself, in the meanwhile, being upstairs to note the effect. When the fireman threw the proper switch, the motor would start, and he would then signal over the telephone.

So after all the 1/4-horsepower motor was running fine and cards passed through the tabulating machine at high speed, and the systematizer was delighted to add to his collections a few hundred more cards; but in about fifteen or twenty minutes the motor began to slow down, and then it stopped suddenly. The scientific systematizer rose in wrath; the fireman was playing a trick on him and had turned off the power. In about three jumps he found himself downstairs in front of a frightened fireman protesting his innocence, and then they both entered the engine room. To a great systematizer the sight was probably not so horrible, but we hate to think of the words that the engineer used when, disturbed by a hurry-up call in his Thanksgiving celebration, he came in and saw it. The engine had been running without oil—there being no card index indicating how often the engine should be oiled—and the babbitted main bearing next to the flywheel had become overheated. More than that, it had become so excessively overheated that it had partly melted away, and the flywheel was tipped at an angle as if it, too, had been celebrating Thanksgiving in an improper manner. At the other end, the rotor of the dynamo was dislocated and the armature had scraped against the pole pieces.

Just how much it cost to repair the damage is recorded only in the card index of the scientific systematizer, and what the general manager said to him the next morning, when the full details of the matter had been established, is not recorded anywhere.

CHUCKING METHODS FOR IRREGULAR PARTS*

FIXTURES FOR HOLDING UNUSUAL LATHE AND BORING MILL WORK

BY ALBERT A. DOWD†

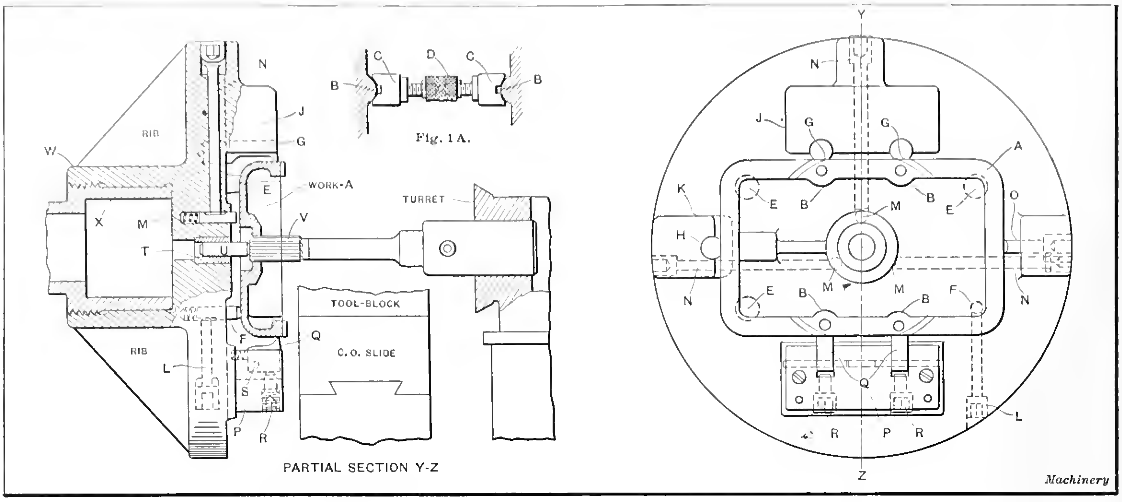

Fig. 1. Chuck for Rectangular Aluminum Castings used on Horizontal Turret Lathe

CASTINGS or forgings of irregular form usually require some method of holding (for the purpose of machining) other than chuck jaws, although there are many instances when the latter can be used to advantage. The form and size of the work have a great influence on the method of handling, and the accuracy required is also an important factor. The work itself may be in the rough state without any machining previous to the chucking operation or it may have been milled, planed or drilled. In the former case it is necessary to design a method of holding suited to the rough piece, and care must be exercised in selecting the surfaces best adapted for locating the work. It may even be necessary to have additional lugs or bosses cast or forged on the piece in order to facilitate holding it in position on the fixture. If walls are thin care must be used also in the method of clamping so that no distortion will take place. In case a previous operation of milling or planing has taken place, it is essential that the fixture be so designed that this surface be used for locating in order that accurate work may be assured. There are occasional instances when both milling and drilling operations have preceded the chucking. This may possibly complicate matters somewhat or it may simplify them depending on the conditions. Sometimes a series of holes has been drilled in a flange which has been surface milled, and in a case of this sort the holes may prove useful for clamping purposes. When a case is encountered with a milled surface and an angular hole, or some other condition of a similar nature, there may be more difficulty in designing the fixture.

The type of machine upon which the work is to be accomplished is also a factor which largely influences the design, and this matter should be decided positively before any attempt is made to draw up the device. The types of machines for which fixtures of this sort are most frequently designed

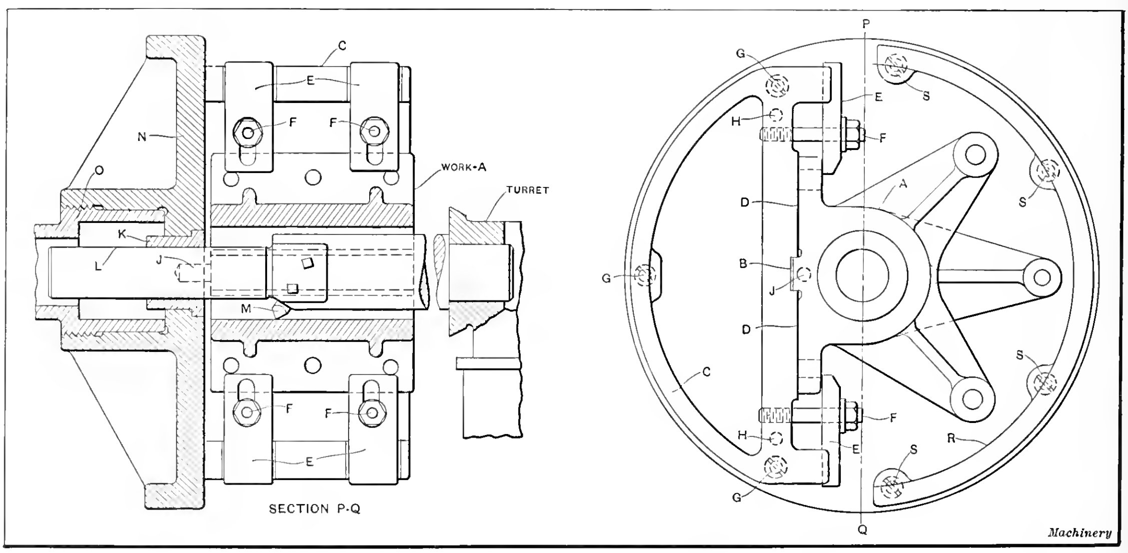

Fig. 2. Fixture for boring Irregular Castings on Horizontal Turret Lathe

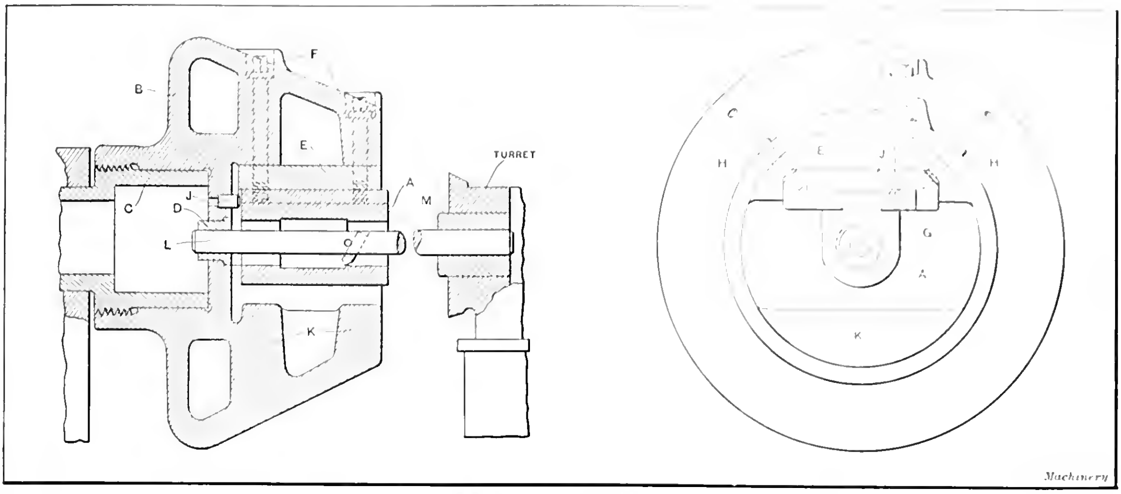

Fig. 3. Fixture for boring Small Bronze Castings on Horizontal Turret Lathe

are the horizontal and vertical turret lathes and the vertical boring mill. The engine lathe is also occasionally fitted with an arrangement for this kind of work, but as the construction of the fixtures is very similar to those used on the horizontal turret lathe it is not necessary to differentiate between the two in this article.

It is obviously out of the question to attempt to cover or describe all the conditions which may be encountered in the chucking of irregular work, but the examples here given represent a variety such as may prove of considerable value in elementary design. Adaptations to suit various conditions will suggest themselves to the progressive designer. Attention is called to a few of the important points in the design of fixtures of this character.

Important Points in Design

1.—*Locating points or surfaces.* These are very important and should be selected with care, having in mind any ribs, lugs or raised lettering on the casting, so that no trouble can be caused through faulty locating. Make use of the vee principle when the shape of the work will permit it. If four points are needed in the same plane for proper support or location of a rough surface, be sure that one of these points is movable to compensate for inequalities in the surface. If a finished surface is to be used for locating, the pads on which it rests should be as small as possible (consistent with sufficient surface for proper clamping) and should be easily accessible for cleaning.

2.—*Clearances around the casting.* These should be made ample to accommodate variations in the work. As a rule one-quarter inch on all sides of the rough piece is sufficient, on medium-sized work, such as that machined on horizontal turret lathes. On larger work for the vertical turret lathe or boring mill, one-half inch is none too much and even a little more than this is safer, for larger castings vary greatly in size and the writer has seen a fixture (within the last two years) which had to be machined to obtain sufficient clearance, although it was designed to give one-half inch clearance all around. Needless to say this was made for a large casting, and was used on a boring mill.

3.—*Clamping.* Methods of clamping are many but the plain strap is perhaps more used than any of the others, partly on account of its simplicity but also because it is very efficient. Hook-bolts are good if overhang is not too great, but they are worthless if not well backed up. They are also rather expensive. It is advisable to so design the clamping devices that they can be rapidly operated so that valuable time may not be lost in setting up or taking down the work. It is not considered good practice to use clamping screws which are tapped into a cast-iron body. It is much better to make these in the form of a stud with a nut and washer on the clamp. This brings the wear of the clamping action on steel instead of cast iron.

4.—*Chips.* Provision should be made for the removal of chips so that accumulations of these will not cause trouble. Accessibility to bearing or locating surfaces is important so that cleaning can be readily accomplished. When fixtures are of the pot variety cored openings may be arranged for this purpose. When fixtures are designed for use on vertical boring mills this point is of great importance and must be carefully considered in the design.

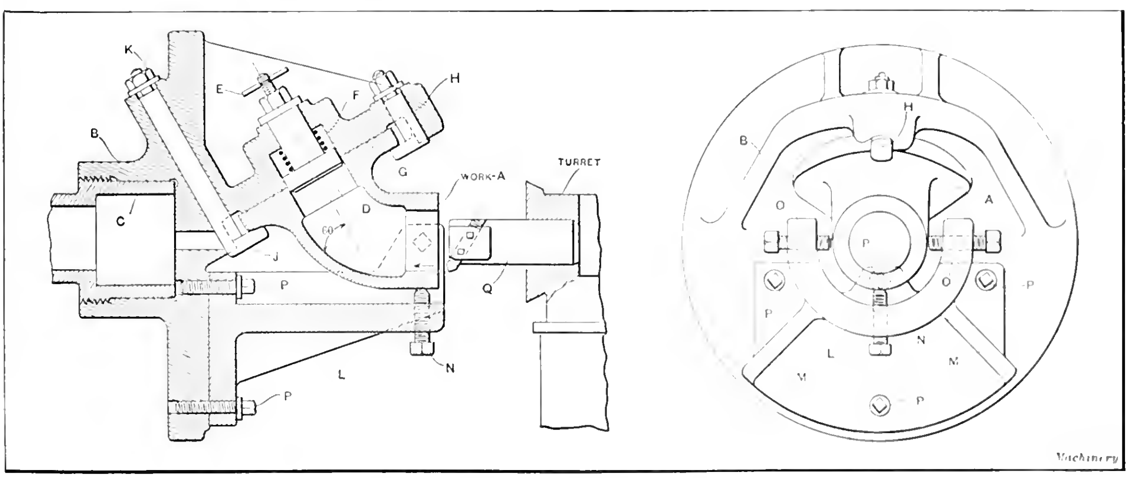

Fig. 4. Fixture for machining Angular Cast-iron Fitting

5.—*Rigidity.* On the horizontal type of machines this point is largely dependent on the overhang from the spindle. Therefore the fixture should be designed in such a way that this will be as short as possible. Ribbing may also be used when needed to give additional stiffness, especially around the clamps, as at these points the strains are excessive and changes may take place in the work itself unless provision is made to neutralize distortion. On the vertical type of machines fixtures should be made of generous proportions to resist the heavy cuts which these machines commonly take.

6.—*Safety.* The operator should be considered at the time the designing is done and not afterward. Projecting lugs, set-screws, etc., should be avoided as far as practicable, especially when their location is at the outer portion of the fixture. Lugs can be easily made so that they have round corners which will not catch in the operator's clothing, and set-screws of the hollow variety may now be obtained in many different forms suited to almost all conditions.

7.—*Cost.* This should be to a certain extent proportional to the accuracy required in the finished work and also to the number of pieces of one kind which are to be machined. A very elaborate and costly fixture should not be designed for a case calling for only a few pieces as this cost distributed on the work would greatly increase the cost of each piece.

The work was placed in the fixture so that it rested on the three fixed pads *E* located at the corners, and a spring pin *F* acted as an adjustable support at the other corner. The coil spring under the pin is just strong enough to insure positive contact with the work without danger of springing. The set-screw *L* is of the hollow type and serves to lock the pin securely in position. The side and end locations of the work are determined by the pins *G* and *H* which are flatted off to form a knife-edge where they touch the casting. This arrangement causes them to sink in and prevents any tendency to pull out of the fixture. It will be noted that these pins are set into the blocks *J* and *K* which form a solid backing and prevent springing. A steel block *P* is screwed to a finished pad on the fixture body and is doweled in place. Two knife-edged clamps *Q* fit slots in the block and are pivoted on the pins *S*. They are forced into the casting by means of the hollow set-screws *R*, and have coil springs for the purpose of keeping them back when not in use. In connection with these clamps, attention is called to the points on which they pivot; these are placed well back from the knife-edge so that the clamping action also has a pulling-in tendency. As a means of support for the center of the work, the three spring pins *M* are provided, these being arranged in the same manner as the pin *F*, and locked in position by the set-screws *N*. The

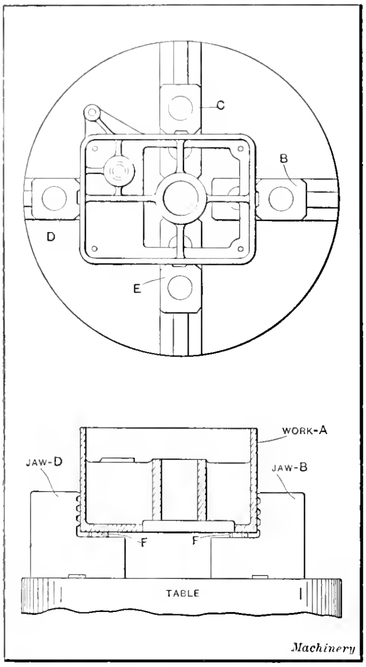

Fig. 5. Use of Four-jaw Chuck for holding Rectangular Work on a Vertical Lathe or Boring Mill

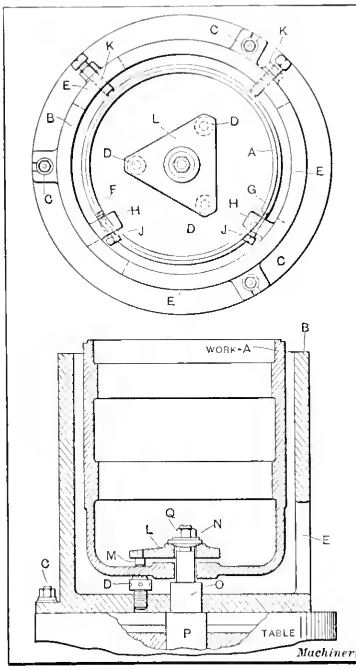

Fig. 6. Pot Casting Fixture for holding Steel Castings on Vertical Turret Lathe

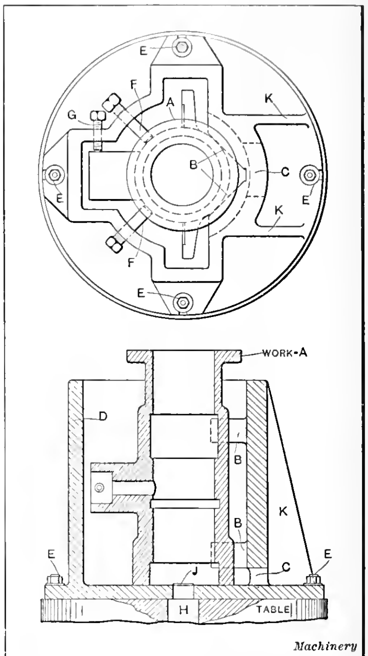

Fig. 7. Pot Casting Fixture for holding Irregular Steel Castings on Vertical Turret Lathe

When a large number of castings are to be handled, however, the first cost may be almost overlooked and every improvement used which will tend to decrease the production time.

In the examples given herewith attention will be called to some of the important points in design and construction, faults will be emphasized, and suggestions made. It should be borne in mind that the examples illustrated have been selected with a view to simplicity rather than complexity of design, so that basic principles will be readily grasped.

Chucking Fixture for a Rectangular Aluminum Casting

The work shown at *A* in Fig. 1 is an aluminum cap for an electric generator. The casting is somewhat rectangular with round corners and is of rather thin section with practically no reinforcement in the shape of ribs. No work has been done upon it previous to this setting so that the casting is in the rough. The machining necessary for this series of turret lathe operations consists of boring, reaming and facing the inner hub; facing the rim and sizing the segmental circular tongues on the face of the rim. An accurate job was required, and no distortion of the casting was permissible.

body of the fixture *W* is well ribbed up at the rear and is bored out and threaded to fit the spindle *X*. A tool steel, hardened and ground bushing *T* is forced into the center of the body, and acts as a guide for the boring and reaming bars. The pilot *U* of the floating reamer *V* is shown in position.

After this fixture had been completed it was tested and was found unsatisfactory, due to the spring of the work at the clamping points *B*. In order to remedy this defect, a pair of special supporting jacks were made such as shown in Fig. 1A. Two steel vee-blocks *C* were turned down and threaded with right- and left-hand threads, respectively, to fit the knurled collar *D*. These jacks were placed in position in the casting before it was placed in the fixture, and were tightened by the fingers, a piece of drill rod being used for the final pressure. By the use of this device a perfectly rigid effect was produced and the work obtained thereafter was entirely satisfactory. In the design of this fixture as a whole, attention is called to the freedom from projecting set-screws, and other protuberances likely to catch in the operator's clothing.

Special Fixture for a Bearing Bracket

The work A shown in Fig. 2 is a cast-iron bearing bracket of somewhat peculiar shape. This has been planed in a previous setting, on the base D, and the tongue B has also been machined to size. The body of the fixture N, made of cast iron, is screwed to the spindle O of a horizontal turret lathe. It was faced off in position on the machine so that the face would be perfectly square with the spindle. The semicircular pot casting C, carefully located on it by the dowels H, is held in place by the screws G which enter it from the rear. The work A is located on the face of this casting by the tongue B which fits a slot cut to receive it. The clamps E are of steel and are slotted so that they can be pulled back out of the way when placing the work in position or removing it. The studs F are threaded to a tight fit in the casting C, and are provided with nuts and washers which bear on the clamps. In this construction the wear due to the operation of the clamps all comes on the steel of the screw rather than on the cast iron, this tending to make the life much longer, and the up-keep better. The lugs on which the ends of the clamps bear are slotted in order to prevent twisting while they are being tightened. These slots are not machined but are cast and afterward smoothed out with a coarse file. The pin J in the body of the casting simply acts as a longitudinal stop.

Partly as a protection to the operator and partly as a counterbalance, the segmental piece R is screwed to the body by the four screws S. This arrangement is valuable because the work is revolving at a fairly good speed (120 R. P. M.) so that good balance is important, and danger to the operator is avoided on account of the guard over the projecting lugs on the work. Attention is called to the accessibility for cleaning the locating surfaces and also to the ease with which a wrench can be used on the clamping nuts. A point in the design which could be improved is the amount of surface used for locating. Small pads under the clamping surfaces and a rim on each side of the tongue would have been ample and could have been kept clean more easily. A tool steel bushing K is forced into the body of the fixture and acts as a guide for the pilot L of the boring-bar, which greatly assists in preventing chatter while the tool M is cutting. The work accomplished in this fixture was satisfactory.

High Speed Fixture for a Bronze Bearing

The bronze bearing shown at A in Fig. 3 has been previously machined on the dovetail portion, and it is of importance that the bearing should be in a fixed relation and parallel with this dovetail. As the hole is of small size and the work of bronze, it is necessary that the fixture should run at high speed in order to produce the work in a reasonable time. The body of the fixture B is made of cast iron and is fitted to the spindle C of a horizontal turret lathe. A steel locating block E is fitted to the dovetail of the work and is fastened into its seat in the body by the screws H. Two screws F are tapped into the dovetail gib G, so that they can be used to tighten the work in the fixture without chance of distortion. The pin J acts as a longitudinal stop. The lugs K are provided for the purpose of balancing the fixture so that it will run without vibration which might otherwise be caused by the high speed and spindle overhang. It will be noted that the outside of the fixture is smooth, thus offering no danger to the operator. Obviously a socket wrench is used to tighten the gibs which secure the work in position. A tool steel hardened and ground bushing is forced into the body at D and acts as a guide to the boring-bar L which is necessarily small and needs support. The other end of the bar is held by the bushing M in the turret hole. This fixture is quite simple but the method used is a little out of the ordinary. It should be noted that the clamping device is efficient and does not tend in any way to distort the work. Its action is in two directions on account of the angle of the dovetail and therefore makes a positive location, as it crowds the work into the dovetail and draws it back at the same time. The fixture was used with satisfaction.

Fixture for an Angular Cast-iron Fitting

The rather awkward piece of work shown at A in Fig. 4 is an angular cast-iron fitting which has been previously machined at G and had the hole at this end bored. The angle required between the two openings is sixty degrees. The machine to which this fixture is fitted was a horizontal turret lathe. The body of the fixture B is of cast iron and is screwed to the spindle C in the regular way. The angular pad which receives the finished portion G of the casting is machined to give the correct relation between the holes in the joint. A spring plunger D is located centrally in this pad, and serves to locate the work in relation to the previously bored hole. The pin E is used to pull the plunger back when placing the work in position. The hook bolts H and J grip the piece by the flange and hold it firmly against the locating pad. It will be noted that J passes through and is operated by the nut and washer at K on the back of the fixture. In order to insure rigidity to the forward portion of the piece where the work is being done, a segmental casting L is used, which is secured to the body by the four screws P. The set-screws N and O are cup-pointed, and greatly assist in keeping the work rigid at this end. It will be seen that the bracket is well ribbed up at the points M to secure additional stiffness. A plain boring-bar Q is held in the turret.

Simple Arrangement Using Four Jaws

The motor bracket casting shown in Fig. 5 is of cast steel and has been previously machined on one of its faces. Four jaws in a chuck of the independent type are used in this setting of the work, and the machine employed is a vertical turret lathe. The bracket which is to be machined is located by the two jaws B and C which are left set to fit the work. The function of these jaws is to take the place of a vee-block and the other jaws are used for the purpose of holding the work securely. The shape of this piece of work being rectangular, it is feasible to use this method for locating, by allowing them to act as a vee. In action, E and D are brought up alternately until the work is securely held. The surface of the work which has been previously machined is supported by the steel buttons F which are positively located in the jaws. This method is adaptable to work which comes along in small lots but it is open to objections. The principal one of these is the possibility of the operator's shifting one of the vee-jaws unconsciously thereby ruining valuable castings. Another is the possibility of variations in the squareness of the machined face with the gripping surface, which will naturally result in work which is not absolutely true. But as a makeshift method when only a few pieces are to be machined, it is satisfactory in the majority of cases unless a very careless workman is employed.

Pot Fixture for an Electrical Piece

The steel casting A in Fig. 6 is a piece of work which is handled in the rough, no previous machining having been done on it. This casting is of large size and being of steel is subject to variations in size and shape. As this is the case it is necessary to make suitable provision for these so that compensation may be obtained to suit the various conditions. The vee-principle is made use of in the locating device as far as the cylindrical portion is concerned, the set-screws K being adjusted to suit the casting, so that it is centered from the rough exterior. The pot casting B is of cast iron and is centered by the plug P in the center of the table. This plug is forced into the pot casting at O. The work is dropped into the fixture and forced over against the vee-screws K, by the square-head set-screws J which are tapped into the lugs H, and come against the open portion of the work at F and G. Support is obtained by the screws at the three points D, two of which are movable and the third fixed. The movable points are as shown in the lower view, and they are adjusted by means of a piece of drill rod so that the entire casting can be tipped one way or the other to compensate for inequalities in the rough casting. The steel triangular plate washer L is fitted with three clamping points M which bear on the inside of the rough casting and are equalized so that they all get the same amount of pressure, by the spherical washer N, operated by the nut Q. The entire fixture is held down on the table of the machine by the tee-bolts C which fit the table tee-slots. This fixture gave results which were satisfactory, but the setting-up time required was rather long. The openings E shown in the illustration permitted

access to the jack-screws and also allowed cleaning to be easily accomplished. The projecting set-screws are a rather bad feature, as they are dangerous to the operator, but as the speed was not excessive, no trouble was experienced with them. This defect could have been very easily remedied.

Fixture for a Piece of Hydraulic Work

The casting *A* shown in Fig. 7 is of steel and is handled in the rough, no previous machining having been done. This work could have been handled in a three-jaw chuck combination, had it not been for the projecting lugs on the casting, and even these could have been taken care of by cutting away the sides of the jaws. A pot casting method was decided upon instead of this, however, on account of the greater rigidity. The body *D* is of cast iron and is fastened to the table with the four tee-bolts *E*. On one side of this body are two pads *B* which are planed out to form a pair of vee-blocks in which the cylindrical portion of the casting locates. It is forced into position by the screws *F* in the wall of the pot casting. The entire fixture is located on the table by means of the steel plug *H* which fits the table center hole and is forced into the fixture at *J*. A driver is provided in the screw *G* which bears against the hub of the casting and takes the thrust of the cut. Although this is a very simple fixture it illustrates the principle of the vee-block to advantage and should therefore be carefully noted.

The examples illustrated in this article have been selected from a number of fixtures for irregular work, principally because they are of a simple nature and yet illustrate various conditions fully as well as if they were of a complicated structure.

* * *

"MOVIES" MEETING OF THE EFFICIENCY SOCIETY

On the evening of May 26 the Efficiency Society held its regular monthly meeting. This session was designated as a "Movies" meeting, because of the fact that motion pictures and their relation to greater efficiency in the manufacturing and selling interests were discussed. The meeting, which was preceded by a dinner, was held at the Aldine Club, New York City. Major Charles Hine, the presiding officer, stated that it was through the efforts of Fred Hawley, the chairman of the plan and scope committee, that the various films shown to demonstrate the greater efficiency in business that could be secured by the moving picture, were obtained. In connection with the showing of the films, the secretary of the society, Elihu C. Church, made explanatory remarks.

The films shown were divided into two classes, those of interest as efficiency promoters in the factory, and those of interest for promoting selling efficiency. The program under the first class included an interesting film made in the United States Steel Corporation's plant at Gary, Ind., vividly calling attention to accident prevention and self-development for workers in the industries. This was followed by a manufacturing descriptive film from the Ford Motor Co.'s plant; then by a demonstration of the oxygraph. After this followed several microscopic analysis films, in which the motions of a ball balanced on a column of water were analyzed, and the trajectory of a bullet was shown. Time and motion studies were also shown, illustrating the advantages to be gained by the efficiency engineer by analyzing motion through the medium of the moving picture.

As a promoter of selling efficiency, films were shown to illustrate the advantages to be gained by the farmer in using dynamite. In this film the tools and methods of procedure for blasting stumps and felling trees were shown. This was followed by a film showing the operations of a ditch digging machine, bringing out the point that even if impossible for a salesman to show his prospect the actual apparatus, the moving picture film formed a good substitute. The final film was a selling educational film to illustrate various electrical devices as used in the home.

The evening's program did much to demonstrate to the efficiency engineer that the moving picture, like the phonograph and similar inventions that were originally laboratory experiments and later entertainers, are finally evolving into valuable adjuncts to business.

A CONVENIENT TOOL COMPARTMENT

A convenient type of tool-holding compartment especially adapted for screw machine tools is in use in the plant of the DeVilbiss Mfg. Co., Toledo, Ohio, manufacturer of atomizers. This tool-holding compartment is of simple arrangement and keeps all the tools separate and all the tools for one job in one place. As shown in the accompanying illustration, it comprises five compartments, each of which contains sixty boxes. On the door of each compartment is a card which gives the job number, the number of tools used, and the number of the box in which these tools are contained.

The screw machine cams are numbered, as they cover several jobs, and are held on a separate rack provided with pins which fit into the large hole in the cam. All collets,

A Convenient Tool Compartment

spring fingers and standard tools are held in racks inclined at an angle of about 45 degrees, which form the last compartment of this row. These racks are arranged in shelf form and are spaced so as to give plenty of room for all the tools. There are spaces for six tools in a row. The special feed tubes are held on the rack shown to the left of the compartment. D. T. H.

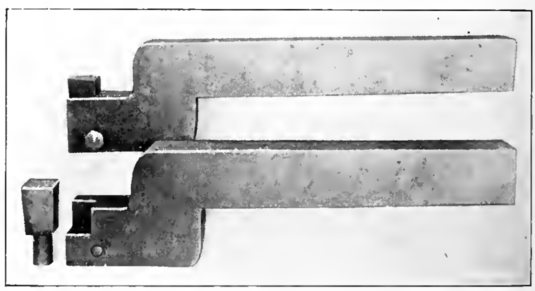
A NON-CHATTER PLANER TOOL

To overcome the chattering encountered on a hard job of planing, the Stockbridge Machine Co. of Worcester, Mass., made a special planer tool with an inserted cutter, shown in the accompanying illustration. The illustration shows two of these tools, right- and left-hand; one has been disassembled and the other is shown with the cutter in place. The tool-holder is of the familiar gooseneck form and the cutter is held in by a clamping bolt at the side. The cutter



Right- and Left-hand Planer Tools made to obviate Chatter

is square in section and fits snugly in a machined section of the tool-holder, being supported on two sides. A round shank is provided that fits into a corresponding hole in the tool-holder. A section of the round hole extends through a slip bushing through which the clamping bolt passes. Thus, when the clamping bolt is tightened, it pulls against the shank of the tool and binds it firmly in place. In using this type of planer tool, there is not the slightest tendency to chatter.

ELECTRIC ARC WELDING*

APPLICATION OF THE CARBON AND METALLIC ARC IN CUTTING AND WELDING

BY ALAN M. BENNETT†

ELECTRIC arc welding as a means of uniting metals—particularly iron and steel—has been rapidly developed in the past few years, and apparatus for doing this work is now a standard product with a number of manufacturing concerns. This process of welding is particularly applicable to certain classes of work encountered in foundries, railroad shops, tank and boiler shops, steel mills, locomotive shops, and shipyards; and the demand for welding apparatus from these sources is well established. In addition to the field covered by these industries, where the use of this process has become more or less standardized, there are countless other lines of manufacture, each representing a great variety of work to which arc welding is adapted.

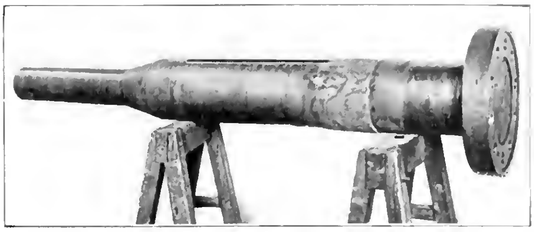

Fig. 1. A Built-up Fit on an Armature Shaft done with the Metallic Arc

Fig. 2. Head, Flange and Branches welded in a 42-inch Tank with the Metallic Arc

Various methods of using the arc for welding have been devised from time to time, the majority of which have met with indifferent success. At the present day practically all welding, in this country at least, is confined to the method in which an electrode and the object to be welded are connected in a simple electric circuit, and an arc of limited size is drawn between the two by bringing the electrode in contact with the work at the point at which the weld is to be made. The size of the arc is capable of adjustment to suit various classes and conditions of work.

The Carbon Arc

In practice there are two methods of applying this process to the making of welds and the cutting of metals. In the first, which makes use of the carbon arc, a rod of graphite forms the electrode; and the arc drawn between this rod and the work heats the latter to the point of fusion. This method is used for cutting or burning off metal, and is the simplest application of the arc. Its principal use is for reducing scrap material to sizes capable of being easily handled, and in foundries for cutting risers and fins from large castings. By extending this process of fusion and introducing pieces of metal within the influence of the arc, actual welding or building up of the work is accomplished. The metal supplied, which may be either in the form of small pieces of scrap material or a rod held in the operator's hand, is fused and unites with that part of the work already raised to a molten state by the heat of the arc, forming a solid mass of even structure upon cooling.

Fig. 3. Fractured Section of Locomotive Frame before repairing

The principal field for the use of the carbon arc is in foundries and steel mills, for the repair of broken and imperfect castings of large size. The loss from this source, which is always high, can be reduced to a very small percentage, as castings containing blow-holes, cracks, shorts, etc., can readily be repaired with a small expenditure for material and labor. For all work of this nature in which the carbon arc is used, comparatively heavy currents are required, ranging from 300 to 600 amperes. Owing to the ability to use these heavy currents, and to apply the heat quickly and concentrate it at the required point, the heat generated at any particular point is very intense and the process of cutting or welding becomes a very rapid one.

The Metallic Arc

The second method in this process of welding makes use of a metallic electrode—usually of a soft grade of iron or steel—which during the operation of welding is fused by the heat of the arc and carried over in the form of small globules that are deposited at the point on the work from which the arc rises. The work itself is raised to a state of incandescence at this point, and the fused metal unites with it as it flows from the electrode. The operation of welding by this method is very rapid, as the fusing of the electrode is continuous after the arc is started, the drops of molten metal following each other in close succession. This method is extensively used in all classes of repair and reclamation work, such as filling in cracks of broken castings, building up the worn parts of rolls and rails, repairing cracks in boilers, patching locomotive fireboxes, and in many industries as a manufacturing means in the process of getting out the finished product. Examples of this latter use are the welding of heads and branches to tanks, joining the seams of tanks and boilers, welding fireboxes, flue sheets, boiler tubes, etc., and all classes of pipe and sheet metal work.

Fig. 4. Section of Locomotive Frame after repairing

The current required for the metallic arc is small compared with that used in connection with the carbon arc, rarely exceeding 175 amperes for the heavier classes of work just described, and ranging from this down to as low as from 12 to 15 amperes for

* For other articles on electric welding which have appeared in MACHINERY, see "Point and Ridge Method of Electric Welding," September, 1911; "Electric Butt Welding," October, 1910; "Electric Welding of Copper, Brass and Aluminum," March, 1910; "Electric Welding," February, 1909; "Electric Welding of Tools," October, 1908; "Electric Welding of Dissimilar Metals," July, 1908; "Some Examples of Electric Welding," April, 1908; and "Notes on Electric Welding," April, 1903.

† Address: 324 Prospect St., Westfield, N. J.

thin sheet metal work. The size of the electrode used also varies with the nature of the work and current required, the average being from 3/32 to 1/8 inch in diameter. That it is necessary in every case to have a proper relation between the current strength and the size of the electrode can be seen, when it is considered that the heat of the arc must be sufficient to raise a spot on the work to the point of fusion, in order that there may be actual union of the metal from the electrode with the work. If this condition of right temperature does not obtain, there will be an imperfect union of the oncoming metal with the work, and a poor weld will be the result. On the other hand, if the metal is overheated there is danger of burning it. Oxidation also takes place more rapidly, thus impairing the weld, and heavier heating and cooling strains are set up in the metal. The current must, therefore, be regulated to bring about the condition of a proper temperature rise in the work, and the size of the electrode should be selected to carry this current without danger of its being overheated

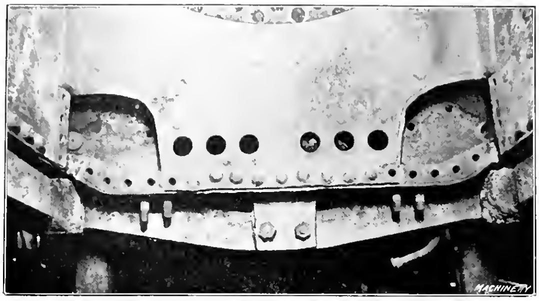

Fig. 5. Fractured Mud-ring of Locomotive Firebox prepared for making the Welds

and oxidized. On the other hand, the size of the electrode must not be too large for the current used, as this will result in slow and imperfect fusion, and equally slow and unsatisfactory welds.

Combined Use of Arc

In many cases, and more particularly in repair work, it frequently becomes necessary to remove parts of the metal at the place where the weld is to be made. For example, to widen out a crack in order that the metal from the electrode may be more readily deposited in it; or to cut out a burned, broken or worn spot for the insertion of new material. This operation of cutting is most readily performed by means of the carbon arc. In such work, therefore, the alternate use of the carbon and metallic arcs becomes desirable and to meet this requirement, as well as to make the outfit as general in its application as possible, means are usually provided whereby both classes of welding can be done from the same outfit. This feature also makes preheating possible, by which means work of large section is raised in temperature by use of the carbon arc, before the welding is actually done. The operation of welding on the hot metal results in the strains being more evenly distributed, both during the process of welding and when the work is cooling off. Welds of greater strength are thus obtained, and the structure of the metal in the weld is more homogeneous with that of the surrounding parts.

Description of Apparatus

The simplest possible outfit for welding would consist of a source of direct-current supply, an adjustable resistance for regulating the current, and an electrode holder. In practice, for reasons which will be explained later, the current is usually furnished by a low voltage generator which may be driven by a motor, engine or belt. In addition, the outfit usually includes a switchboard having on it the starting apparatus for the motor end of the outfit, if motor driven; the control and indicating apparatus for the generator, consisting of a field regulator, voltmeter, and ammeter; and the regulating apparatus for the arc circuits, consisting of a set of current regulating switches with resistance, and usually some form of automatic switch or contactor.

The generator should be compound wound in order that the voltage may be maintained constant under varying load. The need for close voltage regulation will be found to be greatest in connection with the metallic arc, and to increase as the size of the arc and the amount of current used decreases. The smaller arcs will be found to be very sensitive to even the slightest voltage variation, the direct result being an uneven deposit of metal, and burnt welds in the case of very light work. With the carbon arc, where the current used is generally large and where a certain amount of current regulation can be had by lengthening or shortening the arc, the need for close voltage regulation is not so great.

Of the resistance, a certain part is in circuit with the arc at all times when working, this resistance causing the difference between the voltage drop in the arc and the terminal voltage of the machine. It will vary with the amount of current required for welding, and is adjusted by the current regulating switch. When no contactor is employed in the arc circuit, the current at the time the arc is started is limited only by the resistance in that circuit, which is the amount required for welding. This may be of low value, particularly when using a heavy current. There is, therefore, danger of short-circuiting the generator until the arc is established and its resistance introduced into the circuit. The function of the contactor in the arc circuit is to cut out resistance after the arc is established, leaving in the circuit for welding that amount previously determined from the current to be used. By this means the chance for short-circuit is removed, and the apparatus made more automatic in its operation.

After the current is adjusted to give the size of arc needed, no further adjustment is necessary and the arc may be drawn and broken at will, the automatic character of the apparatus always insuring a return to normal conditions. By this means the operator is relieved of all concern as to current regulation, and his whole attention may be given to directing the arc over the work. The operation of welding by either of the methods described makes necessary the renewal of the electrode, though the rate at which the metallic electrode is consumed—owing to the fact that it constitutes the filling material—is much more rapid than that of the graphite rod. To facilitate the act of renewal or of feeding down as it is consumed, the rod forming the electrode is secured to a holder by some form of clamp that readily permits of its being released. The holder is designed to carry the current to the electrode with the least amount of heating of the operator's hand.

Fig. 6. The Completed Weld with Sections of the Throat Sheet replaced

Owing to the intense nature of the light and heat rays from the arc, the necessity for careful protection of the operator's hands, face and eyes is very important. This is particularly so in the case of the carbon arc, where the volume of light and heat is very great. Heavy gloves serve to protect the hands, while for the face, some form of shield held in the hand or supported from the head is generally used. This is provided with an opening filled with several thicknesses of ruby or blue glass, which afford protection to the eyes and still permit of the welding operation being closely followed.

Potential Required for Welding

The potential which has been found to give the most satisfactory results for welding varies from 65 to 75 volts. A

higher potential can, of course, be used, but as the drop in the arc rarely exceeds 65 volts, a potential in excess of this would have to be reduced by means of resistance in series with the arc. The wasteful effect of using a higher voltage, or of welding directly from shop or commercial circuits by means of resistance banks or water rheostats can be seen. The higher the voltage of the circuit from which welding is done, the greater the amount of resistance needed and the greater the energy loss due to this resistance. Assuming that 75 volts is the maximum required for all cases of ordinary welding, if a 220 volt circuit is used for this purpose the efficiency is seen to be approximately 33 per cent, while at 500 volts it is as low as 15 per cent. It will also be found that when heavy currents—such as are required for welding—are taken directly from the line, serious voltage fluctuations will result, with corresponding ill effects on the apparatus connected to the line.

Flexibility of the System

Any number of operators may weld from the same outfit, each working independently of the other and taking the amount of current required for his own particular work, the self-regulating feature of the generator insuring a constant voltage. All of the arc circuits may be taken from the one welding panel or they may be divided among several smaller panels, which may be located at various centers at which it may be desired to do welding, these panels being connected by leads through the shop to the main panel. The latter, in this case, would contain only the motor and generator control apparatus. This arrangement is particularly desirable in locomotive and railroad shops, where the majority of the work is of such a nature that it cannot be moved around conveniently for welding. For doing work of this nature, the electrode holder is often fitted with leads of sufficient length to allow the work to be reached.

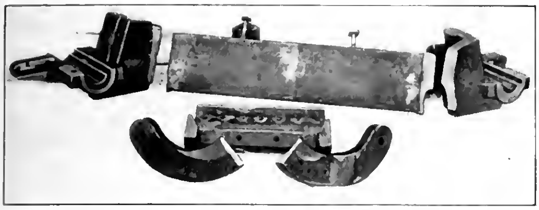

Fig. 7. Broken Casting from a Wood-working Machine

Welding can thus be done up to any distance from the outfit, the only limit being the allowable voltage drop in the lines to the work and the electrode. This, in turn, can be regulated to a certain extent by increasing the size of the cable as the distance increases. Beyond 500 or 600 feet, however, this method is hardly practicable for any work other than that which can be done with the metallic electrode, as the size of the cable required for carbon work with its large currents would increase to such an extent that its cost would be prohibitive and the handling of the cable exceedingly difficult. To meet conditions of this character a complete portable outfit consisting of generating and regulating apparatus, mounted on a truck that can be moved from place to place, is most appropriate. For land use the generator end of such an outfit is usually motor driven, while for marine work steam-driven outfits mounted on barges afford the most convenient arrangement.

Special Features

In connecting the work and the electrode in the welding circuit, the former should be connected to the positive side of the source of supply. There are two reasons for this, the first being that the positive side of the arc is by far the hotter of the two. The point on the work under the action of the arc is thus brought to the required fusing temperature in less time than if it were connected to the negative side of the circuit. A better distribution of heat between the electrode and the work is also secured by this means, as the electrode which is usually of small mass compared with the work should naturally be subjected to the less amount of heat. But a more important reason for this arrangement is that when the electrode is made positive the resulting arc is found to be very erratic and unstable, and its control becomes practically impossible.

It is not necessary that the operation of welding always take place in a downward direction. While work with the carbon arc has to be done in this position, due to the flowing of the metal in the weld, the metallic arc can be used as readily on vertical or overhead welds as on downward ones, the only difference being in the rate at which the metal is applied. Owing to the fact that in any position other than downward, the metal is applied against the force of gravity, its rate of flow from the electrode is necessarily slower. This feature of being able to weld with the work in any position occasions a great saving in the amount of handling which would have to be done were it necessary that all welding take place in a downward direction. The arc process of welding is thus seen to be exceedingly flexible in its application, covering work of practically all classes and degrees of accessibility, and this feature greatly facilitates the operation of welding. Handling of the work is reduced to a minimum, and welds are made with an ease and despatch not approached by any other method.

Character of Welds

A large measure of the success attained by this process is accounted for by the satisfactory character of the welds from the standpoint of efficiency. By a proper selection of the grade of filling metal, and the exercise of care in making the weld, it is possible to obtain a tensile strength in the weld of from 95 to 97 per cent of that of the original section. Welds made under the average conditions of everyday work show a tensile strength of from 80 to 90 per cent of the metal. It is possible by slightly reinforcing the welded section to make the strength of the weld even greater than that of the original section. This may be very desirable in many cases where a part has broken through having an undue strain put upon it. By a proper increase of section at this point, a repetition of the break may be avoided. Welds made by this process present a neat and finished appearance. With the metallic arc, the filling metal added from the electrode can be deposited exactly where it is wanted; and with the carbon arc, where the added material is reduced to a molten state in the weld, it may be run at pleasure, extra material being added where needed and the surplus metal being fused

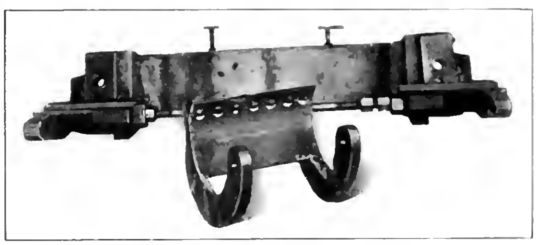

Fig. 8. Same Casting repaired with the Carbon Arc

down to the desired level. In either case, little or no trimming of the finished weld is necessary.

Examples of Work done by the Electric Arc

The illustrations show examples of electric arc welding. While these are of a varied character and show work done with both the carbon and metallic arcs—with a considerable range of current—they do not in any way represent the complete possibilities of the process of arc welding and cutting. Fig. 2 shows an example of tank welding, in which the head, flange and branches of a tank 42 inches in diameter were welded with the metallic arc. The current required was approximately 165 amperes at 70 volts. The finished appearance of the welds and the necessity for little subsequent trimming will be evident from this illustration. Figs. 3 and 4 show a fractured section of a locomotive frame before and after welding. In repairing a break of this nature the metal is cut away along the line of fracture, forming a V-shaped opening. This is filled with the repairing metal. The current required for work of this kind will vary from 500 to

600 amperes. It will be noted that the section has been reinforced where the metal was added.

An armature shaft that had been turned too small at the spider fit is shown in Fig. 1; to remedy this error metal was added by means of the metallic arc, thus increasing the diameter sufficiently to provide for refinishing the fit to the required size. This was done with the metallic arc, using current of approximately 160 amperes. Figs. 5 and 6 show the repair of a fractured mud ring of a locomotive firebox. It will be seen that part of the throat sheet has been cut away in Fig. 5 in order to give access to the mud ring. The fractures in the corners are first opened up with the carbon arc preparatory to welding, and after the weld is completed the sections of the throat sheet are replaced and welded as shown in Fig. 6. In this illustration, it will be noticed that the weld on the right-hand side has been dressed, while that on the left has not. The latter shows the appearance of the weld immediately after making a repair with the metallic arc. Figs. 7 and 8 show a broken casting of a wood planer before and after being repaired with the carbon arc. In cases of this kind the broken part is in use again in a short time, as the delay occasioned by having to replace it with a new casting is avoided.

Cost of Welding

The cost of making welds by this process can best be illustrated by examples covering operations of a common or familiar nature. The work capable of being done by arc welding is of such a varied character that it is not possible to give specific costs for each and every case that may present itself. The cost of generating current, the price paid for labor and the time required for doing any particular job will vary, and this will influence the cost of the weld. Of these three factors the first will be found to vary between the widest limits, the price of labor for the various classes of welding being fairly well standardized, and the time required for making welds not varying greatly where expert welders are employed. The cost of producing the following welds is figured on the basis of labor at 30 cents per hour, and current at 2 cents per kilowatt hour, the voltage in each case being approximately seventy.

A broken shaft 2 inches in diameter was welded and ready for refinishing in one hour; the current used was 350 amperes and the total cost 79 cents. A crack in the back sheet of a locomotive boiler 12 inches long was welded in nine hours, the current used was 175 amperes and the total cost $4.90. The risers on steel casting, 4 by 4 inches in size, were cut off in four minutes; the current used was 350 amperes and the total cost 5.2 cents. A cast-steel tender frame broken in three places was welded in twenty-seven hours; the current used was 300 amperes and the total cost $19.44. The journals of a worn 2-inch armature shaft were built up in three hours; the current used was 165 amperes and the cost $1.59. As an example of straight welding on sheet-metal work, seams on 1/8-inch steel can be welded at the rate of from 15 to 16 feet per hour, and on 1/4-inch steel at the rate of from 12 to 13 feet per hour.

Conclusion

From a consideration of the foregoing the principal reasons for the popularity and success of electric arc welding—both as a repair means and as a manufacturing means—will be readily appreciated. They may be briefly summarized as follows: The adaptability of the process to work of an exceedingly varied character, practically all cases in which iron or steel have to be united being covered by the two methods of using the arc. To this may be added the opposite case, or that of cutting, where the arc is equally effective. The fact that vertical or overhead welds can be made as readily as downward welds greatly increases the availability of the process for certain classes of work, and reduces to a minimum the labor which would otherwise be required for handling. The low cost of welding by this process, as seen when comparison is made with like results obtained by other methods, is a decided argument in its favor. In many cases of repair work, where the electric process is not available, the entire replacing of the broken or worn part would be necessary at a cost many times greater than that required for welding.

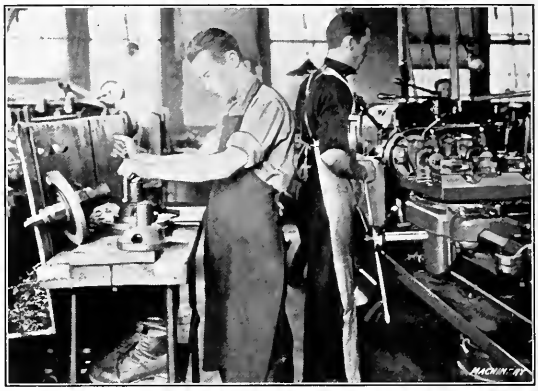
Any number of operators may work from the same outfit up to its capacity. They may be doing different classes of work, and at any distance from the outfit up to limits fixed by the allowable voltage drop in the lines. This feature is particularly effective in those cases where the job is large enough to permit of several operators working at one time. The low voltage used for welding precludes all chance of accident to the operator from contact with current-carrying parts of the apparatus. Welds made by the electric arc possess a degree of strength only slightly below that of the original section, and by reinforcing this can be increased to any desired amount. They present a neat and finished appearance, are homogeneous in structure and may be easily machined. From every standpoint they are of a highly satisfactory character.

* * *

EFFICIENCY IN THE TURRET LATHE DEPARTMENT

The ordinary machine tool represents an investment of several hundred dollars capital, and it would seem that one of the first steps in efficiency would be to keep the machine running as nearly full time as possible. And yet in many shops the operator spends half of his time in preparing work for the machine.

The management of the Brown-Lipe-Chapin Co. at Syracuse, N. Y., has applied efficiency methods in the turret lathe department to Jones & Lamson double-spindle flat turret lathe operation, as shown in the illustration. The work consists



The Boy chucks the Work and the Operator runs the Machine

in machining two diameters, the sides of two flanges and the end of a differential gear housing casting. In chucking the work, the pieces are first put on a faceplate and thus held on the spindle of the machine. To save the operator's time, who is a specialist on this machine, a boy is employed to chuck and unchuck the work. He works back to back with the operator and as soon as one piece is finished the operator passes it to the boy who in exchange gives the operator a piece chucked and ready for the machine. The proficiency that these two men display in working together on this job is remarkable. Notwithstanding the fact that the length is held to within 0.005 inch and the diameter to 0.0005 inch, these operators regularly produce two finished castings in four minutes. In a recent test for speed they turned out forty of the housings in thirty minutes. C. L. L.

Copper can be welded by the oxy-hydrogen blowpipe by placing two pieces of copper in position so that they can be heated at the proper point by the blowpipe until the requisite degree of softness is attained. Complete reduction is then effected in the flame by the use of purified hydrogen, and the welding is completed by hammering. The joint is said to be invisible and the metal at the weld is claimed to be as homogeneous in every way as the remainder of the metal welded.

THE USE OF PHOTOGRAPHS IN GRINDING AND POLISHING DEPARTMENTS

BY GEORGE B. MORRIS*

Marking up photographs of the finished parts is a unique method of instructing foremen and inspectors that is used in the grinding and polishing departments at the Pierce-Arrow Motor Car Co., Buffalo, N. Y. The photographs are on extra heavy Azo paper (requiring no mounting) 5 by 8 inches in size, the same as the operations cards, and the photographs and cards are filed together. The cost of prints per thousand is surprisingly low. The greatest expense is the preparing of parts for photographing, and right here is the great advantage of the system. It is necessary to study each piece carefully; learn its function and location; determine just what surfaces should be ground or polished, and how much; and cut out needless grinding where surfaces are later machined, as in Fig. 1, where the "Do not grind" surfaces are machined in the next operation. In many cases, even surfaces that are later machined have to be ground, as shown in Fig 2, because of jigs and fixtures. It is not expected of a foreman or inspector to look after these points.

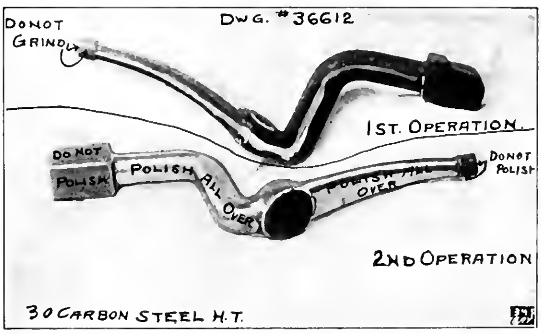

Fig. 3. Instructions for Two Operations included on a Single Card

As a record, the photograph system is excellent; and should a foreman leave, the new man would be greatly assisted by it. Furthermore, there would be no excuse for over- or under-doing a job. As a means of instruction to the workman, the simple words, "John, make like picture" are enough for a new man. The lettering is all done on the photograph, not on the negative, making it possible to use the same negative for several similar parts. A change is also easily made, without exposing another plate, by simply re-marking a new print. The photograph system is being extended to other departments, where one, two or more photographs give instructions in assembling for cases when printed instructions are not clear.

Before taking up this system we outlined two other methods, which were subsequently discarded. The first of these consisted of marking up blueprints for use in the grinding department, while the second was to supply finished samples of the pieces to be ground to serve as a guide in finishing similar pieces of work. Both of these methods were unsatisfactory, and the latter had the further disadvantage of the expense which it involved. A surprising reduction in manufacturing costs has been brought about by the adoption of the photograph system of issuing instructions, and as this method is capable of quite general application, it would appear that many manufacturing companies would do well to adopt it.

ALLOYS OF ALUMINUM AND ZINC

Experiments undertaken by Dr. W. Rosenheim and S. L. Archbutt indicate that alloys of aluminum and zinc may be made to resist corrosion very effectively by using zinc free from impurities. The addition of zinc to aluminum facilitates the production of good castings. An alloy containing 25 per cent of zinc can be rolled into bars and drawn into wire. The addition of a small percentage of copper to these aluminum-zinc alloys greatly increases the tensile strength. In general, the alloys should contain not less than 15 per cent of zinc, and if dynamic as well as tensile strength is considered, the alloy should contain not less than 20 per cent zinc. Aluminum-zinc alloys lose strength rapidly as the temperature rises. Even 100 degrees F. produces a very marked effect. Alloys containing from 10 to 30 per cent of zinc can be easily worked by machine tools of all descriptions, and in most cases without the use of cutting lubricants.

GRINDING MULTIPLE DIAMETERS

A curious and interesting development of grinding practice is going forward which apparently will make still greater the revolution effected in machine shop practice by the cylindrical grinding machine. This is grinding to size without lateral traverse of the wheel or work. A few years ago it would have been considered rank heresy to advocate the grinding of work to close limits by feeding the wheel in to the required depth without traversing it back and forth over the work. Now it is the accepted practice for shouldered shafts, crankshafts and other parts having bearings or other cylindrical portions not exceeding five inches in length.

The practice was developed in grinding multiple-throw crankshafts for automobile engines. The bearings between the crank cheeks were short, and very short traverse only was possible. The operation of grinding crank-pins was slow and costly. Cylindrical grinding machines sufficiently heavy and powerful to drive grinding wheels of the full width of the bearings were built, and the practice of grinding crankshafts without lateral traverse was soon recognized as a quick and low-cost method of machining a difficult part.

Now the practice of grinding motor shafts without lateral traverse is accepted as being a practicable and rapid method, quickly acquired by the operator and very satisfactory in results. A further development makes possible the grinding of two or more diameters simultaneously, the wheel having been turned with a diamond to the required diameters.

The limitations of this method are the practicable width of the grinding wheel and the strength and rigidity of the machine. One well-known expert places the limitation of wheel width as being perhaps one foot. The possibilities of rapid production with a stepped wheel one foot wide on electric motor shafts, for instance, are startling. Evidently if three or four diameters on the shaft can be ground simultaneously in about the time now required for one, the grinding time will be cut to one-third or one-fourth what it now is.

ON GETTING JOBBING WORK

Builders of special machinery often find it difficult to convince prospective customers by mail that they have the skill and equipment to produce the desired apparatus. A booklet illustrating the machine tool equipment and showing a number of examples of machines built will be found one of the best means of pulling business from a doubtful prospect. Every concern looking to do high-grade special work should make a point of photographing every job done, and in time it can easily compile a booklet to slip into letters answering inquiries, that will prove a very effective business getter.

Let these concerns also advertise in the trade papers that they are builders of special machinery and offer to send booklets on application and they will soon find themselves in touch with many who want work done. There is no better way of getting employment at anything than by showing what you have done. The fact that you have done certain things well is pretty good evidence that you can do other things acceptably to those who want them done.

* * *

UNIFICATION OF WEIGHTS AND MEASURES

Some of our English contemporaries have of late devoted considerable space to the metric system, and conservative minds have tried to improve upon the existing English system of weights and measures, so that—while retaining the old names and main units—the benefits of a decimal system could be realized. This seems futile and serves no purpose whatever.

Nor do mere academic discussions of the advantages or defects of the metric system, on the one hand, and the English system, on the other, serve any useful purpose. A uniform system of weights and measures for the whole civilized world is greatly to be desired, and there is little doubt that it will ultimately be achieved. The longer the work of unification is put off, however, the more difficult will it be to accomplish the change. As it is hardly reasonable to expect that the part of the world which uses the metric system will change back to the system used by the English-speaking nations, it seems inevitable that the English-speaking nations must ultimately conform in this matter to the rest of the world, especially as such a change in the opinion of many is in the line of progress.

This editorial is not an argument in favor of the metric system as such, but it is an argument in favor of a *uniform* system of weights and measures which would be a great boon to the industries and to the trade of all nations. When the importance of such a uniform system is recognized, the adoption of the metric system is a foregone conclusion, simply because it is already used by three-fourths of the civilized world.

* * *

DRAWING AND FORMING DIES

Comparatively little definite information has been published in the mechanical journals relating to the drawing of metals in presses. Numerous examples of practical press work are shown every month, but the fundamental principles governing the work have yet to be worked out. In fact, the art of drawing and forming may still be considered, in some respects, to be in its infancy. While an enormous amount of this kind of work is done daily in hundreds of shops in the country, there is still a scarcity of definite information as to the principles involved. Some day this subject will be taken up and thoroughly investigated, as F. W. Taylor investigated the art of cutting metals, and then exact rules and formulas may be worked out governing the drawing of metal sheets into shells. At present the mechanic interested in this work must content himself with studying a few general principles based upon practical experience.

It is possible, however, that even with the knowledge at present available on this subject, it could be treated for publication purposes in a far more comprehensive and analytical manner than has heretofore been done, and right here is an opportunity for men of practical experience, with ability to analyze principles and express themselves in clear language, to contribute to the engineering literature of the day information that would be of great value, because it would be original, practical and in constant demand.

It is a curious fact that on nearly every other mechanical subject there are books dealing with fundamental principles. In punch and die work writers seem to be satisfied with merely showing examples of work that has been done.

THE COEFFICIENT OF MECHANICAL FRICTION

When the surfaces of two bodies are in contact and under pressure, there is resistance to motion of one body on the other, due to the mutual interlocking of the minute projections on the two surfaces. Hence, to obtain relative motion, these projections must be disengaged, abraded or overridden and their resistance to these actions causes sliding friction. Thurston says: "The greatest force with which relative motion is resisted by friction is obtained by multiplying this total pressure (on the contact surfaces) by a *constant* coefficient (of friction) to be determined experimentally for every pair of surfaces of definite character"; and in citing the so-called "laws" of sliding friction, he states that this resisting force is dependent only on the nature of the surfaces and the normal force with which they are pressed together, and is independent of their area of contact, of the velocity of rubbing and of any other conditions than those noted above.

Thurston wrote thirty years ago and his statements were justified by the meager information then available. While later experience and experiment have shown that they are in many respects inaccurate with regard to machine bearings, his broad conclusions still find a place in some text and reference books in which the subject is treated very briefly, and hence they may deceive the young and inexperienced engineer. As a matter of fact, they are true, as a whole, only for surfaces whose normal pressure is low, whose velocity is very moderate and which have little, if any, lubrication—all conditions which are, in general, the reverse of those which the machine designer must meet.

For any two metals of the same character of surface, lubricant and normal pressure, the coefficient of friction is very far from being a constant—as Thurston states—in bearings of different types. On the contrary, it is one of the most variable factors to be found within the whole range of machine design. Take a familiar example: in a high-speed, reciprocating engine, the customary pressures per square inch of projected areas of the bearings may be taken in pounds as, roughly: crosshead guides, 100; shaft bearings, 400; crank-pin, 800; crosshead pin, 2200. Now, the metals in contact in all of the bearings are usually the same and the character of the surfaces is identical, but the allowable normal pressure differs in each case. Why? The only answer is that, for each case, there is a different coefficient of friction. A bearing is so proportioned that at its maximum pressure and velocity its temperature shall not rise above a "working heat" so that "seizing" shall not occur. Now, as the coefficient of friction varies inversely as the normal pressure, it is evident that the less the allowable pressure to prevent heating, the greater the coefficient of friction in that bearing must be—which, broadly, is the reason for the wide variations in normal pressure shown in the foregoing examples.

For machinery in general, the coefficient of friction for the same pair of metals depends upon a large number of conditions. Its value is affected not only by the nature of and the pressure upon the surfaces, but by their temperature and relative velocity, the latter having sometimes a marked effect. Again, the character of the motion and the steadiness or intermittent nature of the pressure influence it. For example, in a shaft bearing, the motion is continuous and the general direction of the pressure is steady; in a crank-pin journal the motion is also continuous, but the pressure changes from one side to the other; and with a crosshead pin, the motion is reciprocating and the pressure intermittent. The steadiness of pressure and the nature of the motion have much influence on the effectiveness of the lubrication. Again, the form of the surfaces—flat or cylindrical—and the character of their contact—through a surface or a line—are both factors of moment. Finally, the nature of the lubricant and the effectiveness of the lubrication are all important; every journal should run on a film of oil.

It is apparent that, for given metals, the coefficient of friction is not a constant, but rather a frequently changing factor or ratio.

NOTES AND COMMENT

The popularity of that type of automobile which has been termed the "cycle car" is on the increase, according to the *Scientific American*. There are now said to be nearly thirty companies building cycle cars in Detroit. Many of these find a ready sale for their products in Great Britain, and one maker has just announced the signing of contracts for 10,000 cars for England. As yet these cars are not very frequently seen on this side of the Atlantic.

A cheap material for making concrete waterproof, which is being used with success in some parts of the country, consists of finely divided iron filings, borings, turnings, etc. The iron has the property of making concrete waterproof because of rusting; the rust fills the pores and seals them up tightly. This simple means of making concrete waterproof has been sold as a trade secret with considerable profit to the promoters. The cost of the process is not as high as of some other waterproofing methods not as effective.

Rifles have been used to punch holes in iron wagon tires in emergencies, but it remained for F. A. Robarge of South Milwaukee, Wis., to use a rifle for the first time to cut down a chimney. A steel chimney of the Rundle Mfg. Co., Milwaukee, composed of sheets about 3/16 inch thick had been broken off by the wind about twenty-five feet from the top, and the broken part hung suspended from the stump. It was considered too dangerous for a steeple jack to climb and cut the part loose, so the rifle man was called on the job. Five or six shots through the supporting shred were sufficient to loosen the hanging piece and send it crashing down to the ground.

Cast iron is a common material of construction that has many characteristics little understood. It can be made glass hard by casting it in contact with chills—that is, cast iron forms of sufficient mass to cool the metal quickly. But if poured in cast-iron molds and removed as soon as the surface has solidified, the casting will be soft and easily machined. It even possesses a slightly malleable property. A still more interesting characteristic is its capacity for hardening when heated and quenched. Lathe and planer tools have been made from permanent mold castings, it is claimed, which, under favorable conditions, equalled the best high-speed steels in cutting performance.

Another giant hydro-aeroplane, rivaling in size the Sikorsky machine, has been built by Messrs. Jeanson and Collieux, in France. The machine is provided with a single boat having a length of 28 feet 6 inches and a beam of 8 feet 6 inches. The aeroplane portion consists of two sets of biplanes arranged in tandem. The span of the wings is 88 feet 6 inches and the total lifting surface, 1560 square feet. The boat body is provided with two 200-horsepower motors, connected with a single air propeller, 16 feet 6 inches in diameter. The total weight of the machine with pilot, assistant pilot and two passengers, and fuel for a thousand-mile (fifteen hours) trip, is slightly over 10,000 pounds.

A German contemporary states that the setting of Portland cement is assumed to be due to the formation of a gel, which ultimately hardens to a lime-aluminate-silicate mass and forms a close-fitting network around any embedded inert material. With concrete, such a network surrounding angular gravel or sand would be stronger than one enclosing rounded grains, and the strength attained with washed sand would be greater than with unwashed, since, in the latter case, the intervening layer of soft clay prevents the surrounding network from directly gripping the grains of sand. Similarly, with ferroconcrete, rust is detrimental as it prevents close contact between the iron and the surrounding gel.

Signs in shops prohibiting workmen from doing something they are likely to do are to be deplored unless means are conveniently provided for doing it in the prescribed way. Then they are not likely to do it in the prohibited way if it is

understood to be contrary to the practice of the shop and signs will not be needed. "Workmen will be discharged who use this grinder without wearing goggles," posted over a grinder used in common is a poor means of discipline if the goggles are not kept close at hand. In practice, the injunction will be ignored. If ignored with impunity, the probability is that cautionary regulations, in general, will not be observed when the convenience of the workmen dictates otherwise.

One of the difficulties with moving picture cameras is that they must be supported by a firm stand while the picture is being taken, in order to prevent vibration. A hand camera for taking moving pictures, however, has been developed in Europe, the front of the camera containing a rapidly rotating gyrostatic wheel which keeps the camera steady in any desired position. The motive power for driving the film and the gyrostat is obtained from cylinders containing compressed air fitted at the back of the camera. A paper describing the device has been read before the Royal Photographic Society in England, and the excellent results obtained by it were also demonstrated at the same time.

Experiments have been made to determine whether lubricating oil "wears out" or not in long-continued service. These tests were made by Professors Carpenter and Sawdon at Cornell University. The tests indicated that oil gains in specific gravity by continued use, as would be expected on account of the loss of volatile constituents. The used oil shows a higher viscosity than new, indicating that it gains in "body" with use. Friction tests showed that new oil has a slightly lower coefficient of friction at low bearing pressures, but the reverse is true for high pressures. The differences, however, are so small that for all practical purposes the coefficient of friction may be taken as being equal for new and old oils.

Germany now uses between forty and fifty million gallons of denatured alcohol a year, of which over thirty million gallons is sold to the general public for burning purposes. France uses about eighteen million gallons, the United States about ten million gallons and the United Kingdom only four million gallons. Denatured alcohol is gaining in favor for general burning purposes, and efforts are being made to use it as a substitute for motor fuel in place of high-priced gasoline. A monograph by Charles A. Crampton entitled, "Production and Use of Denatured Alcohol in Principal Countries," has been published by the United States Government and copies may be obtained from the superintendent of documents, Government Printing Office, Washington, D. C., at 5 cents each.

Wheel spindles of cylindrical grinding machines run up to as much as 1500 feet per minute peripheral speed. The bearings are plain bushings provided with means for collapsing to fit the spindle closely. The rule is to give only 0.001 inch clearance, that is the bearing is only 0.001 inch larger than the grinder spindle. The space for oil film then is only 0.0005 inch around the spindle and thin oil must necessarily be used. Spindles will run without appreciable shake in bearings 0.005 inch larger than the spindle but will run out of true if the running parts are not in perfect dynamic balance. The unbalanced part tends to rotate about the center of gravity, thus making the oil film thicker on one side than on the other. But the eccentric oil film does not remain in the same relation, the result being that the wheel runs out of true.

Vanadium has been used to some extent in brass, having been added in the form of cupro-vanadium. The resulting brass is generally known as "vanadium-bronze." The mechanical properties of this alloy are superior to those of ordinary brasses. The elastic limit is raised and the alloy is harder. At the same time the ductility is not affected to any appreciable extent. Published results of tests of vanadium brasses indicate quite a considerable increase in strength, and it is also stated that cupro-vanadium additions to brass reduce the tendency to corrosion. It is probable that the beneficial effect of vanadium is largely due to its deoxidizing action, but it is difficult to determine the exact effect of vanadium, owing to the comparatively large amounts of aluminum and other metals present in most samples of commercial cupro-vanadium.

The great change that has come in the business of steam engine building is indicated by the experience of one of the well-known concerns in this line. After having enjoyed a deserved reputation as a builder of high-grade automatic steam engines for many years, its business declined in the face of competition to the point that made necessary its discontinuance. The president has seen the work of a lifetime vanish in the march of progress. A melancholy aspect of the case is that he is one who has done much to promote better methods and ideals and to encourage the putting off of the old in favor of the new when the new is better. A large user of the company's engines recently sold it several discarded engines, still in first-class condition, at the price of scrap iron! To find customers for these engines, even at an absurdly low price, apparently will not be easy. The steam turbine, the gas engine and the electric motor have come to stay.

Roller rests for heavy lathe work are used much more abroad than in the United States, and they are used for good and sufficient reasons that should command our adoption of the idea. A roller rest will stand much use with little wear. The work revolves freely and is held up to the same height from start to finish of long jobs. This is an important consideration on gun lathes that may carry a gun weighing a hundred tons for weeks. The plain rests used in American shops generally are cheap and that is about the only merit they have. They oppose the movement of the work with unnecessary frictional resistance and wear considerably when supporting heavy parts in motion for several days. The work drops out of line with the lathe centers and the boring tools are affected. Improved steadyrests are greatly needed on heavy lathes. They require all the care in designing and making that any other important part of the lathe receives.

In a summary of the waterpower of various countries, the *Mechanical World* gives the possible horsepower of France as 4,500,000, of which only 800,000 is utilized. About an equal amount of power is available in Italy, but only 30,000 horsepower is utilized. The estimate for Switzerland is incomplete, but about 300,000 horsepower is in use. Germany has 700,000 horsepower available with 100,000 applied. Norway has 900,000 horsepower available, with a large part already developed. In Sweden there is 763,000 horsepower available, but mostly at a considerable distance from any industrial center. In Great Britain 70,000 horsepower is already utilized, and an equal amount in Spain. The resources of Russia are estimated at 11,000,000 horsepower, of which only 85,000 has been developed. The United States is credited with 1,500,000 horsepower, while Japan has 1,000,000, of which 70,000 has been exploited; in India 50,000 horsepower has already been developed.

A leading machine tool builder once solved a problem in screw cutting in an ingenious manner. He was required to cut a large long lead-screw to a metric pitch. The limits of tolerance were so narrow that the common translating gears, including a 127-tooth gear, would not exactly produce the required pitch when working under normal shop conditions. The difficulty was overcome by expanding the lead-screw of the lathe which is about sixty feet long, by heating it with a steam coil. The shop temperature was maintained equable night and day, while the screw was being cut, and the lead-screw was kept several degrees warmer by the steam coil boxed in with the screw as far as possible. A multiplying indicator on the end of the bed showed the amount of expansion obtained, and this was maintained as uniformly as possible. In this way the screw was chased to a very close approximation of the desired metric pitch. Its diameter was six inches and length about forty feet.

FLUTING HOBS

BY GUY H. GARDNER*

I recently received a letter asking for information relative to the fluting of hobs. The text ran as follows: "I have turned and threaded a hob of 2.125 inches pitch diameter and 15 degrees 30 minutes thread angle. I intended to mill twelve spiral flutes in the hob at right angles to the thread. I found the lead for these flutes by multiplying the pitch circumference by the cotangent of 15 degrees 30 minutes, which gives 24.0622 inches for the lead. Gearing the milling machine for a lead of 24 inches, and trying the job with a scriber in place of the cutter, I found that there are neither 12 nor 13 teeth in one complete turn of the hob thread; I judge that there are approximately 12 15/16 teeth to each turn. I can set my relieving attachment for 12 teeth or for 13 teeth, but not for any intermediate number. I am anxious to do a good job; how can I do it?"

The writer of the letter quoted has met with a difficulty which is practically unknown in large shops where hobs constitute one of the regular products, as such shops have skilled designers to make the necessary calculations, and in some cases, at least, relieving machines are available which are equipped with special differential gearing to enable them to handle teeth of fractional pitch. For men like my correspondent who only make a hob occasionally, the problem is somewhat difficult; and if one may judge from the hobs seen in use, it would appear that a satisfactory solution of the problem is not always arrived at. The purpose of this article is to point out one simple way in which work of this nature may be done on an ordinary relieving lathe.

It is first necessary to find the number of teeth that would be formed in each turn of the hob thread if the flutes were milled at right angles to the threads. Any one who can use a table of logarithms can easily ascertain this number by dividing the number of flutes in the hob by the square of the cosine of the thread angle, *i. e.*, the angle which the thread makes with a line perpendicular to the axis of the hob. The

Machinery

table presented in this connection provides an even easier method of determining the number of teeth for the angles given. In using it, it is only necessary to find the number corresponding to the thread angle and multiply it by the number of flutes. For the present case the result would be $1.0769 \times 12 = 12.9228$.

An ordinary relieving attachment cannot be set for this number of teeth, but by making a slight change in the lead of the spiral flutes, we can make them give 13 teeth in each turn of the hob thread. The accompanying illustration shows the method of procedure in determining the necessary change in the lead of the flutes. AB is the pitch circumference of the hob, BC is the lead of the hob thread and AC represents the length of one turn of the thread. Calling F the number of flutes milled in the hob, it has already been explained that the number of teeth produced in the length of one turn of the thread AC is $\frac{F}{\cos^2 \alpha}$. The line BD represents the direction of flutes milled at right angles to the threads AC, and BE represents the required direction of the flutes to produce exactly 13 teeth in each turn of the hob threads. It will be seen that the flutes BE are at an angle β to BG. Let N represent the number of teeth in a turn of the thread AC cut by the flutes having the direction BE.

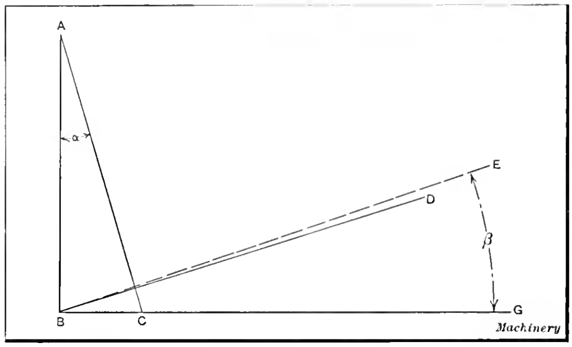

Diagram showing Method of adjusting Flute Angle to give a Whole Number of Teeth

In order to calculate the changed lead of the spiral flutes due to the alteration in their direction, the lead of the hob thread is required; this is usually known or can be found by multiplying the pitch circumference of the hob by the tangent of the thread angle α. In the present case, the lead of the hob thread is represented by BC in the accompanying illustration and has a value of 1.8513 inch. The changed lead of the spiral flutes is then found by multiplying the lead of the hob by the number of flutes in the hob and dividing the product by the desired number of teeth minus the number of flutes. Presented in the form of a formula this result would be given by the following:

$$\frac{BC \times F}{N - F} = \frac{1.8513 \times 12}{13 - 12} = 22.2156 \text{ inches.}$$

As 22¼ inches is the nearest available approximation, the milling machine is geared for this lead and the 12 flutes are milled. To find the angle EBD by which the direction of the flutes differs from that of the line BD which is perpendicular to AC, we divide the pitch circumference by the changed lead, the quotient being the value of tangent β. For the present case, β is found to have a value of 16 degrees 42 minutes. Subtracting from this the value of the thread angle α, which is 15 degrees 30 minutes, we find that the flutes are not at right angles to the hob threads by 1 degree 12 minutes. It will be noticed that no alteration of the lead is required when the thread angle α is either 45 or 60 degrees. The same is true when the thread angle is 30 degrees if the number of teeth F may be divided by 3 without leaving a remainder.

* * *

The possibilities of cost reduction of manufactured products are not fully grasped by many manufacturers who have been in the business for years. Where a single standardized machine is made in large numbers, special machinery and methods can be introduced with telling effect. The claim is made that the Ford motor car costs the company when ready to turn over to the agents less than $200. Compare this with the alleged costs of the higher priced cars selling for $2000 to $3000. There must be either great inefficiency of production or great profit in the business. As a matter of fact, the average maker's methods are inefficient but his profit is large.

SUB-PRESS DIES FOR ARMATURE MANUFACTURE

SECTIONAL DIES FOR FIELD AND POLE PUNCHINGS, AND FOR ARMATURE DISKS

BY FRED K. HUDSON*

IN the January, 1914, number of MACHINERY, Douglas T. Hamilton described the making and use of one-piece armature-disk dies that are used in the factory of the Robbins & Myers Co., Springfield, Ohio. It is the purpose of the present article to describe the methods for making two interesting sectional sub-press dies that are used in the manufacture of armature disks and field and pole punchings. Fig. 1 shows the punchings and also the 0.025 inch sheet steel from which they are made. Fig. 3 shows the assembled punch and die used for making the field and pole punchings, and Fig. 6 shows the assembled punch and die for blanking and notching the armature disks. The other illustrations show parts of these punches and dies from which the construction will be readily understood. The parts A, B, C and D are produced at one stroke of the press. The parts E and F are scrap; and the disk G is stamped from the piece D in a subsequent operation.

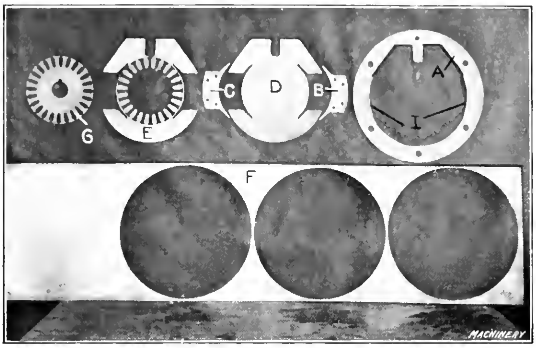

Fig. 1. Field, Pole and Disk Punchings and the Stock from which they are made

The assembled punch and die for making the parts A, B, C and D is illustrated in Fig. 2, and Fig. 3 shows this punch and die taken apart in order that a better idea of the construction may be obtained. In Fig. 4 the lower half of the die is shown with the strippers removed. This illustration also shows the templets for the field and pole punches and the templet drill jig used for drilling the pole punches. The punch for making the field (shown at A in Fig. 1) is made of six sections, comprising one each of parts shown at J and K in Fig. 4 and two each of parts L and M. These sections have flanges on the outside, fastened to a tool steel ring 5/8 inch thick, fillister-head screws and dowel pins being used for this purpose. The ring and flanges are ground to fit into a recess in die-holder N. The pole punches O and P are made 1/8 inch higher than the cutting edge of the field punch and have a flange on the inside. They are screwed and doweled onto a tool steel plate Q, 5/8 inch in thickness, this plate being a sliding fit in the ring on which the sections of the field punch are mounted. Both the ring and plate are doweled to the die-holder N and held in position by fillister-head screws which extend through from the back of the die-holder.

To facilitate grinding the die when it becomes dull, the

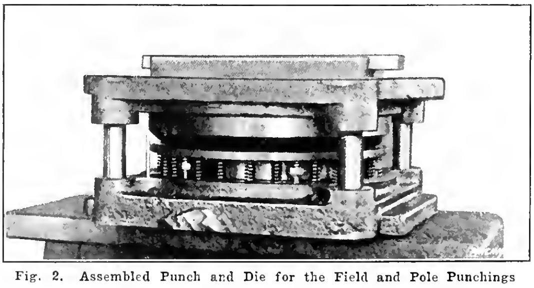

Fig. 2. Assembled Punch and Die for the Field and Pole Punchings

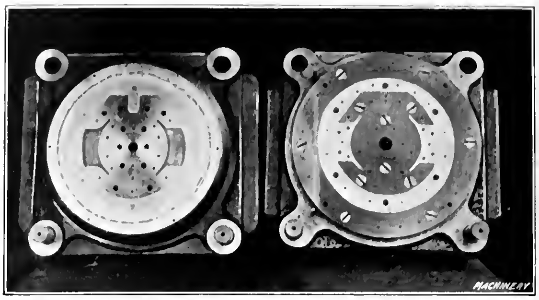

Fig. 3. Field and Pole Die taken apart

screws holding the field punch plate are loosened and the field punch raised to the level of the pole punches, four adjusting screws being provided for this purpose. The dies for the round holes in the field and poles are bushed in the punch sections. This makes replacement an easy matter and the scrap from the holes is allowed to pass down through the die-holder. The spring plate strippers are shown at R and S in Fig. 4. They are held in position by flat-headed screws which have nuts in counterbored holes in the back of the die-holder. Dowel pins are put into the holes to keep the nuts from turning, the method being clearly shown in Fig. 7. Short springs and nuts shown in Fig. 4 are used to prevent the screws from loosening up when the die is in operation.

Fig. 5 shows the upper half of the die used for producing the field and pole punchings. In this illustration the outside die ring, the solid stripper, the knockouts, and the templets for the sections of the punch are clearly shown. The punch is composed of one each of sections T, U, V and W and two of section X. These sections are doweled onto a tool steel plate Y, the plate and 1/8 inch at the bottom of the sections being ground on the outside to fit a circular recess

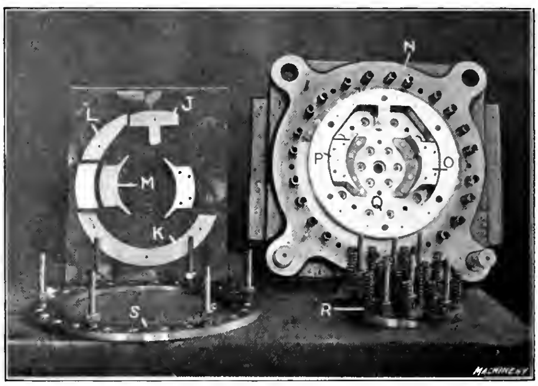

Fig. 4. Lower Half of Die with Strippers removed; also Templets for the Punch Sections

in the holder Z, to which the plate is held by dowel pins and fillister-head screws. The solid stripper a is made of tool steel with two hardened dovetailed sections inserted. These sections sever the pole punchings from the field at the points marked I in Fig. 1. The springs shown in the die-holder Z, Fig. 5, take the thrust of the cut, and as the pole punches are 1/8 inch higher than the field punches—as previously explained—the pole punchings are blanked before the field punchings. The stripper serves as a support for the punches which pierce the small holes in the field, constitutes the cutting edge for the pole dies and also acts as an ejector for the field punching shown at A in Fig. 1. The die ring b is recessed into the holder Z; and the flange on the bottom of the stripper a, which fits into a recess in the blanking ring b, keeps the cutting edge flush with the rest of the die.

As a is ground to a close sliding fit with the inside of the die ring and the outside of the sectional pieces on the plate Y, perfect alignment is always maintained. The knock-outs c, for ejecting the pole punchings B and C in Fig. 1, are fastened to the bar d, which is worked automatically by the punch press.

All cutting members of this die are hardened and accurately ground so that there is absolutely no variation in the size of the blanks. A tolerance of 0.002 inch is allowed, but the dies are made to maintain the maximum size. The punches are made 0.003 inch smaller than the die, thus affording a cutting clearance of 0.0015 inch. A run of from 35,000 to 40,000 blanks is obtained between grindings, the number of pieces produced varying according to the grade of steel from which the work is being produced. Counting the three separate punchings produced at each stroke, this would mean a total production of from 105,000 to 120,000 finished blanks. The height of the punch and die above the holders is $1\frac{3}{4}$ inch. This affords $1\frac{3}{8}$ inch of wearing surface, which corresponds to a total production of from 4,007,500 to 4,580,000 blanks, after which the strippers and flanges can be reduced

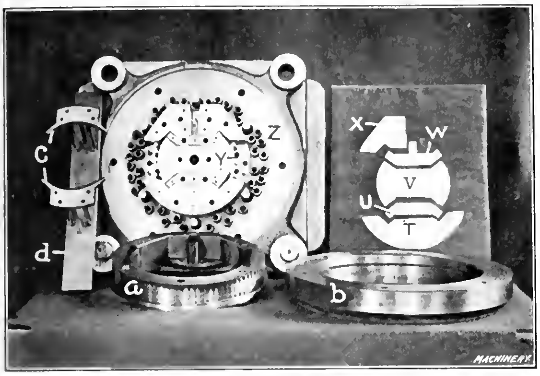

Fig. 5. Upper Half of Die, Solid Stripper, Outside Die Ring, and Templets for Sections

in thickness to give at least $\frac{1}{8}$ inch more of wearing surface.

Fig. 6 shows the assembled die which is used for blanking and notching the armature disks, and also one of the finished disks and the scrap left in making it. It will be seen that the disks are produced from the scrap formed by the die used for making the field and pole punchings, this scrap being shown at D in Fig. 1. The blank for the armature disk is located on the die by means of a nest of spring pins which are shown at e in Fig. 6. The spring stripper plate is recessed to allow the operator to handle the blanks quickly with a pair of pliers. Fig. 8 shows the die taken apart, the lower half being shown at the right-hand side of the illustration. This part of the die is made up of sections having a flange on the bottom, the design of one section being shown in detail in Fig. 9. These sections are accurately fitted together and built around a tool steel plug which is bushed to receive the center hole and keyway die. The assembled sections are fitted into a recess in a tool steel plate and securely fastened by means of screws and dowel

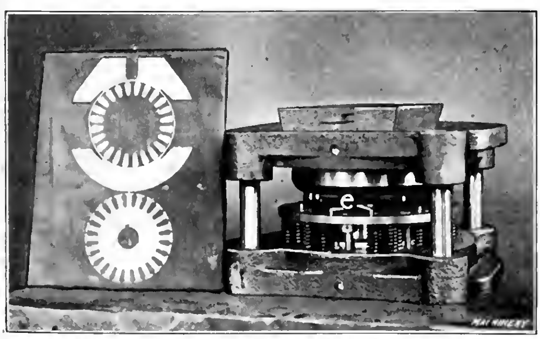

Fig. 6. Assembled Punch and Die for blanking and notching Armature Disks

pins. The plate itself is held in a recess in the die-holder f, and the scrap from the center hole goes down through the die.

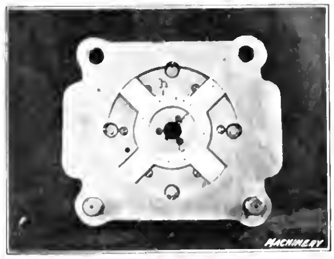

Fig. 7. Back of Lower Half of Die showing Method of securing Strippers

The part marked g is a spring stripper plate; the strippers for the slots are made separate and they are a close sliding fit in the slots, thus helping to support the die sections. Studs threaded on one end are screwed into the bottom of the strippers and the opposite ends of these studs pass through the die-holder and are secured in the ring shown at h in Fig. 7. This ring is fastened to the stripper plate g (Fig. 8) by means of four flat-headed screws and the springs under the plate g operate all of the strippers. One of the punches for the upper part of the die, shown at the left-hand side in Fig. 8, is illustrated in detail in Fig. 10. These punches have a flange on the bottom and are accurately fitted together at the correct angle to obtain accurate spacing and alignment with the lower die sections. The punches are assembled on a tool steel plate and ground on the outside to a snug fit in a tool steel ring which constitutes the cutting edge for the outside diameter of the blank. The knock-out i in Fig. 8 is $\frac{1}{2}$ inch thick; it is made a sliding fit on the slot punches and is connected by three studs to a plate in the head block. This knock-out is worked automatically by the press. The punch for making the keyway is dovetailed into the center hole punch j, the shank of which is made a driving fit in the holder k. The sections of these dies are milled to size so that no filing or fitting is necessary after the parts have left the milling machine. The final finish is obtained by grinding between the joints and this grinding is only necessary when the steel has expanded in the hardening process, the expansion never amounting to

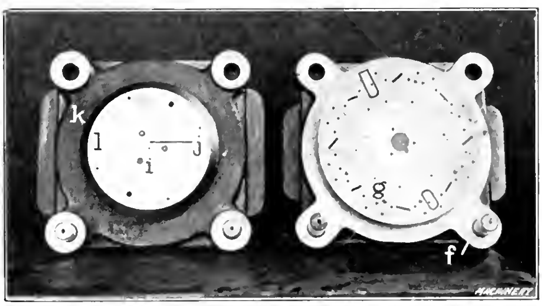

Fig. 8. Upper and Lower Halves of Die shown in Fig. 6

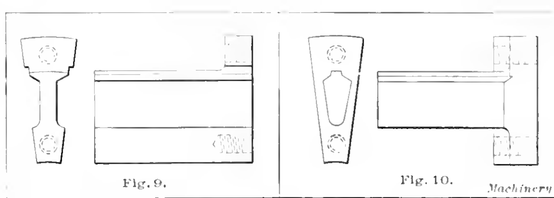
more than from 0.001 to 0.002 inch. The outside cutting edge of the die sections is ground to the correct diameter to give a clearance of 0.0015 inch between them and the ring l in Fig. 8. The center die and punch and the ring l are ground all over, the punches being 0.0015 inch smaller than the dies. The center die j has a tapered hole through it which allows the scrap to drop down.



Figs. 9 and 10. Design of Sections for the Punch and Die shown in Fig. 8

The average number of pieces produced in this die between grindings is 35,000 and at least $1\frac{1}{2}$ inch of the die can be used up. This corresponds to a total production of 4,375,000 blanks. This number of blanks produced from

sectional dies is not unusual and we have some dies that have stood up under this rate of production without requiring any repairs during a period of three or four years. The stock used is Crucible Steel Co.'s 1.25 per cent carbon steel which is hardened so that it cannot be scratched with a file. The first cost of the sectional dies is considered by many to be higher than that of solid dies, but in the opinion of the writer, considering the life of the dies, they are cheaper in the end, providing the number of parts to be produced is large enough to warrant the increase in first cost.

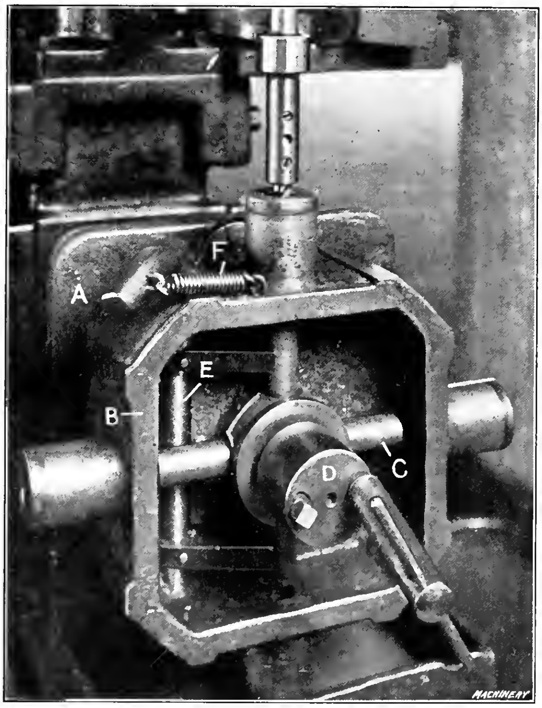
INDEXING JIG FOR COUNTERSINKING DIFFERENTIAL SPIDER ARMS

The ordinary way of making a differential spider is to center the ends of the arms, rough-turn the forgings, harden the spider and grind the arms to the finished size. The Brown-Lipe-Chapin Co. of Syracuse, N. Y., has a better way, however, of finishing the spider. The forging is chucked and rough-turned, including the arms and then, without centering the ends of the arms, the piece is casehardened as it is. A row of hardened spiders is then strung on an arbor and sufficient metal is ground from the ends of the arms to remove the hardened case. This leaves the soft cores exposed for center drilling. By drilling after hardening a better working center is obtained, and one that is not full of scale; moreover the centers are not influenced by any distortion that might occur in hardening.

The jig upon which the center drilling is done is of more than ordinary interest. As shown in the illustration, it consists of the angle-iron base *A*, upon which is swiveled the jig section *B*. The spider, which is indicated at *C*, is slipped over the swiveling stud *D*. In order to locate the spider centrally in the jig, that is, so that the arms will come in average alignment with the four bushings, the centering dog *E* is employed. By means of a spring *F*, whose end is attached to the bent end of the dog, the two aligning fingers are brought to bear simultaneously against opposite arms of the spider. Thus the spider is located evenly in the jig. After this it is a simple matter to drill and countersink the spider arms one after another, indexing the jig by hand for each arm.



Indexing Jig for countersinking Differential Spider Arms

An idea of the facility with which this jig is operated can be gathered from the fact that five hundred of these spiders are drilled and countersunk in a day of nine hours, making a total of two thousand holes per day. The most important part, however, is the fact that the method insures that the centering is done with reference to the *hardened* spider arms, thus insuring that the amount of metal removed in grinding will be practically equal at all points.

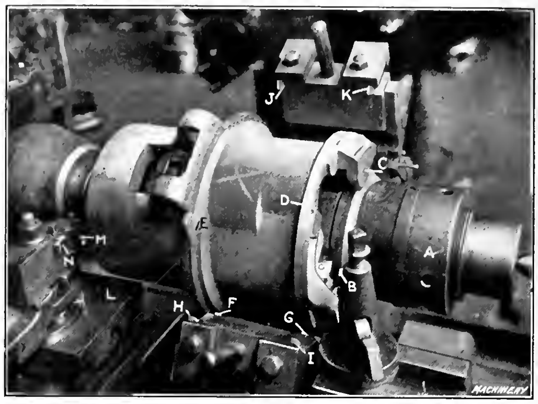
A MULTIPLE TURNING JOB ON AN ENGINE LATHE

Given an old engine lathe, almost ready for the scrap heap as far as general work is concerned, and a very accurate turning job, one would hardly expect to see the two combined harmoniously. Yet this combination was effectively accomplished at the Ritter Dental Mfg. Co.'s factory in Rochester, N. Y.



Multiple-turning on an Engine Lathe

The turning job was the machining of a cylinder for the base of a dental chair, an operation that consumed a great deal of time when done by ordinary turning methods, and it was desired to make a special turning fixture for the work. The illustration accompanying this article shows how the cylinder casting was held on the expansion arbor *A*, which in turn was held on the centers of the lathe. The only change required in the lathe was to make sure that the spindle had no shake and that it would turn straight, and also to put on the special carriage attachments shown. A facing tool *B* is held in the toolpost of the lathe and used for facing the ends of the base. The face that tool *B* machines is indicated at *C*. The most particular part of the work, that of facing off sections *D* and *E*, is well handled by special tooling on a separate carriage with which the lathe is fitted. As each of these sections is only approximately ½ inch wide, by using the two special roughing tools *F* and *G* mounted in fixed positions, only a very short travel of the carriage is required.

After these two surfaces were roughed they were semi-finished by the two tools *H* and *I*. These tools are on a separate swinging latch that the operator swings up to a stop and allows to make the cut. This leaves the two surfaces in a semi-finished condition and the final light chip is taken by tools *J* and *K* on a similar latch block at the top, mounted at the reverse side of the carriage. The latch mechanism that holds the tool-block down while making the cut may be seen at the side of the upper left block. While these cuts are taking place, the operator uses the special auxiliary slide *L* on the carriage, on which are mounted tools *M* and *N*. Tool *M* is a boring tool for facing out a small section within the casting, and tool *N* is a chamfering tool that serves to face and round the corner of this end of the casting.

The limit on this job is 0.002 inch on all measurements. The production is eighty-five cylinder bases in eight and one-half hours. Owing to the complication of the tool set-up, the lathe is kept set ready for this job at all times. Instead of being sent to the scrap heap it has been made an effective machine for this job.

BULLDOZER DIES FOR FORMING STEEL STIRRUPS

BY P. P. FENAUX*

In certain of its products, the General Electric Co. uses steel stirrups of the form shown in Fig. 1. These stirrups are made of high carbon steel of approximately $\frac{3}{4}$ by $\frac{3}{8}$ inch in cross-section. As the quantity of these parts that are required is rather large and as no forging machine was available, it was decided to makes dies in which these stirrups could be produced on a standard bulldozer. As the dimensions are required to be within 1/64 inch of uniform, it was necessary to make dies that would produce work within these limits without requiring any subsequent forging which would leave hammer marks.

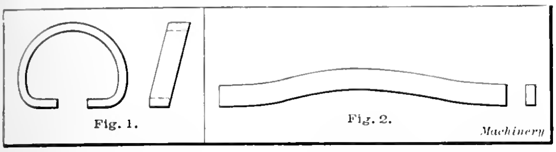

Fig. 1. The Finished Stirrup　　Fig. 2. Blank after the First Operation has been performed

The sequence of operations involved in making these stirrups is as follows: A bar of steel is sheared into blanks of the required size, which are first bent to the form shown in detail in Fig. 2, this form being a development of the finished stirrup. Suitable allowance is made for the spring of the steel in order to obtain the required dimensions. The blanks are bent to the form shown in Fig. 2 between the dies *A* and *B*, which are shown in the operating position, and also in cross-section in order to illustrate the construction more clearly. The die *A* is fastened to the stationary base *C*, which is, in turn, bolted to the ways of the bulldozer and backed up by adjusting screws *D*. It will be seen that the plates *A* and *B* overlap in order to prevent distortion of the work while it is being bent into shape. The die *B* is bolted to a supporting plate *E* which is carried by a second plate *F* bolted to the ram of the bulldozer. The gage *G* provides for locating the blanks in the proper position.

The next step is to complete bending the work to bring it to the form shown in Fig. 1. When the ram recedes after performing the preliminary operation between the dies *A* and *B*, the work is taken out and laid edgewise on the shelves *H* and *J* of die *K*. The gage *X* provides for locating the work in the required position. When the ram comes forward, it pushes the wedge *L* against the slide *M* which travels on ways provided in the block *N*. During the first part of the operation performed in this die, the block *N* is held stationary by a locking-pin; but after the slide *M* has completed its travel, the locking-pin is released and the block *N* moves forward. A more complete explanation of this part of the work will be given in a subsequent paragraph. The slide *M* carries a form *P*, and as the slide moves to the right this form comes into contact with the work and forces it into the die *K*, thus bending the piece to a U-shape.

When the operation has proceeded to this point, the wedge *Q* located on the under side of the base *C* pulls out the locking-pin *R*, thus leaving the block *N* free to move. As the ram continues its forward movement, the die *S*, which is fastened to the ram, comes into contact with one arm of the U-shaped piece on the form *P* and bends it around the form. At the same time the ram continues to move forward and pushes the slide *M* and the block *N* with it. In so doing, the other arm of the U-shaped work is pushed into the stationary die *T*, which bends it around the form *P*. At the end of the forward movement of the ram, both the dies *S* and *T* come in contact with the wedge-shaped end of the slide *M*, which forces the dies against the form *P*, thus setting the work onto the form. The dies *S* and *T* are pivoted at the points *V* and *W*, respectively, to enable the dies to be moved by the tapered surfaces on the slide *M*. While this forming operation is being performed, the work is pushed against a stamping device *Y* set in the die *K*, which produces the necessary marking on the part. When the ram returns, the die is released and the slide *M* is pushed back by the springs in the block *N*; then the link A_1 draws the block *N* back, the pin B_1 being provided in the block for this purpose.

The form *P* is now taken out of the slide with the work in place around it. The third operation consists of setting the work in the dies C_1 and D_1. The purpose of this operation is to overcome the elastic limit of the material so that the piece will be set to exactly the required form. After this final operation has been completed, the form is pushed out of the work by means of the ejecting-pin E_1, leaving it in the shape shown in Fig. 1.

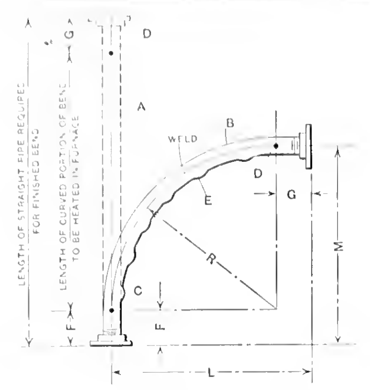
STEAM POWER PLANT PIPING DETAILS—9*

THE DESIGN OF WROUGHT IRON AND STEEL PIPE BENDS

BY WILLIAM F. FISCHER†



Length of straight pipe required = F + 1.57 R + G.

Machinery

Fig. 68. A 90-degree Bend and the Straight Pipe required to make it

In a previous number of MACHINERY rules, tables and formulas were given for estimating the amount of expansion cared for by expansion bends of different types. In this installment, rules and formulas will be given for the design of wrought iron and steel pipe bends in general. When used to convey steam at high pressure, wrought iron and steel pipe bends 4 inches and over in size are usually made up with "rolled" or Van Stone joints, or in some cases the flanges are welded direct to the pipe. In making rolled or Van Stone joints, the end of the pipe is heated in a furnace and then rolled over the face of the flange and finished off to a true bearing surface in a pipe lathe. When pipe bends are ordered with rolled, Van Stone, or welded flanges, it is always advisable to attach the flanges to the pipe and roll or finish the flange faces true in a pipe lathe before bending the pipe to the required form. Therefore it becomes necessary, in cases of this kind, to determine the length of straight pipe that will be required to make the bend to the given dimensions. After the length of the straight and curved portions of the bend have been determined by the designer, the general dimensions are noted on sketch sheets and sent to the pipe shop. A piece of pipe is cut to the proper length and the flanges attached and finished to a true bearing surface, after which the pipe is sent to the bender, who lays off on it the length of straight and curved portions of the bend (see Fig. 68) and places the pipe in the furnace to be heated to the proper bending temperature. The pipe is then removed from the furnace and placed on a bending table, where it is curved to the required dimensions.

In case the designer makes an error in calculating the length of straight pipe required for the finished bend, it will be readily understood that when the bend is made up and curved to shape it will be either too long or too short, as the case may be. Furthermore, unless the error is a slight one it may be impossible to make the bend to the desired dimensions without first cutting a new piece of pipe to the proper length, rolling or flanging new joints and finishing them true in a lathe. Errors of this kind are necessarily expensive and cause considerable delay in getting the piping material ready for erection. As a general rule, after the sketch sheets leave the drafting-room, an error in the length of straight pipe required for the finished bend is discovered only when the bend has been completed and is being checked up for dimensions on the bending table, in which case the material and workmanship represent a total loss to the manufacturer unless the bend can be used on some other job. For this reason, all calculations pertaining to pipe bends should be carefully checked in the drafting-room before the detail sheets are sent to the pipe shop. In the following article, the writer has prepared simple rules, tables and formulas which will enable the reader to determine all of the necessary dimensions required for pipe bends of the types illustrated below. These represent about all of the standard shaped bends ordinarily used in steam power plant work; therefore, the designer should be able to choose the type best suited to his purpose and figure the important dimensions accordingly. As a further guide in choosing the proper bend to use for a given service, the reader is referred to the second, third, sixth and eighth installments of this series, which appeared in earlier numbers of MACHINERY.

TABLE XIV. RADII FOR PIPE BENDS OF WROUGHT IRON AND STEEL PIPE*

Size of Pipe	Actual Outside Diameter of Pipe	Minimum Radius for Bends of Extra Heavy Pipe		Minimum Radius for Bends of Standard or Full Weight Type		Advisable Radius for Bends of Standard or Full Weight Type		Advisable Minimum Radius for Bends used to Take Care of Expansion and Contraction		Length of Straight required at Each End for Flange or Fitting

Machinery

* Note.—Pipe 14 inches and larger is known as O. D. pipe, meaning outside diameter pipe.

Fig. 68 is a typical example of the method employed in laying off or marking straight pipe in the shop when used for bending purposes. The dotted lines *A* show the straight pipe flanged and marked, ready for the bender; and the full lines show the completed bend, true to dimensions. Take, for example, a 6-inch 90-degree bend of the form shown in Figs. 68 and 69, to be made to minimum dimensions *L* and *M*, using extra strong or extra heavy pipe for the bend. By referring to Table XIV, we find the minimum radius *R* for a 6-inch bend of extra strong pipe is 1 foot 9 inches or 21 inches; and the minimum length of the straight sections *F* and *G* to be employed at each end of the bend is 7 inches, making minimum dimensions *L* and *M* in Fig. 68, 1 foot 9 inches +

* The eighth installment of this series was published in the May number of MACHINERY.

† Address: 3959 Fulton Ave., Woodhaven, L. I., N. Y.

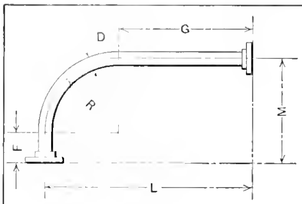

Fig. 69.

Length of straight pipe required = F + 1.57 R + G. Dimensions M, L, and R should be given when ordering the bend.

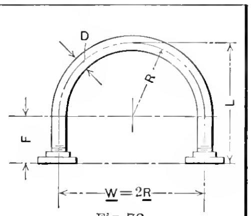

Fig. 70.

Length of straight pipe required = 2F + 3.14 R. Dimensions L, W and R should be given when ordering the bend.

Machinery

Figs. 69 and 70. A 90-degree or Square Bend and a U-bend

7 inches = 2 feet 4 inches from center to face. In Fig. 69, we find the length of the 90-degree circular arc = 1.57 × radius $R = 1.57 \times 21 = 32.97$ or say 33 inches. Therefore, the total length of straight pipe required for the finished bend = $33 + 7 + G = 40 + G$ inches or 3 feet 4 inches + G from face to face of the flanges. The length of the curved portion of bend (33 inches) is marked off, as indicated by the dotted lines in Fig. 68, and that portion of the pipe is heated in the furnace ready for bending. If no error has been made in calculating and laying off the dimensions on the straight pipe, the bend will be true to dimensions when curved to shape as indicated by the full lines.

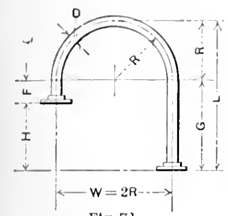

Fig. 71.

Length of straight pipe required=F+3.14 R+G. Dimensions L, W, H and R should be given when ordering the bend.

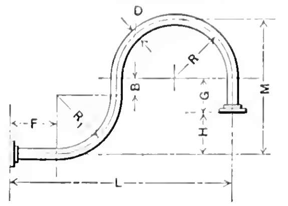

Fig. 72.

Length of straight pipe required = F + 1.57 R_1 + B + 3.14 R + G. Dimensions L, M, H, R and R_1 should be given when ordering the bend.

Machinery

Figs. 71 and 72. A Gooseneck U-bend and a Combination Square and U-bend

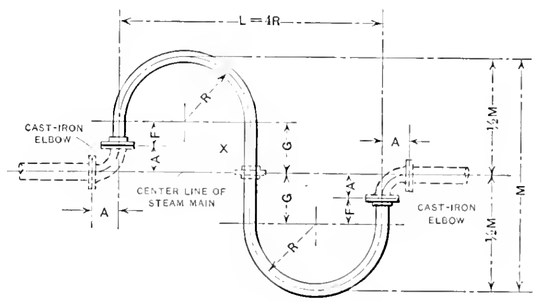
In order to prevent strains on the welded joint of the pipe when bending it to shape, the weld should be placed either up or down, *i.e.*, over the neutral axis of the pipe where it is neither in tension nor compression. The tension side of the bend is indicated by B and the compression side by E, Fig. 68, which also shows the proper position for the weld in bending. If the welded joint is placed either on the tension or compression side of the bend, the seam is very likely to spread or open up, due to the severe bending strains at these points. If the radius R is made less than the values indicated in the third and fourth columns of Table XIV, the pipe is likely to buckle on the compression side of the bend, as shown at E; and it will assume an oval shape in cross-section at these points, thus decreasing the effective area and destroying the general appearance of the bend. Pipe bends curved to a very large radius are also likely to buckle on the compression side of the bend, due to the bender having to take short heats, *i.e.*, heat the pipe two or more times in order to complete the curve. Lap welded wrought iron or steel pipe is to be preferred to butt welded pipe for bending purposes, as the weld is more secure and less likely to spread or open up when bending.

Pipe Bends with Screwed Joints

Although pipe bends having threaded ends and screwed flanges may be cut, threaded, and flanged after bending, it is rather difficult to perform this work satisfactorily by machine, especially if the pipe is of large diameter. In all cases, it is advisable to flange the pipe and finish the flanges true in a lathe before bending to the desired shape. Pipe bends having threaded ends and screwed flanges are frequently made up as "fillers" or closing pieces; these bends are made with long ends, which are cut off by the steam fitter to suit the closing dimensions of the line. In a case of this kind it is, of course, necessary to cut, thread and flange the pipe in the field after the bend is made. In all cases where bends can be made to correct dimensions in the shop, however, much time and expense can be saved by cutting, threading and flanging the pipe before it is curved to shape on the bending table.

Minimum Standard and Maximum Radii for Pipe Bends

Steel or wrought iron pipe bends made up of "standard" or "full weight" pipe (*i.e.*, standard weight pipe not under 5 per cent of card weight, as listed in the manufacturers' catalogues) should not be bent or curved to a radius less than that listed in the fourth column of Table XIV, as these are considered the minimum safe radii to employ for standard light weight pipe, when perfect bends are desired. Although it is possible to bend standard weight pipe to a smaller radius than listed in this table, it is not advisable to do so, owing to the danger of the pipe buckling on the compression side of the bend, as shown in Fig. 68. When bends of a shorter radius are desired, they should be made of extra strong or extra heavy pipe, having approximately twice the thickness of a standard or full weight pipe of the same outside diameter. The dimensions in the third column of the table are the minimum radii to be employed for pipe bends of extra strong pipe. In the fifth column of the table is given the advisable radii to use for bends of standard or full weight pipe. In the sixth column of the table is given the advisable minimum radius to employ for bends which are to be used as expansion bends for relieving the expansion and contraction strains in a long line of piping, as explained in an earlier number of MACHINERY. In this respect, it should be understood that any increase in the radius of an expansion bend adds considerably to its flexibility (see the eighth installment of this series published in the May number).



Length of straight pipe required, if made in one piece without flanges at X = 2F + 2G + 2 x 3.14 R. Dimensions F, G and R should be given when ordering the bend.

Machinery

Fig. 75. Special S-type of Expansion Bend

The maximum radius of curvature for a pipe bend of any description is governed by the character of the bend, the length of pipe required to make the bend to the given dimensions, and the space available for erection, rather than by the design of the bend. If the radius of the bend is too large, however, the bender may find it necessary to take more than one heat for each circular arc, in which case there is always more or less danger of the pipe buckling on the compression side, as previously mentioned. The minimum length of straight pipe to be allowed at

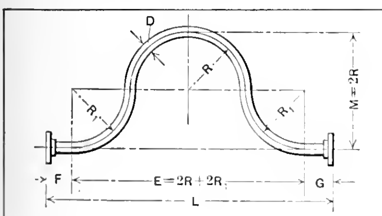


Fig. 73.

Length of straight pipe required=F + 3.14 R_1+ 3.14 R+G. Dimensions L, M, R and R_1 should be given when ordering the bend.

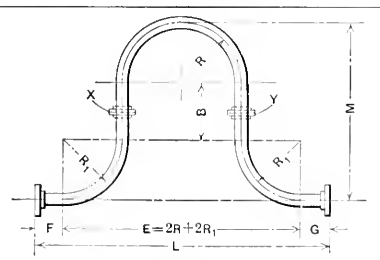

Fig. 74.

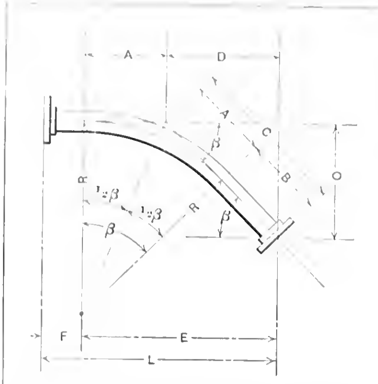
Length of straight pipe required=F + 3.14 R_1 + 2B + 3.14 R + G. Dimensions L, M, R and R_1 should be given when ordering the bend.

Machinery

Figs. 73 and 74. Expansion Bends with and without Straight Sections between the Arcs



Length of straight pipe required,= F + 0.01745 Rβ + B. Dimensions L, O, R and angle β should be given when ordering the bend. A = R × tan ½β, D = O × cot β and E = A + D. Then F = L − E, C = O ÷ sin β and B = C − A. The length of the circular arc of angle β = 0.01745 Rβ.

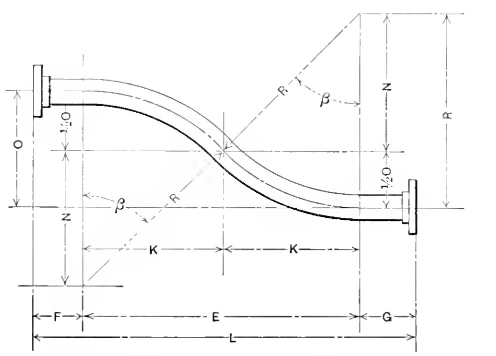
Machinery

Fig. 76. Angle Bend

each end of a bend for the attachment of flanges, or to screw into pipe fittings, is given in the last column of Table XIV. If the length of straight pipe at each end of a bend is made less than given in the table, there is always more or less danger of the pipe flattening or assuming an oval shape at the end while it is being bent, especially on bends of short radius, in which case there is danger of leakage occurring between the body of the pipe and the flange. The dimensions listed in Table XIV are a fair average of those recommended by several of the large manufacturers making a specialty of pipe bending, and may be considered safe figures to work to in all cases.

Rules and Formulas for Determining the Dimensions of Pipe Bends

The 90-degree or square bend illustrated in Fig. 69 is probably the most common type in use today. Bends of this kind are frequently used in place of 90-degree elbows, wherever it is required to take branches off at right angles to the main header. The U-bend shown in Fig. 70 may be used either as a return bend or a cross-over bend between two headers or



Length of straight pipe required,= F + 2 × 0.01745 Rβ + G. Dimensions L, F, O and R should be given when ordering the bend. N = R − ½O and cos $\beta = \frac{N}{R}$, from which the angle β is obtained. K = N × tan β and E = 2K. Then G = L − (E + F). The length of each circular arc of angle β = 0.01745 Rβ.

Machinery

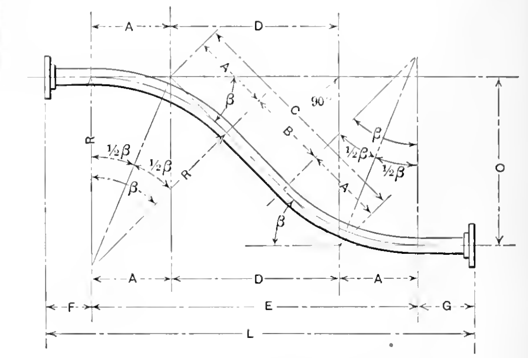
Fig. 77. Offset Bend with no Straight Section between the Arcs

mains; or it may be used in connection with two 90-degree bends or elbows as an expansion bend, similar to the arrangement shown in Fig. 74. The gooseneck U-bend illustrated in Fig. 71 is similar in all respects to the U-bend in Fig. 70, except that one leg of the bend is longer than the other, offsetting the flanges as shown at *H*. The bend shown in Fig. 72 is a combination of a U-bend (Fig. 70) and a 90-degree or square bend (Fig. 69). The expansion bends shown in Figs. 73, 74 and 75, as the name implies, are used for the purpose of taking up or relieving the expansion and contraction strains in a system of steam piping, as described. The length of straight pipe required to make any of the bends illustrated in Figs. 69 to 75, inclusive, may be found by adding together the length of the straight and curved portions of the bend, as described for each case. As these bends are either curved to an arc of 90 or 180 degrees, or to a combination of the two, it is a very simple matter to determine the dimensions indicated on the drawings. The length of each circular arc is readily determined as follows:

Length of 90-degree circular arc = 1.57 *R*.

Length of 180-degree circular arc = 3.1416 *R*.

Owing to the long length of pipe required to make the finished bends illustrated in Figs. 74 and 75 in one piece, it may be necessary—especially in the larger sizes—to make these bends in two or more pieces by adding the flanges as shown dotted at *X* and *Y*. Standard steel and wrought iron pipe may be obtained from the mills in random lengths up to 22 feet, and special welded pipe, for bending purposes, in lengths up to 40 feet. Lengths up to 22 feet are usually kept in stock, but if longer lengths are required they may have to be ordered, in which case it may be necessary to wait some time for delivery. Most of the larger manufacturers of piping materials are equipped with welding outfits and make a practice of welding pipe in suitable lengths for especially



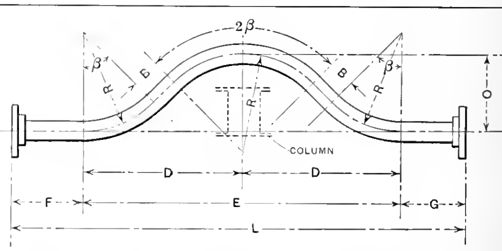
Length of straight pipe required = F + 2 × 0.01745 Rβ + B + G. Dimensions L, F, O, R and angle β should be given when ordering the bend. A=R × tan ½β, D=O × cot β and E=2A+D. Then G=L−E−F. C = O ÷ sin β and B = C−2A. Length of each circular arc of angle β = 0.01745 Rβ.

Machinery

Fig. 78. Offset Bend with a Short Straight Section between the Arcs

long bends. In many cases, large bends made in one piece are no more expensive than those made in two or more pieces, as the cost of rolling the extra joints and attaching flanges will about even up in each case. In order to facilitate shipment and erection of the piping, however, it may be advisable to design the large bends so they can be made in two pieces if so desired.

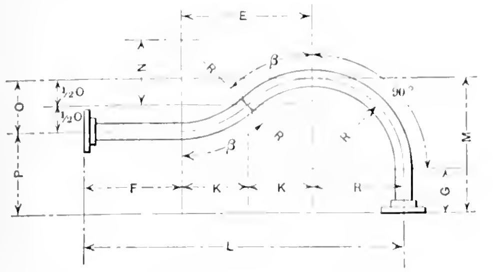
The bends illustrated in Figs. 76 to 84, inclusive, are more difficult to make and measure up than those illustrated in Figs. 69 to 75. The formula for figuring the length of straight pipe required for each type of bend under consideration is given under the illustration. The length of the circular arcs of angle β may be obtained as indicated for each particular case. For example, assume the angle β to be 45 degrees 50 minutes or 45 50/60 degrees, and radius *R* 4 feet 6 inches or 54 inches. Then, the length of the circular arc of angle β = 0.01745 × *R* × angle β = 0.01745 × 54 × 45 50/60 = 43.19



Length of straight pipe required = F + 4 × 0.01745 Rβ + 2B+G. Dimensions L, F, O, R and angle β should be given when ordering the bend. The dimensions B and D may be obtained as explained in Fig. 78. Then E = 2D and G = L − F − E. The length of each circular arc of angle β = 0.01745 Rβ.

Machinery

Fig. 79. Double Offset or Cross-over Bend

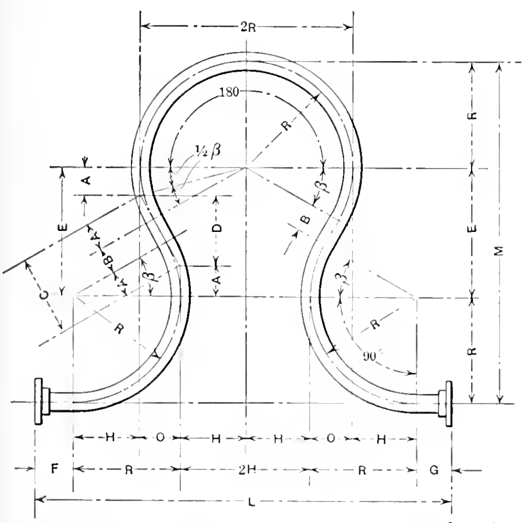


Length of straight pipe required = F + 2 × 0.01745 Rβ + 1.57 R + G. Dimensions L, R, P and G should be given when ordering the bend. M = G + R, O = M − P and N = R − ½O. Cos β = N ÷ R, from which angle β may be obtained. K = N × tan β and E = 2K. Then F = L − E − R. Length of the 90-degree circular arc is 1.57 R and of each circular arc of angle β it is 0.01745 Rβ

Machinery

Fig. 80. Single Offset Quarter Bend without a Straight Section between the Arcs

inches = 43 3/16 inches. If the angle β were exactly 45 degrees, the length of circular arc of angle β would be 0.01745 × 54 × 45 = 42.4 = 42 3/8 inches. The length of any circular arc can be found in a similar manner, and will be determined accurately enough for all practical purposes if angle β is read to degrees and the nearest minute in each particular case. That is, if angle β were actually 45 degrees 49 minutes 43 seconds, it would be close enough for all practical purposes to assume 45 degrees 50 minutes, or 45 50/60 degrees, expressed as a fraction. Having found the length of the curved portion, or portions, of the bend, it is only necessary to add the length of the straight portions in order to obtain the length of straight pipe (from face to face of flanges) required to make the bend.



Length of straight pipe required = F + 4 × 1.57 R + 4 × 0.01745 Rβ + 2B + G. Dimensions L, M, F, G, R and angle β should be given when ordering the bend. A = R × tan ½ β, D = O × cot β and C = O ÷ sin β. Then E = 2A + D, B = C − 2A and H = R − O. Length of each 90-degree circular arc is 1.57 R and of each of the circular arcs of angle β it is 0.01745 Rβ.

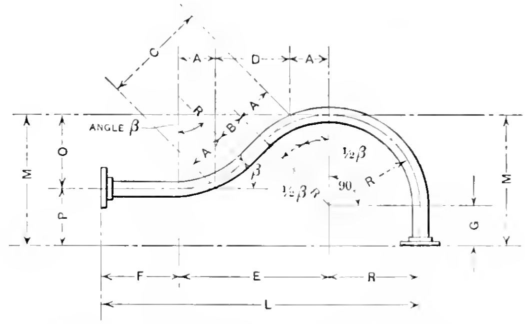
Examples Showing Method of Figuring Dimensions of Pipe Bends

As an example showing the method of figuring the dimensions of an angle bend, similar to that shown in Fig. 76, assume the following conditions: Size of pipe, 6 inches; radius R, 30 inches; distance L, 8 feet 6 inches = 102 inches; distance O, 3 feet, 4 inches = 40 inches; and angle β, 30 degrees 40 minutes.

Dimension $A = R \times \tan \frac{1}{2}\beta$. $\frac{1}{2}\beta$ = 15 degrees 20 minutes and the tangent of $\frac{1}{2}\beta$ = 0.2742. Therefore, dimension $A = R \times 0.2742 = 30 \times 0.2742 = 8.226$ inches. Dimension $D = O \times \cot \beta$. Cot 30 degrees 40 minutes = 1.6864 and O = 40 inches. Therefore $D = 40 \times 1.6864 = 67.456$ inches. Dimension $E = A + D = 8.226 + 67.456 = 75.68$ inches. Dimension L = 102 inches. Dimension $F = L - E$. Therefore, $F = 102 - 75.68 = 26.32$ inches = 26 5/16 inches. Dimension $C = O \div \sin \beta$. O = 40 inches, and sin 30 degrees 40 minutes = 0.51. Therefore $C = 40 \div 0.51 = 78.431$ inches. Dimension $B = C - A = 78.431 - 8.226 = 70.205$ or 70 3/16 inches. Length of circular arc β (curved portion of bend) = 0.01745 $R\beta$. R = 30 inches and β = 30 degrees 40 minutes = 30 40/60 or 30 2/3 degrees. Therefore, the length of the circular arc of angle β = 0.01745 × 30 × 30 2/3 = 16.054 inches. Then the length of the straight pipe (from face to face of flanges) required for the finished bend = length of circular arc of angle $\beta + F + B$ = 16.054 + 26.32 + 70.205 = 112.579 inches, or 9 feet 4 9/16 inches.



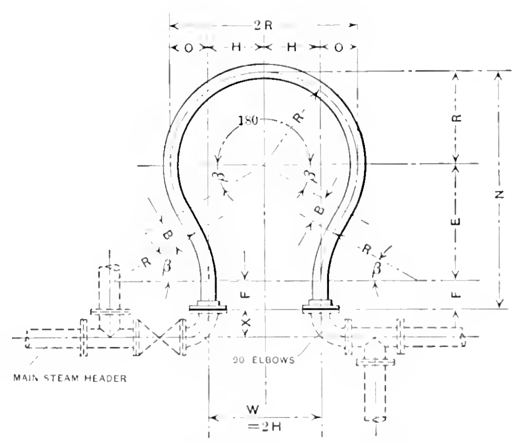
Length of straight pipe required = F + 2 × 0.01745 Rβ + B + 1.57 R + G. Dimensions L, P, G, R and angle β should be given when ordering the bend. M = G + R, O = M − P, A = R × tan ½β, D = O × cot β and C = O ÷ sin β. Then E = 2A + D, B = C − 2A and F = L − E − R. Length of the 90-degree circular arc is 1.57 R and of each of the circular arcs of angle β it is 0.01745 Rβ.

Machinery

Fig. 82. Single Offset Quarter Bend with Short Straight Section between the Arcs

Offset Bend with No Straight Section Between the Arcs

As an example showing the method of figuring the dimensions of an offset bend similar to that shown in Fig. 77, assume the following conditions: Full weight pipe 12 inches in size to be used. Given dimensions are G, F, O and R. The angle β is fixed by the specified offset O and radius R. It is required to make the dimension L as short as possible, using

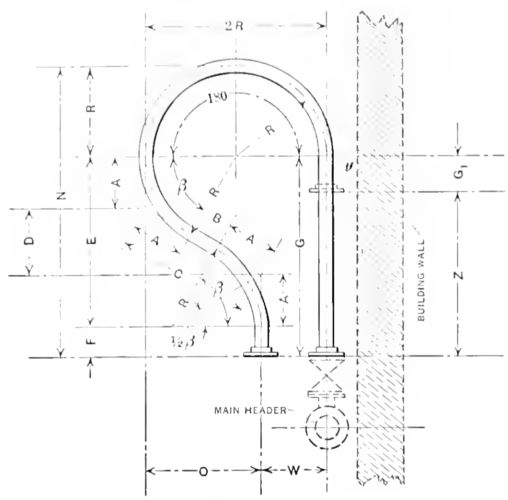


Length of straight pipe required = 2F + 4 × 0.01745 Rβ + 2B + 2 × 1.57 R. Dimensions W, N, R, F and angle β should be given when ordering the bend. The dimensions O, B and E may be obtained as explained in Fig. 82. H = R − O. The length of each 90-degree circular arc is 1.57 R and of each circular arc of angle β it is 0.01745 Rβ.

Machinery

Fig. 83. Double Offset Type of U-bend

minimum dimensions for F, G, and R. Looking in Table XIV, in the fourth and last columns, and opposite 12-inch pipe we find the minimum radius R equals 4 feet 9 inches or 57 inches, and the minimum dimension for F and G equals 1 foot 2 inches or 14 inches. If we assume the offset O as 14⅜ inches, $\frac{1}{2}\ O = 7\ 3/16$ inches. Dimension $N = R - \frac{1}{2}\ O = 57 - 7\ 3/16 = 49\ 13/16$ or 49.8125 inches. Cos $\beta = N \div R = 49.8125 \div 57 = 0.8731$. From a table of natural trigonometric functions, we find that the cosine of 0.8731 corresponds to an angle of 29 degrees 11 minutes. Therefore angle $\beta = 29$ degrees 11 minutes. Dimension $K = N \times \tan \beta$. $N = 49.8125$ and tan 29 degrees 11 minutes $= 0.5585$. Therefore $K = 49.8125 \times 0.5585 = 27.82$ inches. Dimension $E = 2\ K = 2 \times 27.82 = 55.64$ inches. Therefore minimum dimension $L = F + E + G = 14 + 55.64 + 14 = 83.64$ inches $=$ 83⅝ inches or 6 feet 11⅝ inches. The length of each circular arc of angle $\beta = 0.01745\ R\beta$, or length of both circular arcs (curved portion of bend) $= 2 \times 0.01745\ R\beta = 0.0349\ R\beta = 0.0349 \times 57 \times 29\ 11/60 = 58.054$ or 58 1/16 inches. Thus the length of the straight pipe (from face to face of the flanges) required for producing the finished bend $= 58\ 1/16 + 14 + 14 = 86\ 1/16$ inches or 7 feet 2 1/16 inches.



Length of straight pipe required $= F + 2 \times 0.01745\ R\beta + B + 2 \times 1.57\ R + G$. Dimensions W, N, R, F and angle β should be given when ordering the bend. The dimensions O, B and E may be obtained as explained in Fig. 82. $G = E + F$. The length of each 90-degree circular arc is $1.57\ R$ and of each circular arc of angle β it is $0.01745\ R\beta$.

Machinery

Fig. 84. Single Offset Type of U-bend

Offset Bend with Straight Between Arcs

As an example showing the method of computing the dimensions of an offset bend with a straight section between the arcs, as shown in Fig. 78, assume the following conditions: In this case L, F, O, R and the angle β are the given dimensions and should be determined by the designer when laying out the piping system to scale on the drawing board. Assume that a 6-inch pipe is to be used; $L = 9$ feet or 108 inches; $F = 18$ inches; $O = 42$ inches; $R = 36$ inches; and angle $\beta = 45$ degrees. Dimension $A = R \times \tan\ \frac{1}{2}\ \beta = R \times \tan$ 22 degrees 30 minutes $= 36 \times 0.41421 = 14.91$ inches. Dimension $D = O \times \cot\ \beta = O \times \cot$ 45 degrees $= 42 \times 1 = 42$ inches. Dimension $E = 2A + D = 2 \times 14.91 + 42 = 71.82$ inches. Dimension $G = L - (E + F) = 108 - (71.82 + 18) = 108 - 89.82 = 18.18$ or 18 3/16 inches (approximately). Dimension $C = O \div \sin\ \beta = O \div \sin$ 45 degrees $= 42 \div 0.7071 = 59.40$ inches. Dimension $B = C - 2A = 59.40 - 29.82 = 29.58$ or 29 9/16 inches (approximately). The length of each circular arc of angle $\beta = 0.01745\ R\beta$, or the length of both circular arcs $= 2 \times 0.01745\ R\beta = 0.0349\ R\beta = 0.0349 \times 36 \times 45 = 56.538$ inches. The length of the straight pipe (from face to face of flanges) required for the finished bend $=$ length of both circular arcs $+ F + B + G = 56.538 + 18 + 29.58 + 18.18 = 122.298$ or 122¼ inches $=$ 10 feet 2¼ inches. The double offset bend shown in Fig. 79 is figured exactly the same as the above.

Double Offset Expansion Bend

As an example showing the method of computing the dimensions of a double offset expansion bend, as illustrated in Fig. 81, assume the use of an 8-inch pipe with the following given dimensions: Radius $R = 4$ feet 3 inches $= 51$ inches; angle $\beta = 30$ degrees; length of straight pipe between arcs at $B = 12$ inches; $F = 9$ inches; and $G = 9$ inches (see Table XIV). The other dimensions are to be computed as follows:

$A = R \times$ tangent $\frac{1}{2}\ \beta = 51 \times$ tangent 15 degrees $= 51 \times 0.26795 = 13.665$ inches; $C = 2A + B = 2 \times 13.665 + 12 = 39.33$ inches; $O = C \times \sin\ \beta = C \times \sin$ 30 degrees $= 39.33 \times 0.5 = 19.665$ or 19⅝ inches (approximately); $D = C \times$ cosin $\beta = C \times$ cosin 30 degrees $= 39.33 \times 0.866 = 34$ inches; $E = 2A + D = 2 \times 13.665 + 34 = 61.33 = 61\ 5/16$ inches or 5 feet 1 5/16 inch; $M = 2R + E = 2 \times 51 + 61\ 5/16 = 163\ 5/16$ inches, or 13 feet 7 5/16 inches; $H = R - O = 51 - 19\ 5/8 = 31\ 3/8$ inches, or 2 feet 7⅜ inches; and $L = F + G + (2R) + (2H) = 9 + 9 + (2 \times 51) + (2 \times 31⅜) = 182¾$ inches or 15 feet 2¾ inches. The length of each 90-degree circular arc $= 1.57\ R = 1.57 \times 51 = 80.1$ inches, or approximately 6 feet 8⅛ inches. The length of the 180-degree circular arc $= 3.1416\ R = 3.1416 \times 51 = 160.2$ inches, or approximately 13 feet 4 3/16 inches. The length of each 15-degree circular arc of angle $\frac{1}{2}\beta = 0.01745 \times R \times \frac{1}{2}\beta = 0.01745 \times 51 \times 15 = 13.349$ or 13⅜ inches (approximately). The length of each circular arc should be computed separately, as explained above, in order to mark off on the straight pipe the different lengths to be heated for bending. When computing the total length of straight pipe required for the finished bend, however, it is more accurate and more convenient to compute the curved portions of the bend as follows: Total length of the complete curved portions of bend $= (6.2832\ R) + (0.0698\ R\beta)$. Therefore, total length of straight pipe (from face to face of the flanges) required for finished bend $= (6.2832\ R) + (0.0698\ R\beta) + 2B + F + G = (6.2832 \times 51) + (0.0698 \times 51 \times 30) + (2 \times 12) + 9 + 9 = 320.44 + 106.80 + 24 + 9 + 9 = 469.24$ inches or 39 feet 1¼ inch.

When laying out the piping system to scale on a drawing board, the designer should fix the general dimensions of the pipe bends and take care of all clearances; that is, he should fix the governing dimensions of the bends so that proper clearance will be allowed between other members of the piping system, machinery, building walls, columns, etc.

* * *

IMPORTANCE OF STRONG BENCH VISES

The importance of providing bench vises heavy enough for the work to be done, thereby obviating loss of effect because of work being inadequately supported was forcibly brought out by an incident occurring in a Western Pennsylvania shop recently. A great deal of casehardening of small parts is done in this shop. The inspector customarily tests the work on an old vise by holding one of the pieces of the lot in the vise and striking it with a hammer in order to observe the depth of case. He recently used a much larger and heavier vise when testing a lot of casehardened parts and did not immediately consider the effect of the larger and heavier vise. He noticed that the piece struck by the hammer snapped off very easily, and for the time being assumed that the pieces were casehardened to a depth that made them brittle, but as the depth of case appeared to be normal he tried another piece with the same result. Then the thought occurred to him to employ the same conditions as formerly, and taking one to the old vise he found that it broke with the customary number of blows.

This little incident indicates again the well-known truth that a given blow has the greatest effect on work that is massive or massively supported. This holds true no matter what the work is—chipping, filing, etc. Workmen too often are inclined to think that a vise is a vise, overlooking the fact that weight and rigidity of vises are an extremely important factor in efficient bench work. Of course the vise must not be too heavy and too cumbersome for light work, but in all cases it should be chosen with due regard to weight and strength as compared with the work to be done.

POWER PRESS GUARDS*

A VARIETY OF DEVICES FOR PROTECTING THE OPERATOR FROM BEING INJURED

BY MANCIUS S. HUTTON†

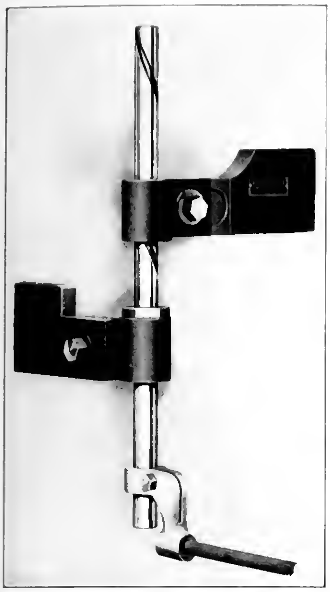


Fig. 1. Hemphill "Push Guard"

In discussing the subjects of safeguards for power presses all machines will be considered on which punching, embossing and stamping is done, both in the large and small sizes. There are two classes of power presses: first, those in which the piece is fed mechanically under the descending ram; and second, those which must have the metal placed in position by hand. Very few accidents happen to employes operating presses of the former class, but in the case of the latter, a large number of operators have their fingers crushed or sheared off by the descending ram. There are four types of mechanical feeds for primary operations and four for secondary operations, any of which is absolutely safe provided the press is stopped at the end of each stroke. A primary operation is one that is done by the machine upon merchant stock in the form of a sheet or bar, and which gives a shape or form to such stock. The secondary operations are done upon this shaped or formed blank.

There are two means of throwing the clutch into mesh to cause the ram to descend: first, by the operator pressing his foot on a treadle; second, by the operator moving a lever with one or both of his hands. To prevent power press accidents, the hands of the operator should be kept from under the ram when it descends by means of safeguards put on the machines for this purpose. There are four methods by which this can be done. First: by having a guard which pushes the hand away before the ram descends. Second: by having a device which prevents the clutch being thrown, locking the ram in its upper position while the operator's hands are under the ram but releasing it when the hands are removed. Third: by having a guard entirely surrounding the danger zone. Fourth: by requiring both hands to be used to operate the machine. The machines which are operated by the foot will require guards of the first, second or third classes, as the hands will be free to get in the way of the descending ram. A machine so designed as to require the use of both hands to operate it is a safety device in itself; but if only one hand is required, then it would be advisable to adopt one of the other three methods.

Foot Operated Machines

To prevent the occurrence of accidents, it is essential that the persons who operate power presses should not have their minds diverted from the work in hand. It is a fact that the continual working of the foot treadle by the operators, and the feeding of pieces with the hands soon becomes second nature. The result is that they acquire a certain automatic rhythmic movement which is likely to prove disastrous, should a mental disturbance of the rhythm be caused by a sudden noise or movement in the vicinity of the operators, or a desire on their part to look around at something happening near them. It might be safely said that practically all power press accidents occurring on this type of machines, in which the operator has one or more fingers crushed, are due to his mind being diverted for the instant, causing him to forget to take the fingers away from the point of danger before the treadle is depressed and the ram descends.

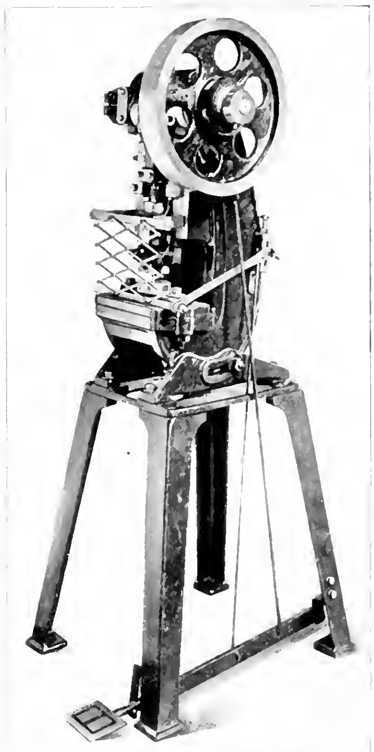

Fig. 3. Geuder, Paeschke & Frey "Lock" Type of Guard

In operating these machines, the ram should be allowed to come to a full stop in its upper position before the treadle is depressed again. In piece work it often happens that the operators do not take time to allow this to be done; and to remedy this condition, several of the press makers have a device by which the clutch lever detaches itself from the treadle action each time the latter is depressed, by means of a cam upon the main shaft which, itself, performs the stopping action of the clutch. Accidents are sometimes caused by the clutch getting out of order or by the flywheel seizing due to improper lubrication, thus causing the ram to descend when it is least expected. Where small objects are required to be formed or repunched, necessitating placing them between the dies, they should be inserted and removed with a stick of pine wood instead of the fingers.

Fig. 2. A Safeguard of the "Lock" Type

* For additional information on the safeguarding of power presses and allied subjects published in MACHINERY see also "Safeguards for Power Presses," by Edward K. Hammond, November, 1912; "A Mechanically and Electrically Operated Safety Device," by Benjamin C. Waite, July, 1912; "Prevention of Industrial Accidents," by F. R. Hutton, April, 1912; "Accidents in the Machine Shop," November, 1911; "Safety Device as Applied to Machine Tools," by Clarence Bolton, November, 1911; "The Prevention of Industrial Accidents," November, 1911; "The Mechanical Engineer and Prevention of Accidents," March, 1911; and "Practical Safeguards in the National Cash Register Co.'s Plant," by Ethan Viall, January, 1910.

† Address: 257 West 86th St., New York City.

It sometimes happens that an operator places a piece in the die in the wrong position, and then at the moment of depressing the treadle with the foot he discovers his mistake. An accident will occur if he attempts to remedy the mistake with his hands at the moment of discovery. This is not an unusual thing to occur in a machine shop. If the fingers are required to be under the ram while doing repair work or in changing the dies on the machine, a block of wood or metal should be placed in such a manner that the ram will be unable to descend if the treadle is depressed accidentally. The same thing should be done in case the clutch gets out of order or the flywheel seizes. The gears on the front of the presses should be enclosed with metal guards and the belting should also be covered. These guards are especially needed on machines which are operated by women, in which case there is a possibility of their hair being caught.

Push Guards

The guards in this class push the hand of the operator away from the danger zone before the clutch engages the flywheel and causes the ram to descend. One of the first of this type of guards to be put on the market is that shown in Fig. 1, which is made by A. J. Hemphill & Co., 11 Broadway, New York City. From the illustration it will be seen that the hands of the operator are forced away from the danger zone by a radial arm, which swings across the face of the lower die as the ram is descending. This arm is actuated by means of a nut which fits in a helical groove in the upright at the left-hand side of the machine. Another guard which belongs to this class but which works on a little different principle is that illustrated in Fig. 4. This guard is made by the H. & A. Lock Co., 156 Fifty-third St., Brooklyn, N. Y. It consists of a metal plate which lies flat on the bed plate of the press when the ram is in its upper position, but which swings outward and upward toward the operator by means of a bell-crank operated by the treadle, throwing his hand away from danger before the clutch becomes engaged.

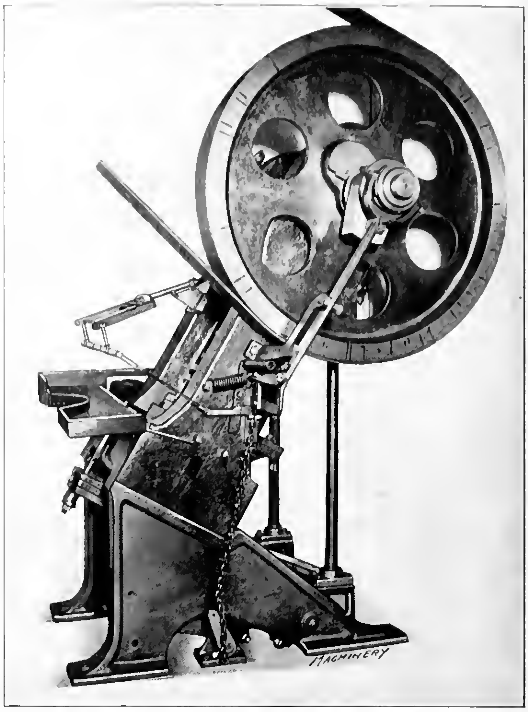

Fig. 5. Corbin "Lock" Type of Power-press Safeguard

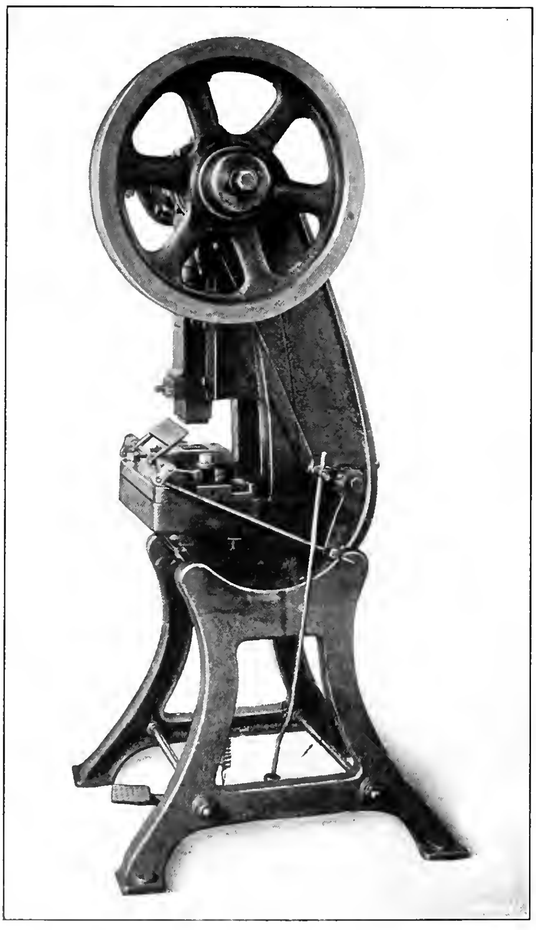

Fig. 4. H. & A. Lock "Push Guard"

Lock Guards

In this class belong those guards which so lock the clutch that the treadle will not operate the machine until the fingers are removed from the danger zone. In Fig. 2 there is illustrated a safeguard which is in use in a large number of factories in the United States. It is a product of the Lockhart Hodge Co., 12 Waverly St., Buffalo, N. Y. As the foot of the operator depresses the treadle of a machine equipped with this guard, a long lever swinging on a pivot is drawn down and carries with it the gate that descends in front of the dies. This gate drops almost to its lowest point before it reaches the bottom of the yoke, and it is only when the bottom of this yoke has been reached that a downward movement is communicated to the rod leading to the latch which sets the press in motion. From this it will be seen that the gate must be flush with the bed plate before the latch will operate to set the machine in motion. Therefore, should a person's fingers be under the gate at the time he depresses the treadle, the machine will not operate until such time as he withdraws them. Means are provided in connection with this guard to prevent the gate from rising until the press is again at rest.

Another make of guard working on somewhat the same principle as that just mentioned is shown in Fig. 3. It consists of a lever fulcrumed to one side of the press frame and attached at the end to a folding gate. A rod joins this lever to the rod leading to the clutch treadle and, depressing the treadle, causes the gate to unfold before the clutch engages. Should the operator place his fingers or anything else which is more than 1/8 inch in thickness in front of the descending gate, the clutch will not be tripped until he has removed it. This guard is made by Geuder, Paeschke & Frey Co., Milwaukee, Wis.

One of the simplest, and at the same time a very effective guard of the lock type is illustrated in Fig. 5. It consists of a free swinging rod of wood or other light material which is suspended across the front of the machine. In the operating position it hangs straight, but should the employe put his hand in the danger zone the rod will be swung forward by contact with his arms, causing a second rod attached to it to

lock the trip. The wood rod is attached to a bracket on the machine and can be removed or replaced at will. The Corbin Cabinet Lock Co., New Britain, Conn., is the manufacturer.

Fender Guards

In this class belongs those guards which completely surround the danger zone. There are very few guards of this kind, since they can, by the nature of their construction, be used in only a limited number of cases. In Fig. 6 is illustrated a safeguard of this type which is in use in Germany. The construction closely resembles that of a collapsible cup fitted to the under side of the ram, bottom side up; and the moving ram oscillates, as it were, within the cup. The cup is so adjusted for height that the fingers of the operator cannot pass between the edge of the cup and the bottom die. The sheet metal, however, can be fed through the space that is left. It will be plain, therefore, that the work can be fed to the danger zone but the fingers are not allowed to get through. As the ram descends upon the stock the cup collapses, as the rings of which the cup is formed slide within each other. On the up stroke the cup extends itself again, leaving room for the strip of stock to pass beneath its lower edge. If any variation in the thickness of the strip occurs,

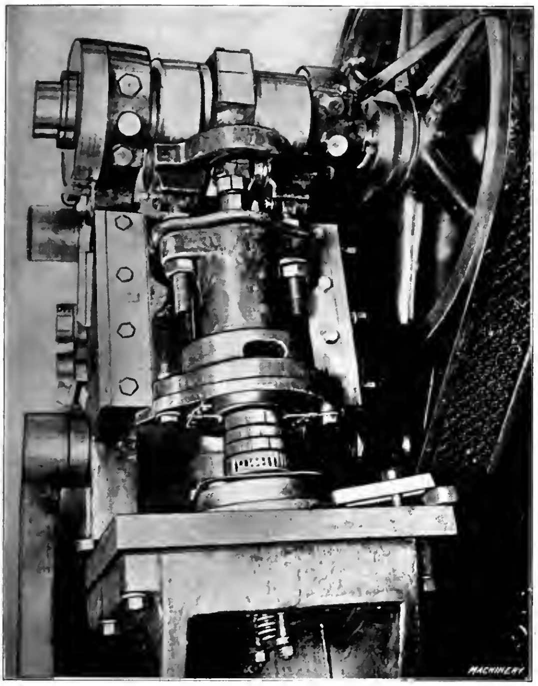

Fig. 6. Fender Type of Safeguard for Primary Operations

the cup collapses accordingly. This guard, which was developed by the Allgemeine Elektricitäts Gesellschaft, Berlin, Germany, can be used in most cases on the large machines, and is only effective for primary operations.

Hand Operated Machines

In the machines previously discussed, the clutch which actuates the ram is operated by the workman's depressing a treadle with his foot. He does not need his hands to operate the machine, only using them to place or feed the stock in the dies. In the class now to be considered, both the feeding—if there is no automatic feed—and the operating are done by either one or both hands. Nothing would be gained as regards safety by having only one hand do the engaging; therefore, practically no machines are in existence which depend on this operating method. Should a machine requiring a lever movement by both hands to make it operative be automatically fed, then the workman would not have to take his hands off the operating mechanism and he would be able to work faster, at the same time keeping his hands away from the danger zone. But should there be no automatic feed attached to the machine, the workman would not be able to work as fast as in the case of a machine having a treadle engagement and fitted with one of the guards previously mentioned. An advantage of this class is that there is no rhythmic movement which will be dangerous, and any noise or movement on the operator's part will not result in an accident. For this reason the two-handed engagement principle is by far the best safeguard.

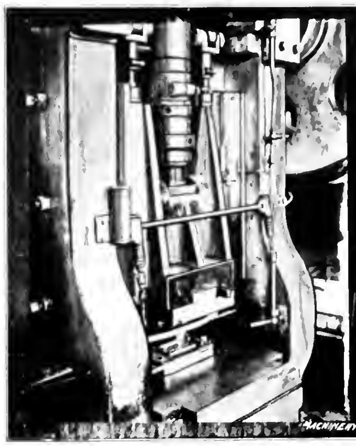

Fig. 7. Type of "Two-handed" Guard

Fig. 8 shows a machine equipped with a safeguard made by the Benjamin Electric Mfg. Co., Chicago, Ill. It has two levers placed one on each side of the machine, which are required to be pressed down by the hands of the operator before the clutch is engaged with the flywheel. The pressing of one lever will not start the machine. Another safeguard of this class is illustrated in Fig. 7 where the two handles in the illustration must be moved forward by the hands of the employe to operate the machine. This guard is used by the National Cash Register Co., Dayton, Ohio.

There are two kinds of guards which cannot be put in any class. The first is an amusing German suggestion to secure safety by placing a belt around the waist of the operator, and from a ring on this belt at each side having a short chain or strap passing around his elbows and then back to the ring. The length of the chain is so adjusted that the operator is able to place the pieces in the feeding mechanism in front of him but is not long enough to get his hands in the danger zone while sitting at his work. This safeguard can only be used where an automatic feed mechanism is attached to the machine, as it would not be a safety device without an automatic feed. This guard will probably never be used on this side of the water as no American workman would stand for having himself hampered in this manner.

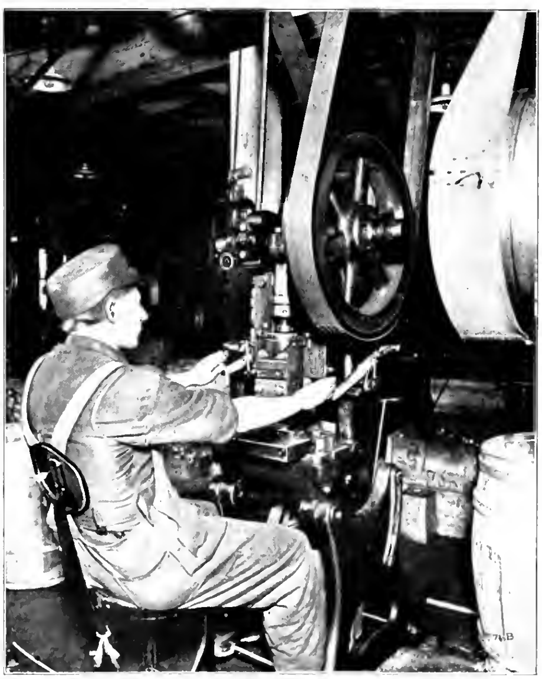

Fig. 8. Benjamin Guard that requires the Use of Both Hands to trip the Press

The second guard referred to, which is a more practical suggestion, is that the bed plate or die shall be in connection with an electric battery, with a condensing coil on the line. The plate shall be put in circuit by the motion which throws in the clutch, so that any fingers resting on this plate will receive a sharp shock and the muscles involuntarily contract, thus pulling the endangered fingers out of the path of the descending ram. This requires that the electrified plate shall be insulated from the metallic strip which the operator is feeding, and that the operator shall be grounded while at work, so that he may receive the shock when his fingers are in the danger zone. This idea is probably taken from central station practice, where the tools on a tool board are electrified to prevent unauthorized persons being tempted to take them. The shock they will receive as the tool is detached will usually cause it to fall from the hand which grasps it, and a considerable surprise and probable alarm is administered to the offender. To use this idea as a safeguard on a power press is both novel and interesting.

A guard should be made so that it will protect the worker against the possibility of his putting his hands in the danger zone from either side of the machine, as well as from in front, if it is to meet all the requirements of a guard. The guard shown in Fig. 6 meets this requirement while those illustrated in Figs. 1, 2, 3, 4 and 5 do not show that this condition has been met. A guard must not hamper the workman by preventing him from turning out the maximum number of pieces per day, and it should be so attached to the machine that it cannot readily be removed and not used. It should also consist of as few parts as possible. The guard shown in Fig. 2 is composed of a number of parts and is almost impossible for the operator to remove without spending considerable time; while Fig. 5 shows a guard which has very few parts and can easily be removed.

It cannot be said that any one of the preceding guards would meet all conditions under which a press may be used. It is a fact that with this class of machines very few of the guards are used continuously in the manufacture of one form or finished piece. It is more than likely that one machine will be used on different classes of work during a period of one year, and it has been found that each class of work would need its own special type of guard. On this account it is very hard for the employer to determine what make of guard he shall purchase.

* * *

The International Engineering Congress which meets in San Francisco, Cal., September 20-25, inclusive, will treat of engineering problems broadly. A symposium of subjects of great interest to all engineers is that on materials of engineering construction. The list of topics that will be treated in this section are as follows:

1. Timber.
2. Preservative Treatment of Timber.
3. Substitutes for Timber in Engineering Construction.
4. Brick in Engineering Structures.
5. Clay Products in Engineering Structures.
6. Probable and Presumptive Life of Concrete Structures made from Modern Cements.
7. Aggregates for Concrete.
8. Slag Cement.
9. Waterproof Concrete.
10. Cements containing Additions of Finely Ground Foreign Material.
11. Economics of the World's Supply of Iron.
12. The Life of Iron and Steel Structures.
13. The Employment of Special Steel in Engineering Construction.
14. The Place of Copper in the Present Engineering Field, and the Economics of the World's Supply Thereof.
15. Alloys and Their Use in Engineering Construction.
16. Aluminum in Engineering Construction.
17. The Influence of the Testing of Materials upon Advances in the Designing of Engineering Structures and Machines.
18. Cement Testing.
19. Testing of Metals.
20. Testing Full-sized Members.
21. Proof Testing of Structures.

Further information may be obtained from W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

METHOD OF CALIPERING A FIVE-FLUTED TAP

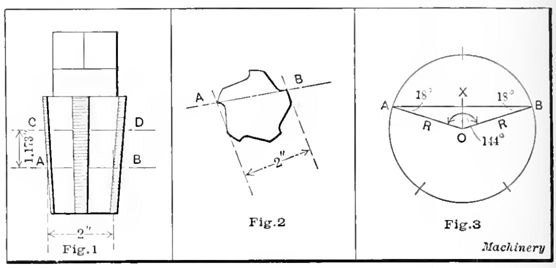
BY JOHN T. ENWRIGHT*

It is often necessary—especially in boiler work—to fit plugs by the size indicated by chalk on a five-fluted tap. For this purpose, the inside of the hole to be tapped is covered with chalk which marks the depth to which the tap has penetrated. When a tool with an even number of flutes is used, the required size for the plug can be taken directly from it. In the case of taps with an uneven number of flutes, however (generally five) a computation is required to secure the desired dimension. The method of making this computation is explained by the following.

The first step is to caliper the tap on the cutting edges at the point which marks the extent to which it has entered the hole. This would be at the line AB in Fig. 1. The dimension so obtained is multiplied by the constant 0.0489 and the product divided by the taper of the tap in inches per inch. The next step is to measure a distance AC parallel to the axis of the tap and then caliper the diameter at this point. The measurement of the tap on the line CD represents the size of the hole which is tapped out when the tool enters to the depth marked by the line AB. The distance AC measured parallel to the axis of the tap is determined by the following formula:

$$AC = \frac{\text{Diameter} \times 0.0489}{\text{Taper in inches per inch}}$$

To illustrate the method of using this formula, the following problem will be carried through. Consider a case in



Figs. 1, 2 and 3. Diagrams showing Method of deriving the Formula

which the dimension of the tap calipered on the line AB is 2 inches and the taper of the tap 1/12 inch per inch. The required distance AC at which the tap must be calipered to obtain the true size of the hole is then found to be

$$AC = \frac{2 \times 0.0489}{\frac{1}{12}} = 1.173 \text{ inch}$$

The method of deriving the formula for the distance AC is as follows: Referring to Fig. 3, AB corresponds to AB in Figs. 1 and 2. The triangle AOB is an isosceles triangle in which the angle $AOB = 2/5 \times 360 = 144$ degrees. The angle $OAB =$ angle $ABO = \frac{1}{2}\ (180 - 144) = 18$ degrees. $OA = OB = R =$ radius of the tap. The next step is to bisect the angle AOB so that $AX = BX$. By construction, the angle OXA is a right angle.

$$\frac{XA}{R} = \cos 18 \text{ degrees}$$

$$XA = R \times \cos 18 \text{ degrees} = R \times 0.9511$$

$$AB = 2\,R \times 0.9511 = D \times 0.9511$$

The difference between the true diameter of the five-fluted tap and the size calipered on the line AB is found to be:

$$2\,R - 2\,R \times 0.9511 = 2\,R \times 0.0489 = D \times 0.0489$$

The product of the diameter D by 0.0489 is divided by the taper of the tap in inches per inch, in order to obtain the distance AC which must be measured parallel to the axis in order to determine the location of the line CD on which to caliper the tap to determine the size of the hole that it will produce when it enters the work to the line AB.

SAFETY AS APPLIED TO GRINDING WHEELS*†

CAUSES OF GRINDING WHEEL ACCIDENTS AND MEANS OF AVOIDING THEM

ALL rapidly moving machine members present possibilities for the occurrence of serious accidents, and in view of the fact that it is necessary to operate grinding wheels at such speeds that the cutting surface travels at about a mile a minute, more than usual precautions must be observed in their operation in order to provide for the safety of the operators. These precautions may be sub-divided under two headings; first, to eliminate as far as possible, all causes which are known to have been responsible for grinding wheel breakages; second, to provide adequate means of protection for men and property in event of a wheel breaking. Reputable manufacturers of grinding wheels test each wheel before it is shipped. This is done by rotating the wheel at a speed which subjects it to between three and four times the centrifugal force that would be exerted when operating under average conditions. The wheel is then marked by the inspector to show that he has found its condition satisfactory.

The design and condition of grinding machines as well as the foundations on which they rest, are very important factors in the prevention of accidents, as such accidents can often be traced to these causes. The modern grinding machine with its heavy spindle and massive base, and its long closely adjusted bearings, is responsible for the elimination of many accidents which would otherwise occur. Grinding machines should be kept in good condition and they should be mounted on a rigid foundation. Machines used for rough work, such as snagging castings, are frequently subjected to severe abuse and it is significant that statistics show that the majority of grinding accidents occur in foundries where such conditions exist.

A somewhat unusual cause of breakage of grinding wheels is that resulting from undue heating of the wheel. In such cases this is usually due to the wheel becoming glazed so that excessive pressure is necessary to maintain the desired rate of production. Where this condition exists, the wheel is unduly heated at its periphery and this leads to uneven expansion, resulting in rupture. This danger is eliminated by keeping the wheel properly dressed at all times. Another source of danger arises from the possibility of damaging wheels used in snagging castings. Where the casting is suspended by a chain hoist as shown in Fig. 1, the operator may allow the casting to strike the side of the wheel with sufficient force to either break it directly or weaken it so that it will break later on.

The relative merits of safety flanges and safety hoods were discussed in a previous paper (see MACHINERY, January, 1914). While one of these measures is very necessary for use on all grinding wheels, the observation of suitable precautions in mounting the wheels is a most important factor in preventing them from breaking. Fig. 2 illustrates an example of dangerous mounting. The outside flange was lost and the operator substituted a small washer in its place. This produces such a severe strain on the wheel that it either breaks immediately upon attaining the operating speed or soon after it is put to use. Fig. 3 shows how an accident was caused in a factory in the Middle West. The operator had a piece to grind that was of such a shape that the outside flange on the wheel interfered with the work. Without obtaining permission from anyone, he removed the nut and the outside flange, and then obtained a rough forged washer in which—for some unknown reason—he was very careful to hammer a lead bushing from an old grinding wheel. He then mounted the wheel as shown. The man lost his life from the breakage which resulted when he attempted to work with the wheel in this condition.

Causes of Grinding Wheel Accidents

1. *The wheel receives a blow from the side.*
2. *The work-rest is improperly adjusted.*
3. *The wheel is unduly heated by forcing the work excessively.*
4. *The operator is careless in handling heavy work, thus causing the wheel to be damaged.*
5. *The wheel is mounted between flanges of unequal size.*
6. *The flanges have an uneven bearing against the wheel.*
7. *The wheel is running out of truth.*
8. *The inside flange is loose on the spindle.*
9. *The spindle is too tight a fit in the hole in the wheel.*
10. *The flanges are not provided with the necessary relief to assure an even bearing.*
11. *The nut on the spindle is tightened excessively.*
12. *The washers are either too small or omitted.*
13. *The spindle and spindle bearings become overheated.*
14. *The wheel is run at too high a speed.*
15. *The wheel is mounted in such a way that the nut on the spindle works loose.*

Methods of Avoiding Grinding Wheel Accidents

1. *The use of protection hoods or safety flanges to provide for the safety of the operator in the event of the wheel breaking.*
2. *The use of wheels which have been subjected to a speed test by the grinding wheel manufacturer to discover any defects which may exist.*
3. *Testing each wheel before it is mounted on the grinding machine ready for use.*
4. *The use of machines of the necessary rigidity and the mounting of such machines on rigid foundations.*
5. *The exercise of the necessary supervision on the part of the superintendent or foreman to be sure that none but wheels of the proper size are used on each machine, and that these wheels are driven at suitable speeds.*
6. *The use of goggles and spark shields to protect the eyes of the operators from injury.*

In order to avoid accidents resulting from broken wheels, be sure that the flanges used are of equal size and that their diameter equals at least one-half of the diameter of the wheel. It is also highly important for the flanges to have an even bearing on the wheel. Where the bearing is uneven, it is usually caused by the flanges being damaged to such an extent that they lose their original shape. In rare instances, flanges have been used which were not machined, but were taken right from the casting in the sand. Such practice brings unequal stresses to bear on the wheel and a breakage is the logical result. The wheel must also run true, in order to avoid subjecting it to uneven strains. When it does not run true, it may be due to the hole in the wheel being much too large for the size of spindle, or to the fact that the flanges do not hold the wheel properly. This, in turn, may be caused by the nut becoming wedged on the spindle before it has been drawn up to the flanges, due either to dirt in the thread of the spindle or in the thread of the nut. The man mounting the wheel gets the impression that he has properly drawn up the flanges against the wheel, when such is not the case. Another cause for wheels running out of true is directly traceable to failure to give proper attention to the machine bearings. The bearings become highly heated, the bearing metal flows, a heavy brake action is produced on the spindle, and when the machine is stopped the momentum of the grinding wheel is sufficient to loosen the mounting. When the wheel is started again the nut will not automatically tighten and the wheel will be running under a dangerous condition.

Wheels should not be allowed to remain partly submerged in water, because they will be badly out of balance when started. Some people seem to believe that water has a detrimental effect on grinding wheels. This is not true of modern grinding wheels; even those bonded by means of silicate bonds are made waterproof. Another noteworthy precaution is to have the inside flange either keyed or pressed on the

* For other articles on the safeguarding of grinding machines published in MACHINERY, see also "Grinding Wheel Protection Devices," by R. G. Williams, January, 1914; "Guards for Polishing Wheels," November, 1913; "Prevention of Industrial Accidents," by F. R. Hutton, April, 1912; "The Bursting of Emery Wheels," July, 1903; and "Fastenings for Emery Wheels and Grindstones," December, 1902.

† Paper by R. G. Williams presented before the National Machine Tool Builders' Association convention, Worcester, Mass., April 24, 1914.

spindle. Accidents have been known to result from the work being rubbed against a loose inside flange, thus exerting a brake action on the flange, which in turn, caused the nut on the spindle to crawl. In this way, enough pressure was exerted on the wheel by the flanges to crush it.

An accident may result by having the wheel screwed on the spindle when the hole is too tight a fit. The illustration Fig. 4 shows the result when the hole is too small for the spindle. The lead bushing becomes deformed by the wheel being screwed on over the spindle, with the result that each flange only bears on the wheel for a small distance. The remedy for this is to make sure that the hole is of such size that the wheel will slide on the spindle easily. Fig. 5 shows a possible result from the use of unrelieved flanges. As an illustration, consider an instance where the operator exerts excessive pressure on the nut when mounting the wheel. This causes straight flanges to become slightly convex, as shown in the illustration, and concentrates the retaining pressure near the center of the wheel instead of distributing it uniformly throughout the area of the flanges. The remedy for such a situation is to have the flanges—either straight or beveled—relieved to such an extent that a bearing surface approximately 1/16 of the diameter of the flanges is left near the rim. By the excessive tightening of the nut, sufficient pressure can be set up between the wheel and the flanges to crush the structure of the wheel. It has been calculated that where the size of the spindle is 1½ inch in diameter, a man with a four-foot wrench can exert a pressure between the wheel and the flanges of over a ton and a half. The nut should not be tightened more than enough to hold the wheel firmly.

Washers of blotting paper or some other compressible material should be used between the wheel and the flanges. These tend to distribute the stresses set up when the flanges are tightened against the sides of the wheel. The washers should be somewhat larger than the flanges. It is possible for a small piece of metal to become caught in some way between the wheel and the flanges, which, if no compressible washer is used, will cause an excessive strain to be set up at this particular point when the flanges are tightened. The use of compressible washers in such an instance tends to distribute such unequal stresses. When the spindle becomes overheated, the heat is conducted to the lead bushing of the wheel, which may expand to a point where it causes the wheel to break. This danger can be readily overcome by proper attention to the bearings of the machine. Another possibility of accidents is due to the fact that a careless workman may so equip the machine that the revolutions per minute of the spindle is far too great for the particular size of wheel in use; or it may possibly be that through a foreman's desire to increase production, he speeds up the wheels so that they will cut faster. Again, where a machine is equipped with cone pulleys and the belt is loose, it is possible for the belt to automatically shift to a smaller step and thus greatly increase the speed of the grinding wheel. Sometimes ignorant workmen will mount large wheels on a machine which is equipped and intended for very much smaller ones, thus creating a dangerous condition.

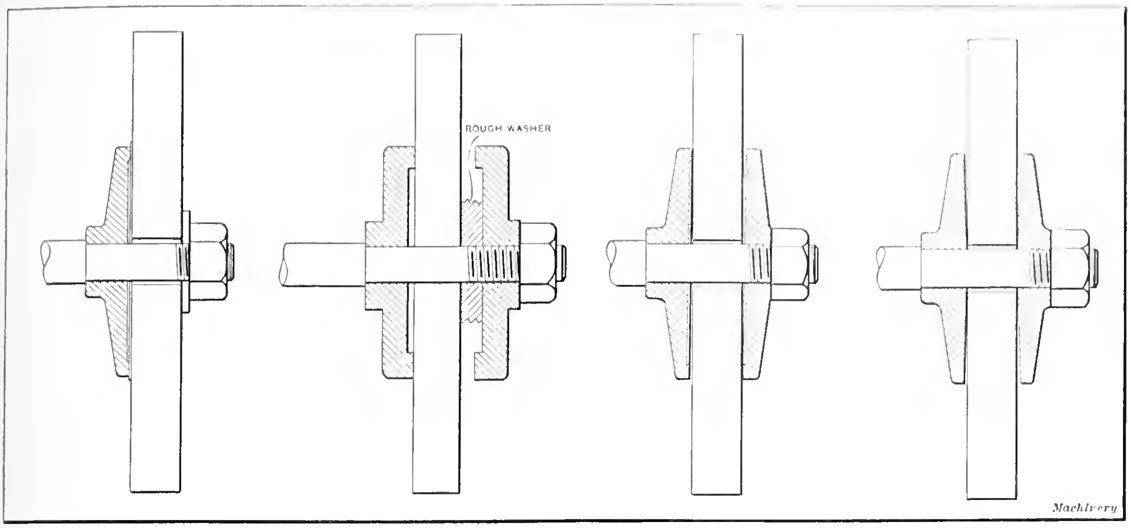
Machinery

Polishing stands are sometimes used for rough snagging work, with wheels which are much too heavy for this type of machine. Bench and floor types of grinding machines are usually designated by the size of the spindle on which the wheel is mounted. It is, therefore, a common practice to designate the maximum size wheel to be used on any machine by tabulating spindle sizes and wheel sizes, as presented in the above table. An accident may be caused by mounting a wheel so that the nut works loose, which will cause the wheel to run badly out of true. This can happen in three ways: 1. A machine is taken apart for repair and when set up the spindle is turned end for end from its original position. 2. The motor or shafting which drives the machine is changed so that it will revolve in the opposite direction from which it should. 3. When putting on a new belt, an unreliable workman may use a twisted instead of a straight belt. All of these conditions can be very easily remedied by a little care on the part of some responsible person. In addition, belt locking devices may be used, and so set in the base of the machine as to make it impossible to mount too large a wheel. To further guard against such mistakes it is good practice to have a special notice attached to each machine giving information as to the size of the wheel to be used, the number of revolutions per minute at which the wheel should be run and the class of work for which it should be used.

Exhaust Systems and the Use of Goggles

Laws in almost every country require the removal of dust from grinding. This necessitates the use of a hood, and if a hood must be used, it might just as well be strong enough to offer protection in case of the wheel breaking. A proper hood affords complete protection, which flanges cannot give; but in instances where a hood would interfere with the proper use of the wheel, flanges offer the next best method of protection. There are many satisfactory types of protection hoods on the market, the reason for more than one type being found in the variety of grinding operations.

There are several satisfactory designs of goggles for grinding, and every operator doing snagging work should be required to wear them. Since the particles cut off by grinding wheels are comparatively small, a heavy type of goggle is not necessary. Goggles should have side guards of wire or



Figs. 2 to 5. Examples of Defective Mountings that are likely to cause Accidents

leather, as particles coming from the side have been known to enter the eye. A glass spark shield which can be attached to the top of a protection hood is found very satisfactory where wheels are used intermittently, as in the case of a general purpose wheel in a machine shop. It is recommended that wire glass be used. Glass spark shields have not been found entirely satisfactory where wheels are used continuously, however, due to the fact that the glass soon becomes pitted from the heated chips of metal. Another form of protection from grinding wheel sparks is a device consisting of a piece of leather attached to the top end of a protection hood and extending down over the face of the wheel, a slot being cut in the leather of the approximate width of the grinding wheel.

Dressers

Grinding wheel dressers are sometimes the cause of accidents. If the work-rest is not properly adjusted there is a possibility of the dresser being caught between it and the wheel, and the revolving cutters sometimes break into pieces large enough to cause serious damage. A type of dresser is recommended which has a hood as an integral part of the handle, the hood serving to protect the user in case the cutters break. The ordinary type of dresser can be made more safe by attaching a thick guard of sheet iron over the cutters.

There is great need for the standardization of grinding wheel protection devices. This subject is to be taken up in the near future by the National Council for Industrial Safety and the National Machine Tool Builders' Association. These two organizations will consider all the important phases of this subject and endeavor to arrive at specifications which can be adopted as standard for protection devices used in connection with grinding wheels. In conclusion, it is gratifying to note that the efforts for safety as applied to grinding wheel operations are accomplishing results, in that the number of serious accidents is rapidly decreasing. We will always have a few unpreventable accidents, but until every preventable accident has become a thing of the past, we should strive for a better understanding and an improved use of the modern safety devices for grinding wheels.

PREVENTING MOISTURE FORMING ON WATCHMAKERS' EYE-GLASS

In certain branches of the machinist's trade, and especially in fine toolmaking, the use of a watchmaker's eye-glass is frequently required for long periods. It will be found that after the eye-glass has been in continuous use for a certain length of time—depending principally upon the temperature of the surrounding atmosphere—the lens becomes covered with mist on the side nearest the eye. This interferes with the use of the glass.

There are many good preparations on the market which can be rubbed on the lens to prevent this "fogging," but as they are more or less opaque, they are not to be recommended when accurate work is essential. A very simple and effective method which is found in use in some shops is to drill four equally spaced holes through the hard rubber shell about 1/8 inch back of the lens. A No. 54 drill is about right for this purpose. If this method is followed the eye-glass can be kept in the eye indefinitely without "fogging" the lens.

THE VALUE OF A PATENT*

BY FORD W. HARRIS†

There are no questions in relation to patents more important than those which deal with their commercial value. Practically all patents are applied for with the idea of making profits, and the value of a patent is the one great question in which every inventor is interested. This article is intended to indicate how an approximate value of a patent may be arrived at. It may be said in the beginning that there is a popular misconception of the true meaning of the grant of letters patent. In the popular mind a patent is a licence for the inventor to build the thing disclosed in the drawing and the specification, and, further, a legal bar to prevent others from building, making or using that thing. These, to the popular mind, are the purposes of a patent—first, to allow the inventor to use, and second, to prevent everyone else from making or using the invention.

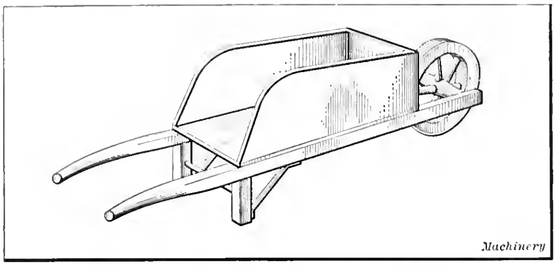

Fig. 1. Wheelbarrow as covered by Jones' Patent

The first of these, that is, the license purpose, is not the intention of the patent. The law does not contemplate licensing an inventor. It merely contemplates giving him a monopoly; that is, he can stop others from making, renting or using the invention claimed in his patent, but whether he can do so himself or not depends on several things. This and the points to follow can best be illustrated by specific cases. For example, let us assume that no one has ever invented a common wheelbarrow and that Jonas Jones has a patent on it, as illustrated by Fig. 1. Let us further suppose that he has claims as follows:

1. A barrow comprising a load-holding means, wheel means at the forward end thereof, and handle means at the rear end thereof.
2. A barrow comprising a load-holding body, a wheel supporting the forward end of said body, legs supporting the rear end of said body, and handles by which the rear end of said body may be raised.
3. A barrow comprising two handle members having handles formed on one end thereof, a wheel supported between the other ends of said handle members, a rectangular body supported on said handle members, and legs extending donwardly from the said handle members.

Let us further suppose that Jones was clearly entitled to these claims and that his invention is the very first that even remotely resembles a wheelbarrow. In this case the government has given him a broad patent and one that is difficult to avoid infringing. Claim (1) is very broad, covering as it does the combination of any sort of a load-holding means, any sort of wheel means at the forward end of the load-holding means, and handle means at the other end of the load-holding means. While it could be avoided by placing the wheel and the handles on the same end or by omitting one of the three elements named, it is evident that if this is done we will not have a wheelbarrow. It will be noted that this claim does not specify any legs. Nevertheless it cannot be avoided by adding legs. In other words, if the three elements specified in the claim are used for the same purpose and in the relation specified in the claim, the claim cannot be avoided by adding another element.

Let us now suppose that Bronson Brown invents the wheelbarrow shown in Fig. 2 after Jones has obtained his patent. The patent office would grant claims about as follows:

1A. A barrow comprising a saucer-shaped metal load-holding means, wheel means at the forward end thereof, and handle means at the rear end thereof.

2A. A barrow comprising a load-holding means, wheel means at the forward end thereof, hinged handles at the rear end thereof, and locking braces for said handles.

To the average person it would seem that Bronson, having a patent which describes and claims a certain type of wheelbarrow, should be entitled to make, use and sell that wheelbarrow. As a matter of fact the issue of the patent has not affected Bronson's rights to make, use and sell in the slightest degree. His invention contains all the elements of the first claim of Jones and clearly infringes it. In other words, he has absolutely no right to make it until the Jones patent runs out.

His patent simply grants him a right to prevent others from making the structure claimed. An examination of Claim (1A) discloses that it is like Claim (1) except that it specifies a "saucer-shaped metal load-holding means." The claim grants to Brown the sole right to use such a load-holding means. Now Jones can prevent Brown from making any kind of a wheelbarrow, but Brown can prevent Jones from using his peculiar type of load holder. The patent to Jones is broad or generic, while the patent to Brown is narrow or specific. If no patent had ever been granted to Jones and the wheelbarrow shown in Fig. 2 was the first of its class Claim (1) could have been granted thereon as well as upon the wheelbarrow shown in Fig. 1. If, however, Brown's attorney were incompetent, and asked only for Claims (1A) and (2A), these would be all the claims Brown would get. In this case any one could build the wheelbarrow shown in Fig. 1, as this neither has the "saucer-shaped load-holding means of Claim (1A), nor the "hinged handles" of Claim (2A). In this case Brown would have lost a valuable invention due to having a poor attorney.

In the same manner Claim (3) of Jones patent specifies "a rectangular body supported on said handle members." If Jones had no broader claim than this, he could not stop Brown from making a body not rectangular, nor could he stop any one from doing this or from making a body supported otherwise than on the handle members. In other words, if Jones had only Claim (3) he would have a narrow, specific patent in the place of a broad generic one.

A patent covers what it claims, not what it shows. Every claim is a patent in itself and may be sued on and adjudicated

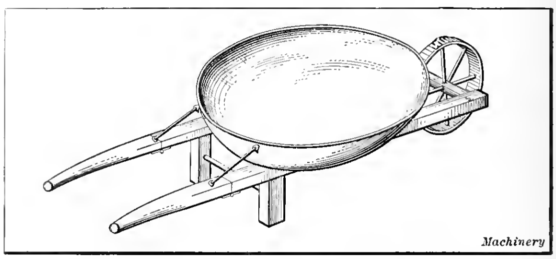

Fig. 2. Wheelbarrow covered by Brown's Subsequent Patent

quite apart from the remaining claims. Each claim consists of a combination of several elements modified by limiting clauses. Omitting one of the elements from a structure avoids that claim so long as an equivalent element is not added in its place. This is the general theory of claims.

Claims are, however, interpreted by the courts in the light of what has gone before. If, for example, Jones had antedated Brown by several years, and was clearly the first inventor of any sort of a wheelbarrow, the courts would not attach much importance to the "rectangular" in Claim (3). It might be argued that this distinction was immaterial and that the word had slipped in inadvertently. If, however, wheelbarrows like Fig. 2 were already known, it would be evident that Jones must limit himself to rectangular bodies to have a valid claim, and that the word "rectangular" would be essential and not inadvertent. The courts will also consider various collateral circumstances, such as the relation of Jones and Brown and the utility and value of the invention

* See MACHINERY, April, 1914, "Patents—Some Essential Facts for the Engineer," and other articles there referred to.
† Address: 1033 Higgins Bldg., Los Angeles, Cal.

at issue. For this reason the wording of claims is not always conclusive, but in general the rule is as stated.

Having now a certain patent, we wish to know its value. Let us suppose that Brown's patent is to be examined to determine its value, and let us further suppose that we know nothing of Jones' wheelbarrow. How shall we arrive at the value of the patent to Brown?

The first thing is to determine the prior state of the art at the time Brown applied for a patent. This can be done by having the patent office make a typewritten copy of the file-wrapper and contents, and send them to us with the references to prior patents found and cited by the examiner in the prosecution of the case. We can then carefully review the case, see what claims Brown made originally and what claims he had to cancel and abandon. We can see further just what the prior patents were with which he had trouble. If the case is very important we may send for file-wrappers and contents on some or all of these prior patents and study them. Further, we would go ourselves to the patent office and search the records for patents that the examiner did not regard as pertinent or overlooked in his search. This would all take time, but would result in a clear conception as to exactly what Brown was entitled to when he applied.

The claims in the Brown patent are then studied to see what the elements of the combination are, and to see if one or more cannot be omitted and yet have a commercial device. If one of these elements is not absolutely essential or if a limiting clause is present which may be omitted without hurting the article it is sought to manufacture, it may be at once said that the patent is of little or no value. Many patents are valueless on their face due to limiting clauses therein or to elements that are not essential. Many others are valueless because they are dominated by earlier and broader patents. The search in the patent office and the study of the data collected should disclose these broader patents if any exist. It may be said, however, that there is no sure way to find absolutely all the prior patents that may affect the right to manufacture an article. This is due partly to the fact that a claim for a collection of elements used, for example, in a wheelbarrow, may be found in a wagon, a railroad car or an aeroplane patent. You may be sure that you cannot manufacture an article due to a prior patent, but you can never be sure you are not infringing the rights of some one else.

Strictly speaking, the only way to determine a patent's value is to submit it to a lawsuit. After a patent has been passed upon by a Federal court and has stood the test of litigation its value may be said to be fixed. This is very expensive and slow, and no business man wants to wait for such action by the courts. There is no reason, however, why a competent patent lawyer cannot arrive very closely at a patent's value at a very moderate expense. Certainly, no one should pay for patent rights or embark in a business based wholly or in part on patent rights without first getting such an opinion.

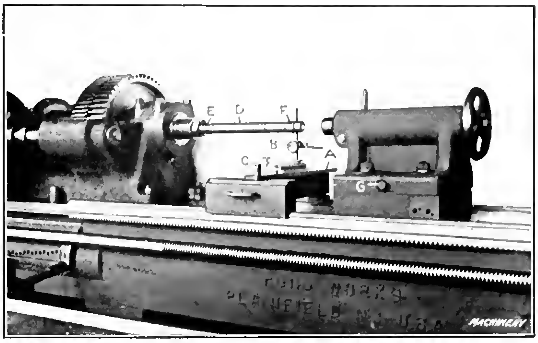
LINING UP ENGINE LATHE HEADSTOCKS AND TAILSTOCKS*

BY ALFRED SPANGENBERG†

The first requirement in aligning engine lathe headstocks and tailstocks on the beds is to determine the horizontal alignment, both as regards parallelism with the ways on the bed and relative height between the headstock and tailstock spindles. This is owing to the fact that if any errors are discovered which exceed the allowable limits of variation, the part at fault must be removed and either filed and scraped to bring it true, or machined if the circumstances warrant such a procedure. By the usual method of making this test, where the indicator is carried in a fixture fitting the bed vees or clamped in the regular carriage toolpost, it becomes necessary to first align the headstock and, tailstock spindles sideways; otherwise, the line of motion of the indicator point in traveling from one collar to the other on the test-bar would not be parallel with the axis of the test-bar and the readings would be false.

A fixture that permits the testing of horizontal alignments regardless of the errors sideways, thereby saving much time, is shown in the accompanying illustration, which also shows a headstock and tailstock in position on the lathe bed ready for the test. As will be seen, the fixture fits the V-tracks on the bed and is provided with a plane surface *A* which is scraped true to support the Brown and Sharpe indicator *B*. The idea is to pass the indicator point under the test-bar in a crosswise direction, the maximum reading indicating the true height. Clamp *C* is used to clamp the indicator on the fixture when testing alignments sideways.

The method of "lining up" is to place the test-bar *D* in the taper hole in the headstock spindle, and with the indicator set as shown, the spindle is revolved slowly by hand to test the concentricity of the taper hole. A chalk mark is then



Fixture for aligning the Headstock and Tailstock, which permits of making Height Tests regardless of Sidewise Alignment

made on the test-bar and a corresponding mark on the spindle nose to denote a point that is a mean between the "high" and "low" points on the bar. All subsequent readings of the test indicator are taken from this point. This test is obviously necessary, since the bar is particularly likely to run out at its free end due to a number of conflicting elements, the error in any one of which may be infinitesimal. The fixture is now moved along to collar *E*. The indicator is passed under the bar in a crosswise direction and the indicator dial is set to zero at the highest reading. A similar reading is taken at collar *F* which shows the error as regards parallelism with the vees of the bed. The bar is then moved over into the tailstock spindle hole and readings are taken on both collars in order to test its parallelism and the relative height of both spindles. Each reading is properly noted on a suitable form, and if the errors are within the permissible limits of variation, the headstock is set parallel with the vees sideways and the dowel pin holes are reamed.

The setting of the headstock sideways is accomplished by again placing the test-bar in the head spindle and indicating on the side of the bar, the clamp *C* being utilized to hold the indicator rigidly. As was previously explained, the spindle was moved a quarter turn before this test so as to indicate on the same point on the bar. The indicator point is, of course, set at a height the same as that of the spindle axis, as nearly as the eye can judge, and at the same time the dial is set to read zero. After the head is set parallel and pinned, the test-bar is moved over into the tailstock spindle hole, and having adjusted the set-over screw *G* to bring this spindle in line with that in the headstock (the reading being zero, the same as before) the tailstock spindle is tested for alignment sideways.

In setting the indicator at the starting point, care should be taken to make the maximum movement of the indicator needle not exceed 0.005 inch above its normal position, as otherwise the spring of the dial supporting arms is likely to cause false readings, especially if there is considerable variation in the different readings.

DYNAMICS OF GAS ENGINE CAMS*

A CONSIDERATION OF THE MUSHROOM TYPE OF VALVE LIFTER

BY M. TERRY†

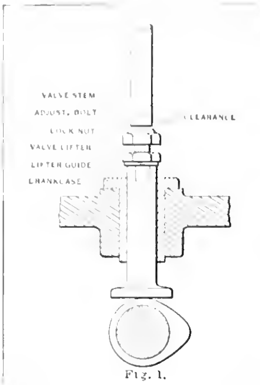

Fig. 1. Valve Gear with Mushroom Type of Lifter

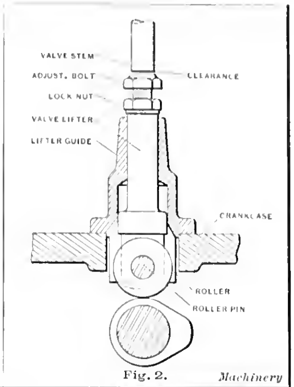

Fig. 2. Valve Gear with Roller Type of Lifter

WHILE this article bears the same general title as those that appeared in MACHINERY for November and December, 1912, it is entirely independent of them, as it deals with a different type of cam. For the benefit of the readers who have missed the former series, the article here presented will be made as clear as possible without going into minute details and repeating what has already been published.

What is generally known as the mushroom type of valve lifter, used for actuating the valves of a gasoline engine, is shown in Fig. 1; and the more popular form of lifter—known as the roller type—is shown in Fig. 2. The main difference between the two types lies in the fact that the valve gear equipped with the mushroom lifter possesses fewer parts and requires less machining, piece for piece, than does a similar valve gear equipped with the roller type of lifter; in short, the former is cheaper to build. Its chief disadvantage lies in its noisy operation, and this characteristic—said to be inherent—has prevented its general introduction on pleasure cars, particularly those of the type that make their appeal to the buying public through their mechanical perfection rather than their low selling price. This statement is not made with the object of condemning the mushroom type of lifter; on the contrary, when we become acquainted with some of its peculiarities, a proper place will be found for it, where from a mechanical point of view it will be on a par with the roller type, and considered from a commercial standpoint will even be in the lead.

We shall now proceed to design a cam-shaft to meet the following requirements: Base circle of cam, 1.000 inch in diameter; cam lift, $3/16 = 0.1875$ inch; clearance between valve and valve lifter, 0.006 inch; timing, as per diagram shown in Fig. 3. All these conditions govern the shape of the two cams, and we shall presently commence with the inlet cam. Referring to the timing diagram, Fig. 3, we observe that the inlet valve is open for 200 degrees of the crankshaft circle. Since the inlet cam which directly actuates this valve is mounted on the half-time shaft, its active angle is 100 degrees. To this we must add twice the clearance angle to compensate for lost motion (due to clearance between the valve stem and the valve lifter) on the up and down strokes. In the mushroom type of valve gear, the clearance angle is determined entirely by the base circle of the cam and the radius of the arc AB, as shown in Fig. 4. The latter, in its turn, is governed by the lift of the cam, its active angle and also by its clearance angle. The relation being mutual and rather complicated, the writer has developed a very simple cut-and-try method which need never involve more than one trial.

In Fig. 4, the cam and its lifter are shown in a position where the latter is ready to rise. When in this position, the arc AB is tangent to the line MN and also to the base circle of the cam at the point A. The center from which the arc AB can be struck to satisfy these conditions must obviously lie on the vertical line AH. The active angle of the cam being 100 degrees, its center line cannot be less than 50 degrees from the line OA; as a matter of fact, the true angle made by the center line of the cam with this line OA is 50 degrees plus the clearance angle. Assuming that the clearance angle is 2 degrees, we draw our preliminary center line OF 52 degrees from OA. Next strike the arc CD with a radius of 0.6875 inch $(0.500 + 0.1875)$ which limits the lift of the cam; arc CD intersects OF at E. Now the arc AB should intersect our assumed center line OF at a point F such that OF is greater than OE. The reason for this is that if OF were less than OE, we would fail to obtain the required lift; and if OF were equal to OE, we would succeed in maintaining the required lift but the cam would terminate in a sharp ridge, which would be a poor design. Also, for the sake of quiet action (as will be proved later on) the radius of the arc AB must be as small as possible. Limited by these two conditions, there is left only a very small range through which the value of this radius can vary, and we select the nearest even dimension, namely 2½ inches.

As the cam revolves in a counterclockwise direction, the lifter rises and the point of contact between MN and AB moves to the right of A; at the same time, the center H of the arc AB describes an arc HH_1, with O as its center. But as long as MN remains tangent to AB, the distance between MN and H remains constant, namely 2½ inches, and hence the rise of the valve lifter at any instant must be equal to the rise of H above the horizontal line HI. If the lifter rises the distance MM_1, or 0.006 inch (clearance), H moves to a new position H_1, such that GH equals 0.006 inch; and the cam,

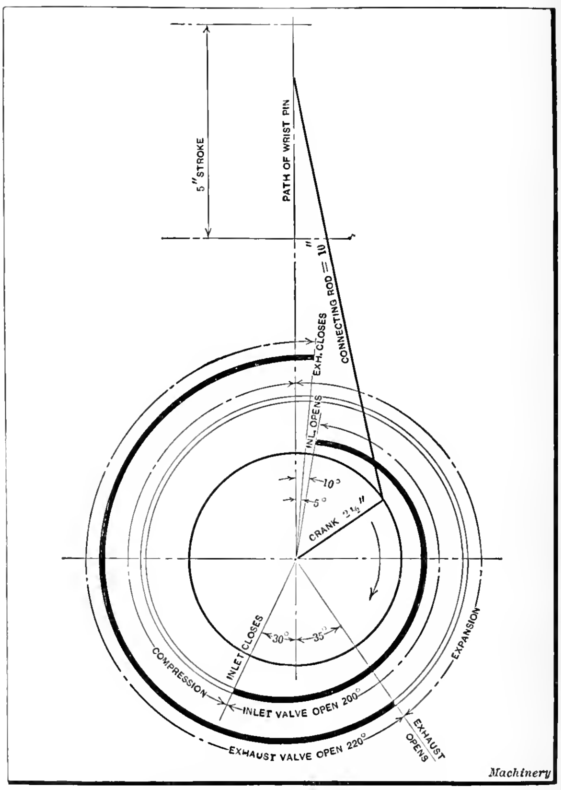

Fig. 3. Timing Diagram for the Cams

* For additional information on this subject see "The Valve Problem on Gasoline Engines," published in the March, 1914, number of MACHINERY, and other articles there referred to.

† Address: 1063 Manning St., Flint, Mich.

in the meanwhile, has turned through an angle α, which obviously is our clearance angle.

$$\cos \alpha = \frac{1.994}{2.000} = 0.997.$$

$$\alpha = 4 \text{ degrees } 30 \text{ minutes}.$$

The real center line of the ram is OE_1, which makes an angle of 54 degrees 30 minutes with OA and the total included angle of the inlet cam is 109 degrees as shown in Fig. 6. The common practice in regard to the fillet is to place its center on the center line of the cam, and our next problem consists in accurately determining the radius of the fillet which will be tangent to both AB and CD and whose center lies on OE_1. From Fig. 5 we find:

$OH = 2.000$ inches $= X$.

$OO_1 = 0.6875 - S$ inch $= Y$.

$O_1H = 2.500 - S$ inch $= Z$.

angle $HOO_1 = 125$ degrees 30 minutes $= \theta$.

$$\cos \theta = \frac{X^2 + Y^2 - Z^2}{2XY}.$$

cos 125 degrees 30 minutes = cos $(90° + 35° \; 30') = -\sin 35$ degrees 30 minutes $= -0.5807$.

$$\text{Hence } \frac{Z^2 - X^2 - Y^2}{2XY} = 0.5807.$$

Substituting actual values for X, Y and Z, we obtain

$$(2.500 - S)^2 - (0.6875 - S)^2 - 4 = 0.5807 \times 2 \times 2(0.6875 - S)$$

$$6.25 - 5S + S^2 - (0.4726 - 1.375S + S^2) - 4 = 1.5968 - 2.3228S.$$

By adding, subtracting and transposing we get:

$$1.3022S = 0.1806.$$

$$S = \frac{0.1806}{1.3022} = 0.139 \text{ inch}.$$

The object of determining the radius of the fillet in thousandths of an inch is to enable the toolmaker to form an accurate templet with the help of which he shapes the first master cam. The templet is shown in Fig. 8; in laying this out, the distance OO_1 must be given in thousandths of an inch, and this, of course, is impossible unless the radius of the fillet is accurately determined. The fillet hole is drilled first—in this case—with an under sized 9/32-inch drill; next, the base circle hole is drilled, and finally the remaining metal is removed by filing.

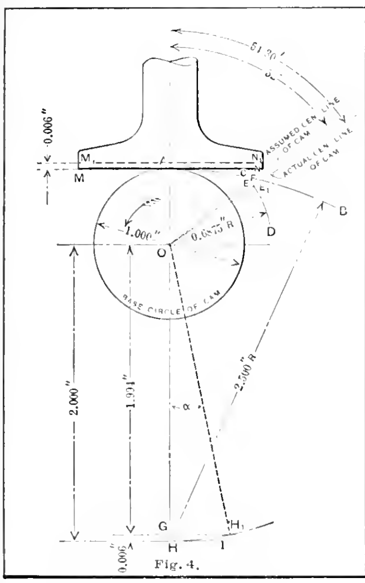

Fig. 4. Method of determining the Clearance Angle

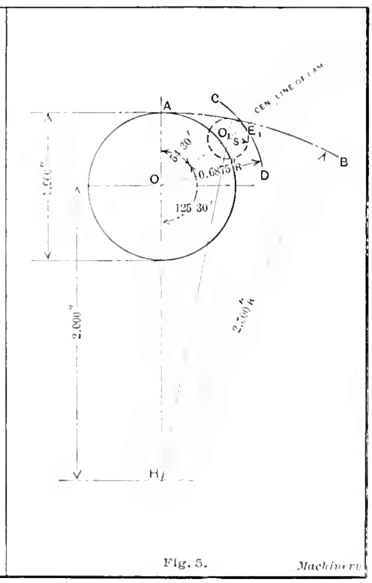

Fig. 5. Method of determining the Radius of the Fillet

The exhaust cam is generally made up of the same arcs as the inlet cam, except that, being wider, it possesses a dwell—amounting in this case to 10 degrees—as shown in Fig. 7. Considerable gain, so far as quietness of operation is concerned, may be secured by taking advantage of the wider angle of the exhaust cam for the purpose of shortening the radius of the arc that controls the clearance angle. It is evident from Fig. 4 that the shorter the radius of the arc AB, the greater is the clearance angle α for a given amount of backlash between the valve stem and the valve lifter; and it will be proved later on that, other things being equal, the greater the clearance angle for a given amount of backlash,

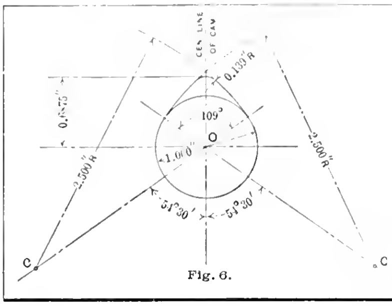

Fig. 6. Method of laying out the Inlet Cam

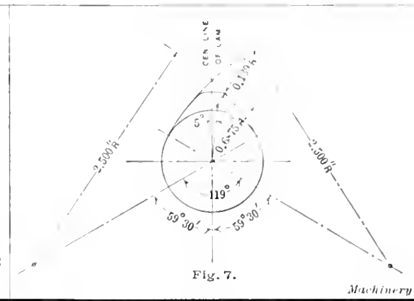

Fig. 7. Method of laying out the Exhaust Cam

the quieter is the valve gear. This principle has been pointed out in the analysis of the roller type of valve gear ("Dynamics of Gas Engine Cams," engineering edition of MACHINERY, November and December, 1912) and it applies equally well to the mushroom type.

Spacing of Cams

Our next problem is to space the inlet and exhaust cams that operate the same cylinder so as to secure the succession of events prescribed by the timing diagram shown in Fig. 3. The Otto cycle consists of four strokes of the engine, generally considered as taking place in the following order: First, suction or inlet stroke; second, compression stroke; third, expansion stroke; and fourth, exhaust stroke. Any suction stroke follows immediately after the exhaust stroke of the preceding cycle; or, to put it in other words, the action of the exhaust cam immediately precedes that of the inlet cam, which is also evident from Fig. 3. A simple graphical method for spacing the exhaust and inlet cams is shown in Fig. 9. With the cam-shaft revolving counterclockwise, we select the horizontal line OA for the center line of our exhaust cam. Fig. 3 calls for 220 degrees of exhaust valve opening; the active angle of the exhaust cam mounted on the half-time shaft will be 110 degrees, and, hence, the "exhaust opens" line OB lies 55 degrees ahead of OA. Again, according to Fig. 3, the "inlet opens" and "exhaust opens" lines are 225 degrees apart; hence, in Fig. 9, OB is 112 degrees 30 minutes ahead of OC. The active angle of the inlet cam being 100 degrees, its center line OD is 50 degrees behind OC. This gives us 107 degrees 30 minutes for the angle between the center lines of the inlet and exhaust cams operating the same cylinder. Fig. 10 is a diagrammatic end view of the cam-shaft designed for a four-cylinder engine; it shows the proper arrangement of the four sets of cams that would enable the engine to fire as indicated, *viz.*, cylinders 1, 3, 4 and 2.

Fig. 11 is what may be properly termed the "broadside" view of the cam-shaft. It shows the usual arrangement of cams along the shaft and the supporting bearings. The size of the center journal might be a source of wonder to the uninitiated; the reason for this lies in the fact that when assembling the cam-shaft in the motor, four of the eight cams must pass through the center bearing—hence, the size of the

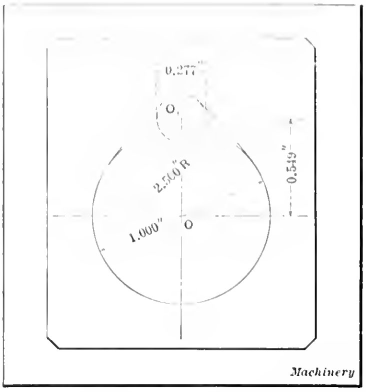

Fig. 8. Templet for the Inlet Master Cam

latter. The cam-shaft shown in Fig. 11 is a one-piece forging, with the cams forged integral with the shaft, which is almost the universal practice today.

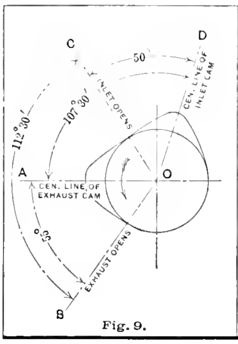
Clearance Angle on the Roller Type of Valve Gear

Fig. 12 is a diagram used for determining the clearance angle on the roller type of valve gear. The proportions are those commonly used, namely, 1 inch diameter for the roller and 1 inch for the base circle of the cam. The cam and its roller are shown in a position where the latter is just on the point of rising, and $OC = 1.000$ inch. When the backlash is closed, the distance between the cam and roller centers is 1.006 inch. The cam, in the meantime, has turned through the angle COC_1 which is our clearance angle a.

$$\cos COC_1 = \frac{OC}{OC_1} = \frac{1.000}{1.006} = 0.994.$$

$$a = 6 \text{ degrees } 15 \text{ minutes}.$$

We shall use this particular valve gear later on for the purpose of comparing it with the mushroom type. Unfortunately, such a comparison cannot be fair to either valve gear.



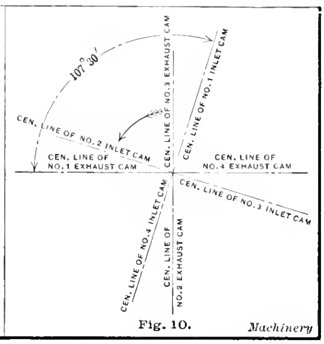


Fig. 9. Method of spacing Inlet and Exhaust Cams

Fig. 10. Diagrammatical End View of a Four-cylinder Engine Cam-shaft

There are so many points of difference between the two types that it is impossible to bring them, figuratively speaking, to the same denominator, as we have done in the preceding series when comparing a tangential and a uniformly accelerated and retarded motion cam operating absolutely the same type of valve gear. Nevertheless, such a comparison will help us to realize what we can expect from either type when built along conventional lines and operating under similar conditions.

Origin of Noises

It has been conclusively proved in the former series that the noise produced by the valve gear is wholly due to the clearance between the valve stem and the valve lifter. The instant this backlash is closed, the valve stem is at rest, while the valve lifter possesses a definite velocity. This state of things results in an impact which is repeated on the down stroke when the velocity of the valve is suddenly checked by the valve seat. Simple observation tends to show that noise increases very rapidly with the speed of the engine, and, hence, with the impact of the various parts of the valve gear. Impact may be defined as the instantaneous transferring of energy from one body to another; the greater the energy stored in the moving parts, the greater the impact, and hence noise, that is produced. From the foregoing it seems reasonable to assume that the noise varies in a direct ratio to the mass of striking parts of the gear and to the square of their velocity.

Mushroom vs. Roller Type

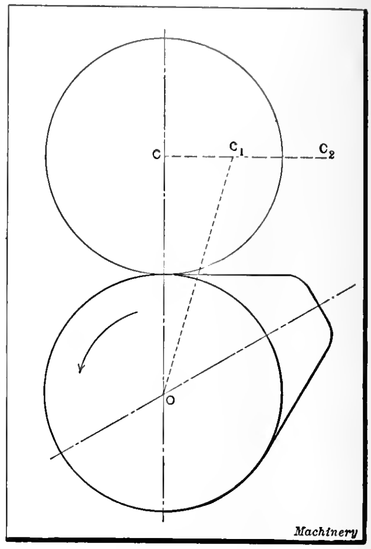

Fig. 12. Relation between the Clearance and the Clearance Angle

Let us assume two similar engines running at the same speed; one equipped with the roller type of valve gear and the other with the mushroom type, but both gears being identical as to their weight, clearance, etc. It is obvious that the quieter of the two engines will be the one whose valve lifters possess the least velocity at the instant the clearance is closed. We need not go into a minute study of the motion of the lifters, as the following simple consideration will help us to decide which of the two types is the noisier, and to what extent. Both lifters start with zero velocity and both rise 0.006 inch before the clearance is closed; but the roller lifter covers this distance in 6 degrees 15 minutes of the cam-shaft angle, whereas the mushroom lifter accomplishes the same result in 4 degrees 30 minutes. With both cam-shafts revolving at the same speed, the mushroom lifter must have greater average velocity in order to cover the same distance as the roller lifter in less time. The average velocity in both cases equals one-half the final velocity, *i. e.*, one-half the velocity at the instant that the impact takes place. While this statement is not strictly true, it is accurate enough for our purposes. Let

S = clearance in inches;

V_1 = final velocity of roller lifter in inches per second;

V_2 = final velocity of mushroom lifter in inches per second;

T_1 = time in seconds corresponding to an angular movement of 6 degrees, 15 minutes of the cam-shaft at any R. P. M. of the engine;

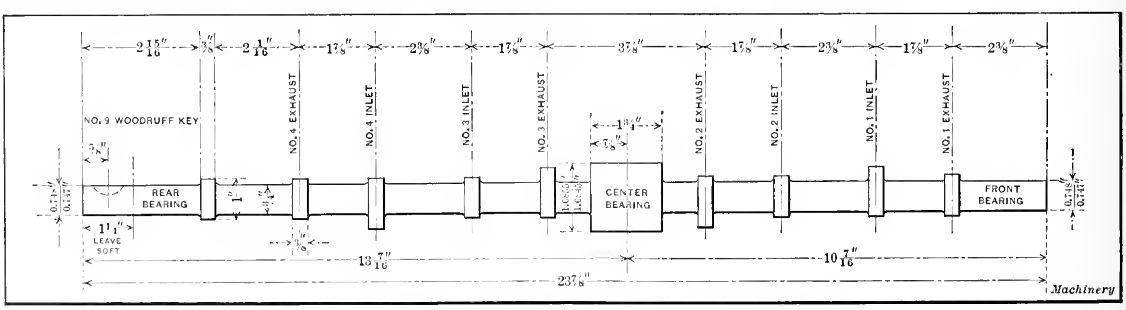

Fig. 11. "Broadside View" of the Cam-shaft of a Four-cylinder Engine

T_2 = time in seconds corresponding to an angular movement of 4 degrees 30 minutes of the cam-shaft angle at the same R. P. M. of the engine.

We then have:

$$S = \tfrac{1}{2} V_1 T_1. \qquad (1)$$

$$S = \tfrac{1}{2} V_2 T_2. \qquad (2)$$

From (1) and (2)

$$V_1 T_1 = V_2 T_2. \qquad (3)$$

$$\frac{V_2}{V_1} = \frac{T_1}{T_2} = \frac{6^\circ\ 15'}{4^\circ\ 30'}. \qquad (4)$$

The noise caused by the two lifters is proportional to the squares of their respective velocities. Hence we may write:

$$\frac{\text{Noise of mushroom lifter}}{\text{Noise of roller lifter}} = \frac{V_2^2}{V_1^2} = \left(\frac{6.25}{4.5}\right)^2 = \left(\frac{25}{18}\right)^2 = \frac{625}{324} = 1.93.$$

In other words, the mushroom lifter is almost twice as noisy as its rival. It is obvious that the only way to diminish this noise is to increase the clearance angle, *i. e.*, to shorten the radius of the arc AB, Fig. 4. Our conclusions in regard to the relative amount of noise hold good for the downward stroke of the valve, since the weight of the latter remains unchanged whichever type of lifter is employed; on the upstroke, however, the ratio of noises is considerably lower, owing to the fact that the mushroom lifter usually weighs from 30 to 40 per cent less than the roller type. About two years ago when designing a new engine, the writer discovered for himself the principles underlying quiet operation of valve gears. While recognizing the advantage of the roller type accruing from its lower speed of impact, he selected the mushroom type and by properly proportioning the cam of the latter, obtained some very gratifying results. This engine is known to have run at over 1800 revolutions per minute and its quietness of action was a matter of comment.

About a year ago the writer chanced to see an engine designed to run at not over 1200 revolutions per minute, the speed being controlled by the governor. The mushroom type of valve gear was used first, but the cam was so poorly designed, the clearance angle amounting to only 2 degrees 30 minutes, that the noise was very pronounced and the roller type of gear was eventually substituted in its place. As compared with the first engine, the impact at the same engine speed was in the ratio of:

$$\frac{4.5^2}{2.5^2} = \left(\frac{9}{5}\right)^2 = \frac{81}{25} = \frac{3.24}{1}.$$

The failure on the part of the designers to recognize the principles governing quiet operation of valves is no doubt responsible for the widespread opinion, often voiced by the technical press, that the mushroom type of gear is a noisy one, and that, as such, is unsuitable for rapidly revolving engines. The writer not only takes exception to this statement, but he contends that the mushroom cam and lifter can be designed to work at their best only on high-speed engines. The latter require early opening of the exhaust valves and late closing of the inlet valves, in accordance with principles explained in an article entitled "Timing an Offset Automobile Engine" published in the engineering edition of MACHINERY for February, 1911. In other words, the angle of the valve opening, and, hence, the active angle of the cam, is greater. Now if we turn to Fig. 4, it will be seen that if the active angle of the cam were increased, *i. e.*, if the center line were brought closer to the horizontal line, it would be possible to describe the arc AB with a shorter radius and thereby increase the clearance angle α. A further slight advantage could be secured by decreasing the lift of the cam. Now, short valve lifts coupled with the use of large valves is a condition which becomes more and more desirable as the speed of the engine increases. The slow speed engines, on the other hand, should have shorter valve openings, and, hence, smaller active cam angles—a condition decidedly unfavorable to a large clearance angle, and in such a case either quietness of action or proper timing must be sacrificed. This is the explanation of the apparent paradox that the noisy mushroom type of valve gear can be used to better advantage on high-speed than on comparatively slow engines.

DON'TS FOR BALL BEARING USERS*

BY ARTHUR V. FARR†

Lubrication and Care

Don't run ball bearings without plenty of lubricant. The highly polished surface of the balls and races suffers if run without lubrication.

Don't use any lubricant that is not chemically neutral, *i. e.*, without acid or alkali. For high-speed machinery, use a light machine oil and for heavy loads use a heavy mineral vaseline.

Don't fail to inspect and clean the bearings at regular intervals, flushing out the bearings with a clean supply of gasoline or kerosene whenever lubricant is charged into the bearings. Remember that dust and dirt may have entered the housing and it should be removed to avoid damage to the bearing.

Don't forget to keep the lubricating and drain holes of the housing closed to prevent the leakage of the lubricant or the entrance of dirt.

Don't tamper with the bearings or their housings unless you are compelled to do so for some good reason.

Shipping and Packing

Don't unpack the bearings from the box until you are ready to install them on a machine.

Don't put bearings on the bench or on the floor until you have provided a thoroughly clean surface for them.

Don't ship machines containing ball bearings unless you are certain that no dirt, grit or water can get into the ball bearing housings during the crating or while in transit.

Don't let ball bearings or machines with ball bearings leave the shop without being certain that the bearings and housings are scrupulously clean and filled with lubricant.

Mounting

Don't mount a ball bearing unless the shaft and housings are turned perfectly true, carefully finished and tool marks removed to insure the proper seating of the races. In case split housings are found desirable, great care should be taken to see that the housing sections do not squeeze the bearing.

Don't forget to clean the housing thoroughly with kerosene oil before mounting the bearing.

Don't use a steel hammer directly on the inner race when driving it into position. Light blows struck with a soft metal hammer or wooden mallet are sufficient.

Don't drive the outer race into the housing. This should have a sucking fit and should go into position without force.

Don't forget to provide for shaft deflection unless the bearing itself provides for it, to allow for inaccuracies of mounting and housing.

* * *

DRILLING HOLES IN GLASS

The following is a satisfactory method of drilling holes in glass. Take a piece of straight copper tubing, the outside diameter of which is the size of the hole that it is required to drill. The tubing should have a wall 1/32 inch or more in thickness, depending upon the diameter. The tube is set up in a drill chuck and driven at a speed corresponding to that of a twist drill of the same size. The tube is fed down onto the glass with an intermittent movement, and a mixture of emery and oil is dropped onto the glass at the point where the hole is to be drilled. After a ring has been cut in the glass on one side, the work is turned over and the drilling operation completed from the opposite side. This will prevent chipping the glass when the drill goes through. The copper tubing is soft so that it holds the emery, and as copper is an excellent conductor of heat, it draws the heat away from the glass, preventing it from being cracked. An idea of the rapidity with which holes can be drilled in this way may be gathered from the fact that a 5/16-inch hole can be drilled through an ordinary sheet of window glass in about seven minutes. The title of the article is somewhat misleading because this is really a grinding rather than a drilling operation.

V. P. C.

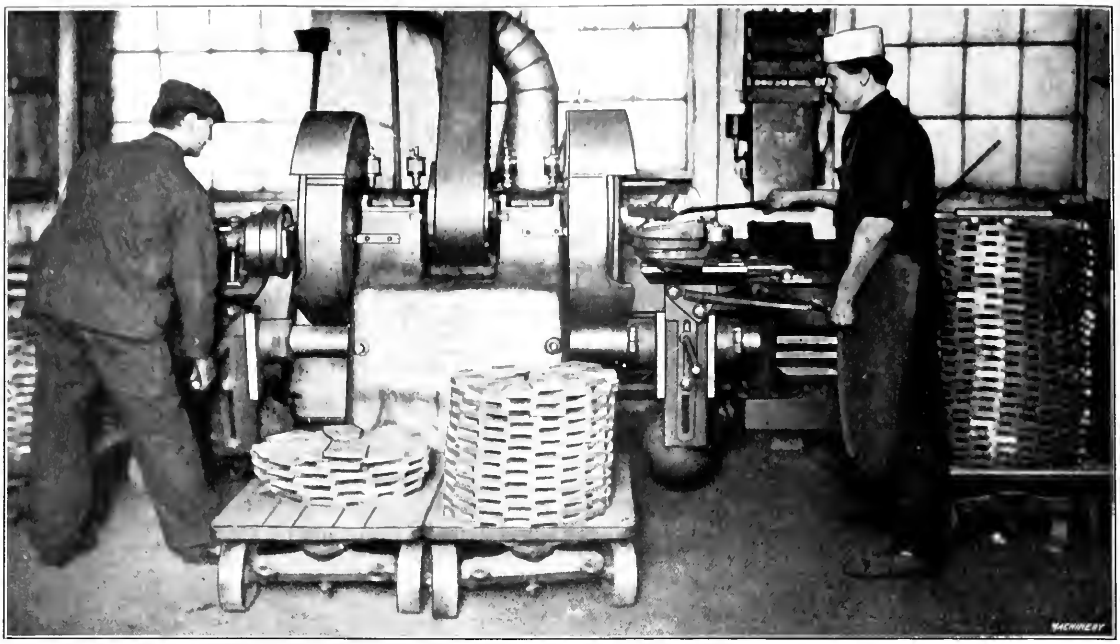

Fig. 1. Finishing Sad Irons on a Ring-wheel Grinder

FINISHING SAD IRONS ON A RING-WHEEL GRINDER

BY CHESTER L. LUCAS*

The machining of castings for sad irons presents difficulties that at first thought are not apparent. There are two general methods of doing this work—milling and grinding. The milling of the faces of flat irons was described in an article in the November, 1912, number of MACHINERY. Through the courtesy of the Simplex Electric Heating Co. of Cambridge, Mass., we are able to describe its method of finishing sad irons by grinding.

The machine on which the grinding is done is a No. 16-24 Besly ring-wheel grinder, shown in Fig. 1. Two men operate the machine, the one at the left working on faces, while the one at the right does the edge grinding. The grinding operation consists of the finishing off of the top face, the lower face, the straight back or heel, as it is called, and the edges.

The operations of grinding the upper and lower faces of the sad iron castings are performed at the left-hand side of the machine. For this purpose, the castings are held on a magnetic chuck shown in Fig. 2. In this illustration the casting is shown in the chuck ready for the finishing of the lower face. The upper face is similar, except that there is only a narrow edge to be cleaned off. The operator stands, as may be seen in this illustration and in Fig. 1, and with the casting rotating with the magnetic chuck, feeds the carriage, chuck and work to the wheel with his left hand, while with the right hand the grinding carriage is swung on its horizontal axis across the face of the ring grinding wheel. This combined rotary and lateral movement rapidly faces off the casting. An idea of the speed with which the face grinding is done may be obtained when it is stated that the upper face is ground at the rate of one hundred and twenty castings per hour and the lower face at the rate of seventy per hour. The next operation consists of grinding the heel or back of the iron. This is a simple grinding operation and is performed on two castings at a time. The heels of one hundred and twenty sad iron castings are ground per hour.

We now come to the most interesting part of this grinding operation—that of finishing the edge. By referring to Fig. 3, it will be seen that the edge of the sad iron combines a straight section near the heel, a long radius section immediately following, and at the point a section that conforms to a much shorter radius. The opposite side of the iron is, of course, the reverse of this. This operation is shown being performed on the right-hand side of the machine illustrated in Fig. 1. The special fixture is mounted on a table of the ring-wheel grinder after the manner shown in Fig. 3. It is held on the grinding machine table and the table swings on the horizontal axis as shown. At the front is a handle to facilitate swinging the fixture and at the rear is a weight to counterbalance it. The grinding of the edge consists of finishing the straight section near the heel, then grinding the long radius section adjacent and finishing up with the short radius

* Associate Editor of MACHINERY.

Fig. 2. Rotary Magnetic Chuck for Face Grinding Use

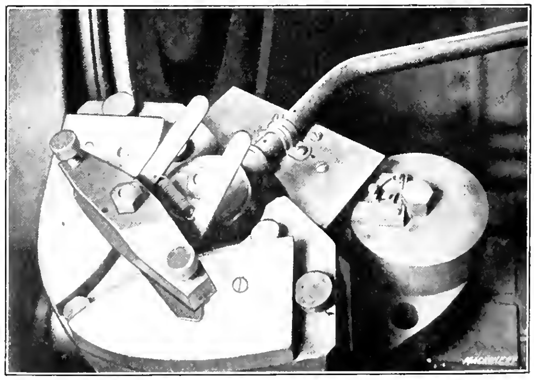

Fig. 3. Edge Grinding Fixture

near the point. By swiveling the fixture with the operating handle, the different sections of the edges are successively ground.

Some conception of the rapidity with which this grinding is done may be obtained from the production figures: Heel grinding, 120 castings per hour; top face grinding, 120 castings per hour; bottom face grinding, 70 castings per hour; edge grinding, 70 castings per hour.

COMPENSATING FOR ANGULARITY IN FITTING TAPER GIBS AND SLIDES

BY HAROLD F. PENNEY*

Everyone who has undertaken to fit taper gibs to their slides knows that whenever the slide is angular or dovetailed the taper on the slide is not the same as that to which the gib was originally planed. Possibly each mechanic has his own method for compensating for the angularity. The writer, with no claim of originality, has worked out a table to be used in connection with a common method that has been found to give satisfactory results and believes that this may be of interest and value to others. While the table covers the general range of practice, its derivation is also included to accommodate any special work.

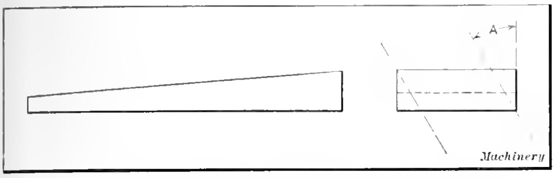

Fig. 1. Gib with Taper planed but with Angles Square

In following this method the gib is first planed to the proper dimensions including the taper, but with the angles square, as shown in full lines in Fig. 1. The corners are then planed off to give the desired angle A as shown by the dash lines. The slide is next planed, one side being kept straight or parallel and the other tapered to agree with the gib. The amount of taper is found from the table by following across under the heading "Original Taper of Gib," through the column headed "Angle of Slide," to the column headed "Taper of Slide." For example, if we were cutting a 40-degree dovetail slide having a gib tapered 1/8 inch per foot, we should find the taper of the slide to be 0.163 inch per foot. The table also gives the angle corresponding to the taper in inches per foot at which the slide should be set.

This method provides a constant means of checking the setting, for as soon as the roughing cut has been taken on the slide the gib can be tried in place. If the setting is correct the dimensions M and N, Fig. 2, which shows the gib in place, will be equal. If they are not equal, adjustment can be made and the cut continued until the readings agree and are of the desired value.

The values for the table were found as follows: Referring to Fig. 3, O represents the original taper at which the gib was cut; and F is the effective taper at which the gib acts, due to the angle A of the slide. From the relation of the parts of right angle triangles:

$$F = \sec A \times O.$$

* Address: Care of Hartford Public High School, Hartford, Conn.

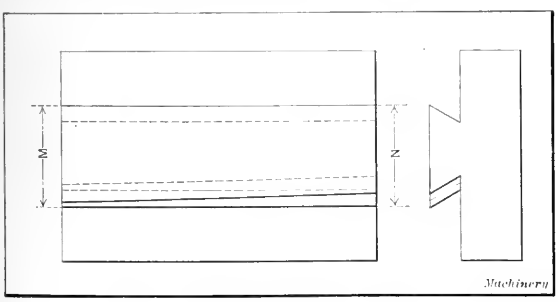

Fig. 2. Dovetailed Slide with Gib in Place

Substituting in the case already used as an example:

$$F = \sec 40 \text{ degrees} \times 0.125 = 1.3054 \times 0.125 = 0.163.$$

The angle corresponding to the taper is found from the following simple equation:

Tangent of taper angle = inches of taper per foot ÷ 12.

Continuing with the same example:

$\tan A = 0.163 \div 12 = 0.01360.$

Looking up this value in a table of functions we find:

$A = 47$ minutes.

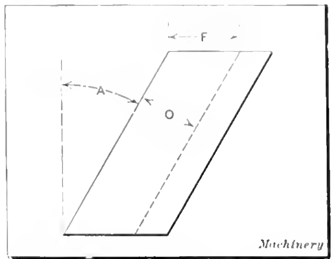

Fig. 3. Diagram showing Method of deriving Required Taper for the Slide

While no reference has been made to a machine other than a planer, it is apparent that the method and tables are just as applicable to the milling machine, or to any other machine which could be used for this type of work.

Several of the largest representative American manufacturing plants in full operation are to be taken to South America by means of the "movies" in order that the merchants there may see the advanced method of making American goods. By this method the makers of road-building machines, conveyors, laundry supplies, and other large machines will show their wares in full operation without the necessity of carrying the actual machinery. Accompanying the expedition will be a party of some thirty American salesmen who will represent the exhibition from sixty manufacturers. The *Kroonland*, upon which the exhibit is to be carried, will visit about twenty of the leading South American cities. This will be the first time that a foreign trade display has been made in this way.—*Moving Picture World.*

Machinery

* * *

The value of the imports of machinery into Norway, in 1913, amounted to nearly \$7,500,000, showing a very rapid increase during the last few years. Seven years ago, the imports amounted to only \$3,500,000 a year. The total value of machinery and tools imported into Norway during the last six years amounts to about \$40,000,000. The Scandinavian countries have undergone a great industrial development during the past ten years.

THE TRUING DIAMOND

BY DAVID D. MACLAUGHLIN*

Much has been written of late regarding truing diamonds for dressing grinding wheels, their selection and the excessive cost of upkeep, etc. While the quality of the stones used for this purpose varies, it will generally be found that with proper handling the length of service which a truing diamond will give is in proportion to the price paid, as most companies handling these stones grade them according to weight, shape and quality. A stone costing $25 ought to show less fracture than one costing say $10. The high priced stone should have a smooth unbroken surface, and be of such proportions that it will withstand shock without breaking. The cheaper stones are usually flat or elongated and show considerable fracture to the naked eye. They should be used only on light work, and will last longer for hand-truing than when fixed on a toolpost or slide-rest fixture. That there are causes, other than poor quality stones, which contribute to make this part of the grinding business troublesome and expensive, I shall try to show. While the quality of the diamond plays a very important part, the poorest stone may be used in such a way that it will give longer service than a good quality of stone improperly handled.

Setting the Diamond

It is necessary, of course, that the truing diamond be set in a suitable holder, and on this operation of setting depends, to a great extent, the length of service which the diamond will give. The usual method is as follows: A hole a little larger than the diamond is drilled in a piece of soft steel or copper of suitable shape to fit the holder supplied with the machine. The stone is then placed in the hole thus provided and held in place by peening the metal close around it; in some cases the piece of metal used is heated to a red heat so that it may be more easily closed around the diamond. That a diamond set in this way may survive the ordeal, goes without question; but unless the greatest care is used in the operation, the stone is only worth so much salvage in the form of diamond dust. Unfortunately, the damage done very often goes unnoticed until the truing diamond reaches the grinding machine operator, who proceeds to true up his wheel. Sooner or later he finds that the diamond is fractured but, fearing that he may have forced it in the operation of truing, keeps on using the stone in the hope that it will hang together. The result is inevitable, however—piece after piece crumbles away until what remains looks like so much granulated sugar. The operator then goes to the head of his department with a long face and a report that the diamond was "soft," "seemed to crumble away," etc., etc. While a perfectly good diamond may easily be ruined in use, the damage, in nine cases out of ten, is caused by improper setting.

One of the points which is often overlooked in setting a diamond by the above method is the manner in which the stone is actually held in its setting. Consider that the truing-diamond is a rough shaped, natural stone with corners or projections, and with flat and concave or convex portions on its surface. Then think of what is likely to happen when this stone is placed in a round hole, bored so that the stone is a loose fit in some kind of metal holder, and the metal closed round the stone haphazard, leaving one corner projecting. On account of the uneven or eccentric periphery of the wheel being trued, the diamond is subjected to a series of knocks in rapid succession, which tend to cause it to revolve or turn in its setting. It is prevented from turning by the projections holding onto the metal in which it is encased. The projecting points, therefore, act like so many levers tending to pry the stone apart. The life of the stone—usually very short in a setting of this kind—will depend greatly on the lay of the grain in relation to these corners.

To avoid the risk of breakage, it is essential that the truing diamond be set in such a manner that the *whole surface of the stone*, except the point exposed, *is in contact with the metal in which it is embedded*. This may be accomplished in several ways as follows: (1.) Drill a hole in a piece of copper bar to a sufficient depth to leave the diamond just exposed, using a drill a little smaller than the diamond; and then with the aid of a small set of chisels comprising a 1/4-inch diamond point chisel, a 1/4-inch cross-cut chisel, and a 1/4-inch round nose chisel, proceed to shape the hole to conform to the shape of the diamond set in position to obtain the best cutting point. Tap the stone very gently in place, using a small block of wood and hammer, and complete the operation by tamping the copper close around the exposed point with a hammer and center punch or nail-set. The greatest care should be used so that the diamond is not subjected to shock, either from the tools coming in contact with it or the copper being tamped against it with undue pressure. (2.) Another method of setting, which has many advantages without the risks attached to the method just described, has been practised with success and is carried out as follows. Drill a hole in a soft steel holder about 1/8 inch larger in diameter than the diamond, and to a sufficient depth so that the cutting point will just show. Undercut the hole so that the setting will dovetail into the holder and complete the operation by melting around the stone in place enough granulated brazing spelter to run flush with the cutting point. For this part of the setting, a blow-pipe is required which will produce a flame capable of melting the spelter. This method has the advantage that the diamond may easily be taken out by melting the setting, when it is desired to reset the stone to obtain a new cutting point, which is a very important advantage, as the stone will last much longer if reset when it is found that the tool is working unsatisfactorily. Also, a diamond set in this way, with its whole surface in contact with the material in which it is embedded, will better withstand the strain to which it is subjected than if set by any other method.

Of the several clamp holders which are sometimes recommended, whereby a diamond is held in a miniature vise, I have nothing to say in this article except that I leave them to the readers' judgment in the light of the preceding suggestions. As in setting the diamond, so in using it, the greatest care should be exercised so that the stone is not abused; the operator should see that the diamond is passed across the work so that it will cut without excessive pressure, and when possible, a great saving may be effected by using a Huntingdon dresser to roughly true the grinding wheel, only using the diamond for a finishing cut. For this purpose, a special detachable rest would be necessary in a great many cases, but the saving would make it worth while. When truing wheels made by the "elastic" process, use a diamond only. A suggestion was made by the writer of a recent article on this subject, that in the near future an artificial stone may be produced as good as the diamond or nearly so, and much cheaper. I might point out that as soon as something of this kind is discovered, the grinding wheel manufacturer who is ever ready to improve his product will pounce on the new abrasive and proceed to make it up into grinding wheels, so that the last state of the grinding man is worse than the first. It may be a long time before anything is found to equal the diamond for truing the grinding wheel. In the meantime give the diamond a square deal.

* * *

The foreman of a repair shop tells the following story in a contemporary: "The other day a man called and wanted a job, saying that he was quite experienced on repair work and had worked in many small repair shops. I put him to work chipping the flanges of a steam chest. He started out fine, but at four o'clock I found him sitting on a bench by the side of his job comfortably smoking. I asked why he was doing this, as smoking was not allowed in the shop. He replied: 'I've always been in the habit of having a smoke at four o'clock in the afternoon, and if so be that you don't like it, you can pay me off.' I did as he requested, but after he had gone, on looking up his job I found that he had knocked a corner of the flange off from one hole to the next, necessitating the replacement of the entire steam chest." This method of getting laid off and drawing the pay before the damage is detected seems more ingenious than honest.

BAD EFFECTS OF SHAFT STRAIGHTENING

BY L. LANGHAAR*

It is frequently necessary in building machinery to straighten shafts which have sprung during the process of manufacture. The company with which the writer is associated is engaged in building a multiple spindle turret machine in which great accuracy and durability are essential. The spindles in these machines are made with standard taper holes, and each spindle slides in its bearings, as well as rotating in them. The taper hole must be exactly central and in accurate alignment. In making these spindles it was decided not to resort to the use of a straightening press, but to machine them to remove any inaccuracy produced in hardening. Needless to say, this makes a considerable increase in the cost of production, as compared with the use of the time-honored straightening press, as it involves several different turning operations before grinding. It is felt, however, that a number of important improvements are obtained.

The chemist and the metallurgist have shown that steel consists of iron and iron compounds, each minute particle of which is held to neighboring particles by a force known as "cohesion." Like every elastic material, a bar of steel exhibits certain well-defined properties when loaded. Up to a certain limit the bar will return to its original form when the load is removed, this statement being based on the assumption that a load—however small—will cause a certain deflection of the bar. This is a proved fact. The limit of loading beyond which the bar fails to return to its original position is generally known as the "elastic limit," but our German friends very appropriately call it the "proportional limit." The reason for this name is that up to the proportional limit the deflection and the load are proportional to each other. Beyond the elastic limit the load and the deflection are no longer proportional, and the deflection becomes permanent, a "permanent set" having been produced in the bar. The strength of the steel is also found to be permanently reduced after it has been loaded beyond the elastic limit. The straightening press would be useless unless it strained a shaft beyond the elastic limit, and, therefore, it is reasonable to assume that the strength of a shaft which has been straightened cold in a press has been reduced.

To further explain this point it may be stated that the elastic limit is the point at which cohesion between the iron particles begins to give way, and this weakening of the cohesive force cannot be overcome by subsequent heat-treatment. It makes no difference whether the straightening is done before or after the heat-treatment to which the shaft is subjected; the steel is permanently weakened in either case. Heat-treatment generally has the effect of springing a shaft, but if this deformation is to be removed without a reduction of strength, the use of a straightening press should never be resorted to. The deformation should be overcome by grinding the shaft. A rule-of-thumb mechanic was recently heard boasting how he had repaired an automobile. The axle shaft, which was made of really high-grade chrome-nickel steel, had broken, and this man felt that particular credit was due him because he had replaced it with a shaft made of cold-rolled steel, which had already been in service longer than the original shaft. From this experience he inferred that what he styled "new fangled" ideas were no good.

The writer happens to have accurate personal knowledge of the construction of the automobile in question. The best materials and the highest grade of workmanship are used. The greatest care is taken in all machining operations, and heat-treatment is conducted along the most approved lines. However, the use of a straightening press is resorted to after the axle shafts are heat-treated. Those that do not show visible cracks after straightening are passed by the inspection department, when, as a matter of fact, many of them are in a state of incipient rupture. There is not one scientifically educated man holding a responsible position in this particular automobile factory, and it is perhaps worthy of mention that the company is now in its second receivership. There are doubtless a number of contributory causes for this state of affairs, but the little trick of straightening shafts in a press may be one of them. The car manufactured by this company is noted for its excessive weight, and it has apparently been found necessary to use a heavier construction than that employed in many other cars of the same power in order to obtain the required strength.

In the case of machine tools, a much heavier construction is necessary than that required in automobiles. Machine tools demand exceptional rigidity in order to turn out a product which is sufficiently accurate to meet modern requirements, and this means that the parts must be of ample strength. The following argument may be advanced against what has been said in regard to the straightening of spindles with taper holes: If the spindles are straightened by grinding, the taper hole will still point in the direction in which it was sprung, and, as a consequence, the hole will be out of alignment with the outside of the spindle that was finished by grinding. To avoid this difficulty, we use an alloy steel which has been previously heat-treated so that it is as tough as it is possible for it to be and still enable the machining operations to be performed by high-speed steel tools. Several adjustments and turning operations in the lathe make the taper hole perfectly true with the turned and splined spindle, and no subsequent heat-treatment is resorted to which will affect the accuracy of the spindle. The final grinding is merely for the purpose of finishing the spindle to the exact size.

To obtain the best results from heavy-duty machinery, the writer believes that the straightening press should be used very cautiously and only on the advice of a competent engineer, who will not be likely to recommend it for parts that are subjected to severe stresses. It appears likely that many so-called mysterious cases of the failure of shafts may be traced to this cause. At all events, it is certain that, other things being equal, shafts which have been straightened under a press cannot equal in strength and driving power those which have been straightened by some more suitable method.

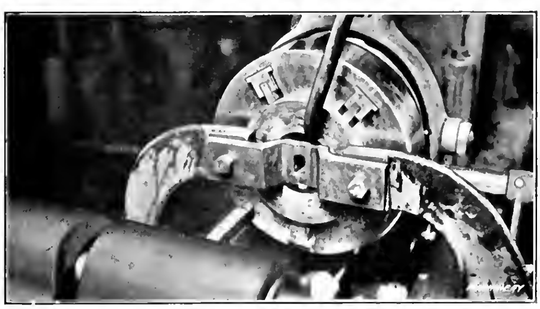
CUTTING PIPE WRENCH THREADS ON BOLT CUTTER

The Acme Machinery Co., Cleveland, Ohio, is using a five-chaser die-head with a special guide for cutting threads on pipe wrench movable jaws of the Stillson type. The accompanying illustration shows the die-head, the guide for the wrench jaw and the wrench jaw gripped in the vise. With five chasers and the guide which holds the part to be threaded closely, it has been found possible to cut very smooth and accurate threads even though the part is of approximately rectangular cross-section.



Five-chaser Die-head and Guide used for cutting Threads on Pipe Wrench Jaws

The company is cutting all sizes of jaws from 3/8 inch to 2 inches on an Acme No. 2 machine. Each size requires a different chuck for holding the jaw and a different guide. The object of the guide is to hold the shank rigidly while it is being threaded, and five jaws are used instead of four in order that one die may always be working. This overcomes any chance of twisting the shank while threading. About five wrenches per minute may be threaded with this rig.

Don't forget that if a sleeve collet slips around in the spindle or a drill slips around in the sleeve collet, the surface of the tapers have become nicked and need smoothing off.

FORMING TOOLS FOR GEAR CUTTERS*

A SIMPLE METHOD OF MAKING A FORMING TOOL ON THE UNIVERSAL MILLING ATTACHMENT

BY JOHN EDGAR†

THE making of a forming tool for forming gear cutters is a job that a great number of shop men would, no doubt, like to tackle; but they would not know just how to go about it if the problem was put up to them. Making forming tools for this purpose is not work that is frequently given to the toolmaker, but there are some instances when a special gear cutter is wanted and lack of time prevents having it made by the cutter manufacturer, who is not always very prompt in filling such orders. The ordinary practice is to lay out the tooth curve full size or several times enlarged, and then make master tools to this drawing, by which the formed tool is planed. Following this method, it is necessary to make a special master planing tool for each side of the tooth and planing tools for the curves at the bottom; and this coupled with the method of using the tools and making the necessary corrections for the distortion due to the angle

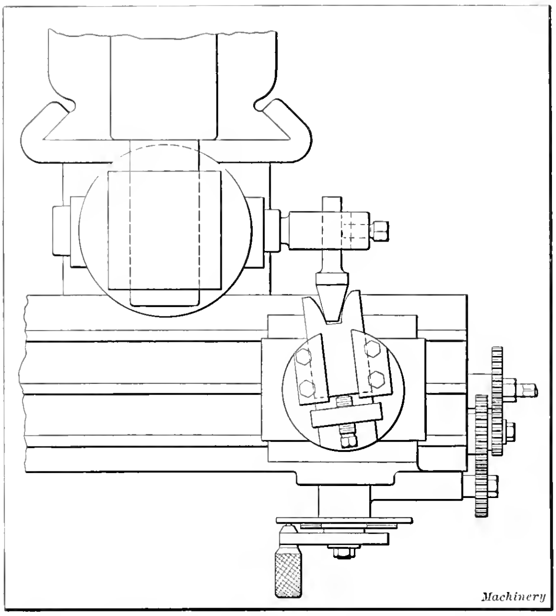

Fig. 1. Milling Machine set up to generate Forming Tool for Gear Cutters with a Rack-shaped Tool

in which each tool is set in planing, are all likely to lead to inaccuracies in the tooth curve, making the results anything but satisfactory. It is the intention to show in this article that all these master tools and complicated settings, and the "mysterious nothings" that hang around the job and make it appear out of the ordinary are unnecessary to the successful production of a forming tool. By the method to be described all the multiplied inaccuracies incident to copying from this original draft are omitted. This method consists of generating the forming tool direct without any intermediate steps, and by mechanical means that alone determine the shape of the tooth curve, so that a correct involute curve is obtained without any approximations whatever.

Probably the greatest drawback to the first method of procedure referred to is the necessity of making the original drawing of the tooth curve, there being so many methods in use that are mere approximations. Such methods are all well enough for the purpose of representing gear teeth on a drawing, but if it is attempted to make the teeth themselves to these layouts, trouble is more than likely to put in an appearance with a loud protest. Almost any toolmaker worthy of the name can produce a tool very close to the original

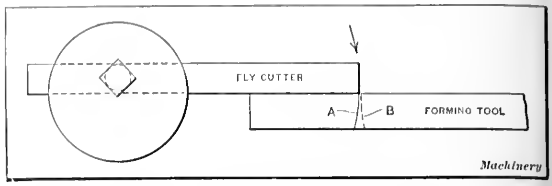

Fig. 2. Shape of Tool produced by Fly Cutter and Shape required for Clearance

curve; but the proposition of getting exactly the original curve is a job that must be left to some mechanical means if we are to get the closest possible degree of accuracy. This means is now to be found in the toolroom of any pretentions, and is the trusty universal milling machine. For the operation of generating the tool, a universal milling attachment is required, which may make the use of the method impossible in some cases; but these attachments are now commonly found in the toolroom in connection with the milling machine. There are two methods by which the tool may be made, that are to be described in the following. (1) By using a rack tooth shaped fly tool or cutter. (2) By using a straight faced tool or plain side mill of narrow face, and setting the axis of the cutter spindle and the ways of the table at the angle of the pressure line.

Fig. 1 shows the set-up of the machine for using the rack-shaped fly cutter. Here we have the forming tool clamped in the special chuck held in the spindle of the dividing head, which is set in the vertical position. The head is shown set up with the change gears as in spiral cutting, the pitch for which the gears are chosen being equal to the circumference of the pitch circle. The universal spindle of the attachment is set at right angles to the axis of the main spindle and parallel to the direction in which the table travels. Set up in this manner, the machine is ready to generate the involute sides of the forming tool, when the fly cutter is shaped like the tooth of a rack of the same pitch. The process is similar to that used in some way in all generating machines. By setting the top of the forming tool blank at the height of the axis of the cutter spindle, and the fly cutter so that the cutting plane passes through the center of the cutter spindle, next adjusting the fly cutter to produce a gash of the proper depth, and then starting the machine and throwing in the feed to the table, we can generate the tooth space shown. This space is of the correct shape at the top of the tool only, as the angle of the fly cutter with the top of the forming tool affects the shape at all other positions deeper in the tool. This is obviously the reverse of the generating method described in my article in the May number of MACHINERY, in relation to the generating of hob tooth shapes. A tool made

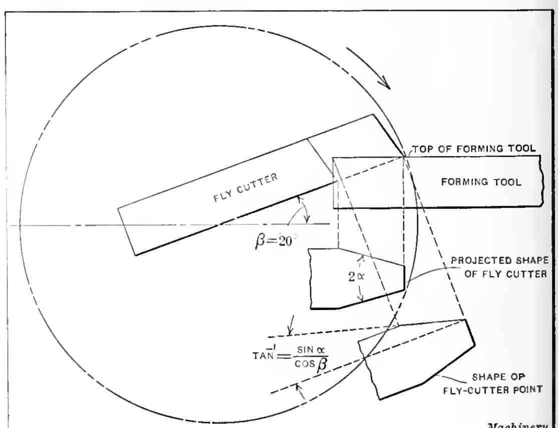

Fig. 3. Method of setting Fly Cutter to obtain the Required Clearance on the Forming Tool

* For additional information on forming cutters and allied subjects published in MACHINERY, see also "Making a Forming Tool for a Gear Cutter," by Earle Buckingham, May, 1914; "Making Formed Cutters," by F. B. Jacobs, April, 1914, and other articles there referred to.

† Address: 61 Bruce Ave., Windsor, Ontario, Canada.

in this manner would appear as shown at *A* in Fig. 2, and to make it of use as a forming tool it must be relieved up to the top for clearance. This can be done by filing or other means, so that the finished tool would have the 20-degree clearance shown dotted at *B*, extending all around the form. With the fly cutter made to close dimensions, the space generated will be of the correct width at the pitch line and to depth; and a forming tool made with it would likewise be of the correct size in relation to thickness and depth.

The necessity for relieving the tool after generating may be eliminated by setting the fly tool as shown in Fig. 3, 20 degrees being chosen as giving plenty of clearance for the tool in the forming and backing off of the cutter. If the cutter teeth are to be given more than the ordinary amount of relief, the angle should be increased. With the use of the fly cutter in this position, a correction will have to be made to counteract the angle at which it is set. This is done by making the angle of the fly cutter such that the angle on a line parallel with the top of the forming tool will be twice the pressure angle. The corrected angle of the side of the fly cutter may be found by the formula:

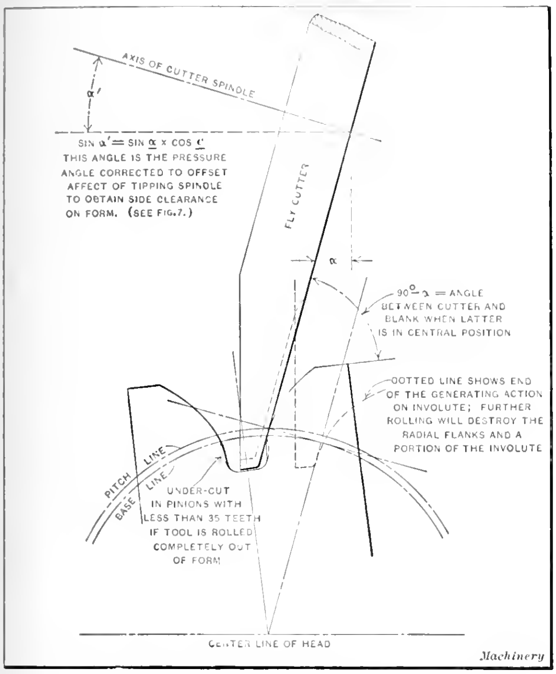

Fig. 4. Second Method of setting Milling Machine to generate Forming Tool for Gear Cutters with a Straight Fly Cutter

$$\text{Tangent of angle of side of fly cutter} = \frac{\sin \alpha}{\cos \beta}$$

where α = pressure angle and β = clearance angle.

The included angle of the tool is twice the angle of the side, and the height at which the forming tool is set above the center of the cutter spindle is found by trial, by setting the fly cutter as shown in Fig. 3 and bringing the forming tool to the height of the tip of the fly cutter. This height is, of course, dependent on the radius of the circle swept out by the fly cutter. The fly cutter should be set to sweep out as large a circle as possible, to give the least possible amount of concavity to the forming tool. The shape generated by the fly cutter is nearly correct throughout the thickness of the forming tool when the latter is thin as compared to the sweep of the fly cutter; and the forming tool can be sharpened by grinding across the top face without greatly changing its form. The clearance of the forming tool decreases as it is worn by sharpening; but the amount of use to which an emergency tool is put will not usually call for much grinding. The clearance, as produced in the case of the fly cutter set according to the preceding instructions, is not adapted to work that requires side relief, as in the case of small numbers of teeth nor for bevel gear cutters.

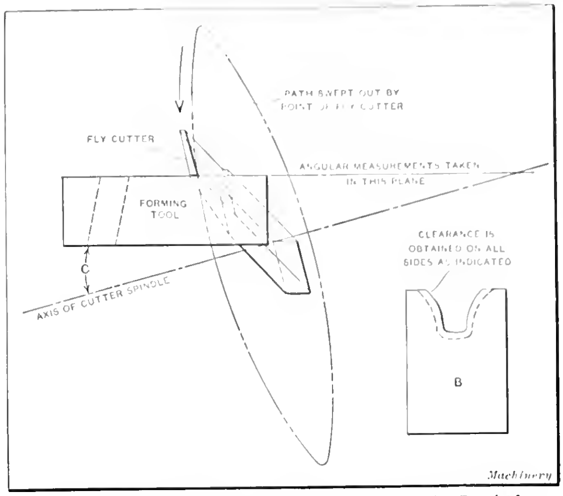

Fig. 5. Method of setting the Fly Cutter to give the Required Side Clearance to the Forming Cutter

The second method of generating the forming tool is shown in Fig. 4. The machine is set in the same manner as in the case shown in Fig. 1, with the exception of the angle between the cutter spindle and the table. This can be obtained by either setting the cutter spindle to the angle of the pressure line, after making a correction to counteract for the effect of the clearance angle, or by swinging the table to that angle—whichever is the most convenient. The cutting edge of the tool is at right angles to the axis of the cutter spindle, which makes it necessary to make a separate setting for each side of the form—setting a tool of the other hand to the opposite angle. The clearance in this case is obtained by setting the fly cutter as in Fig. 3, and giving the cutter spindle an upward tilt—shown by the angle *C* in Fig. 5—that is desired for side clearance. This may be the same as the radial relief or it may be less, a 10-degree angle being plenty for most cases. This sidewise setting is shown in Fig. 5; and the effect of the setting on the clearance is shown at *B*, in the same illustration. In generating with the fly cutter to sweep out the forming tool at this compound angle, the side of the forming tool is not straight as might be surmised, but is warped as in the case of spiral gears. This does not affect the shape of the tool materially, but it increases the clearance angle as the tool is worn down. There is no need of any other correction being made in this case, as the tool sweeps out a plane in which the side of a rack tooth would lie.

The amount of roll to give the forming tool is an important point in the case of pinions with less than 30 or 35 teeth, as it is in these smaller numbers that the teeth of the generated gear are undercut and it is obvious that a milling cutter will not mill undercut teeth. These pinions are made with radial flanked teeth, having that portion of each tooth that is below the base line radial. A full generated forming tool for the

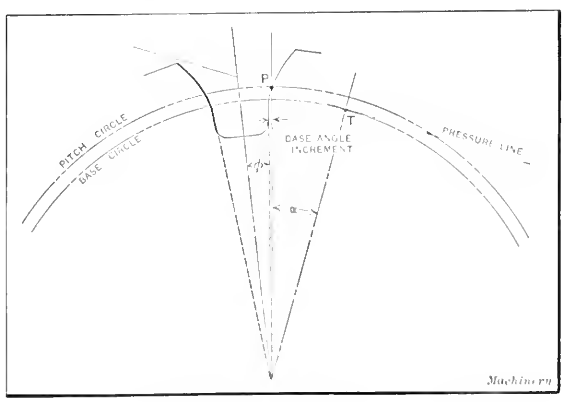

Fig. 6. Diagram illustrating Derivation of Formula for the Value of the Angle φ

cutter for a twelve tooth pinion would be undercut in the manner shown in Fig. 4 by the dotted lines, while the full lines show the proper radial flanked form. This radial flank is obtained by stopping the roll at the point where the fly cutter becomes normal or at right angles to the base line in the dotted position. A convenient way in which this may be done is to find the angle of the radial tooth space, which can be done as follows: In Fig. 6 we first draw the pitch circle and then the pressure line intersecting it at P; and tangent to this pressure line draw the base circle, the point of tangency being T. Next draw the lines intersecting the point of tangency and the point P, and passing through the center of the pitch circle. The length of the pressure line between the points P and T is given by the formula:

$$\text{Length} = \tfrac{1}{2} \sin \alpha \times \text{pitch diameter}.$$

This length projected on the base circle locates the end of the involute curve at the base circle and its distance from the point T. The angle embraced between these two points is given by the following formula:

$$\text{Included angle} = \frac{360 \times \sin \alpha \times \text{pitch diameter}}{2 \times \text{circumference of base circle}} = \frac{360 \sin \alpha}{6.2832 \cos \alpha}.$$

The angle included between the points P and T is the pressure angle α, which subtracted from the preceding result, gives what we will term the "base angle increment." The angle included between the pitch points of the teeth on the opposite sides of the space is $360 \div 2N$, and the base angle increment subtracted from one-half of this gives the angle ϕ which the radial flank makes with the center line of the space. Expressed as a formula this is:

$$\phi = \frac{360}{4N} - \left(\frac{360 \sin \alpha}{6.2832 \cos \alpha} - \alpha\right) \text{ degrees}$$

where N is number of teeth in gear.

Having found the angle of the flank with the center of the tooth space, the rolling of the forming tool is stopped when the angle between the side of the tool blank and the fly cutter becomes equal to the difference between the pressure angle α and the center angle ϕ of the radial space, as shown in Fig. 7. This may be done by stopping the feed when the head has traveled toward the fly cutter an amount equal to

$$\frac{\left[\left(\dfrac{360}{4N} + \alpha\right) - \phi\right]}{360} \times \text{pitch circumference}$$

from the central position in Fig. 4.

In making the forming tool blank, care should be taken to have the end planed square with the sides and the chuck should also be true. The space should be roughed out to depth, leaving sufficient stock for forming; and when the fly cutter is sunk to depth for the generating operation, the side of the blank should be at right angles with the line of travel of the table. It should also be at an angle with the cutting plane of the fly cutter, measured parallel with the top of the forming tool, equal to the complement of the pressure angle or of $90 - \alpha$, which in the case of the $14\tfrac{1}{2}$-degree tooth is $75\tfrac{1}{2}$ degrees. After the fly cutter has been sunk to depth, the tool should be cleared of the gash and the table moved with the gears in mesh so as to bring the fly cutter to the extreme left of the central position in Fig. 4, before the generating is commenced, so as to form the involute curve at the extreme point of the tool. When the gears to mesh are extremes as regards the number of teeth, the points of the teeth of the larger gear will have to be slightly relieved to avoid interference, as shown dotted in Fig. 8, the amount of the relief being a matter on which it is difficult to give a simple rule. The most certain and practical method is to generate templets while the machine is set up in each case, which can be rolled together and the teeth of the larger relieved as much as necessary to make the action smooth. Then the points of both the gears should be further relieved to ease the approach of the teeth so that the bearing of the teeth will not be so hard at the points as near the pitch line. The amount taken off the templets can then be measured in some convenient way and the forming tools relieved a like amount.

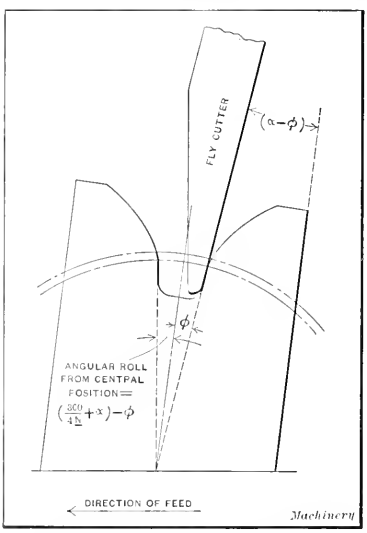

Fig. 7. Diagram showing Angular Relation between Fly Cutter and Forming Tool at Conclusion of Roll to give the Proper Radial Flank

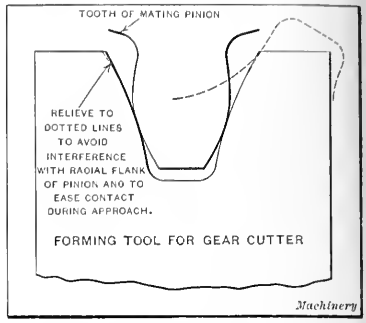

Fig. 8. Correction of Tool Setting to avoid Interference with Radial Flank of Pinions

There are, of course, limits to the application of the preceding methods, but they are capable of use in the majority of cases when the gears to be made are of reasonably moderate size in relation to the size of the miller that is available. The width of the space in the forming tool made by the second method is not made equal to the thickness of the tooth, but may be considerably wider and the cutter tooth formed one side at a time. This is necessary in the cases where a side relief is given.

These methods are especially valuable in those cases where it is desired to make cutters for any special number of teeth where the standard cutter is not satisfactory, as the methods in the hands of particular men are capable of producing a very high grade of forming tool and the second method is capable of extension so that when the fly cutter is replaced with a grinding wheel, the form of the tool can be ground after hardening to produce a tool free from the distortion due to hardening. This grinding also gives the tool a much keener cutting edge, resulting in a better job of forming in the cutter and a better finish on the gears.

Under the law governing the use of trademarks in Argentina, any person may register a trademark if such mark has not been previously registered in the country. This provision has permitted many unscrupulous persons to abuse the privilege by anticipating the advent into this market of a foreign trader or manufacturer. His trademark has been registered and he is then compelled to pay an exorbitant sum for the use of his own trademark. A provision has now gone into effect that a person who has registered a trademark cannot institute criminal proceedings for infringement, unless he himself manufactures or deals in the goods distinguished by the trademark in dispute. This has to some extent improved the conditions.

The permanent international committee for international aeronautics, 19 rue Blanche, Paris, has offered two prizes for competitions relating to aeronautic achievements. One of the competitions deals with the attaining of the greatest difference in speeds with the same aeroplane and the other with means for rising vertically, or nearly so, from a given point into the air, and for descending vertically. Further particulars may be obtained from the Commission Permanente Internationale d'Aéronautique, at the above address.

SCREW MACHINE TOOL EQUIPMENT*—1

STANDARD TYPE OF TOOLS USED ON THE CLEVELAND AUTOMATIC SCREW MACHINE

BY DOUGLAS T. HAMILTON†

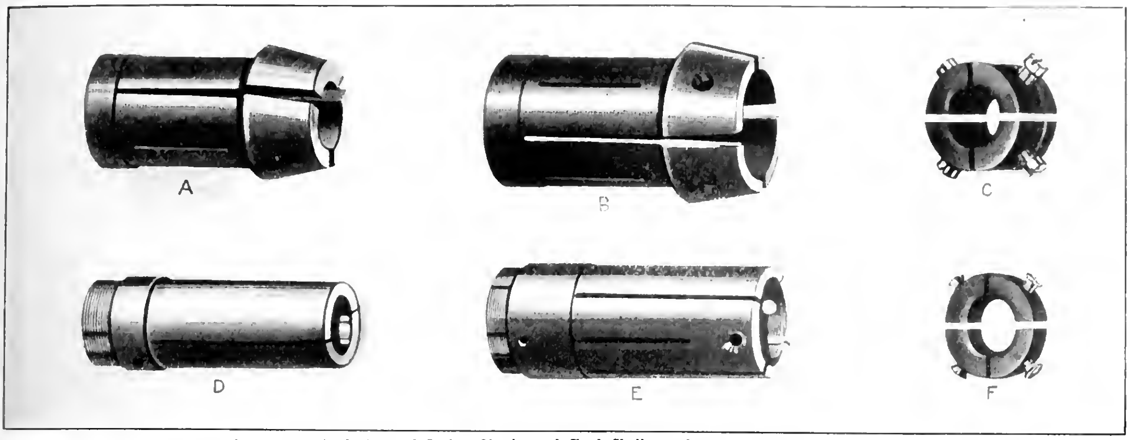

Fig. 1. Standard Type of Spring Chucks and Feed Shells used in the Cleveland Automatic

THE turret and cross-slide tools used on the Cleveland automatic screw machine differ only to a slight extent from those used on other screw machines, but of course there are a few tools particularly adapted to this type of automatic. As a general rule, forming tools of the flat type are are easily sharpened when dull, but the clearance on the sides, especially when diameters differing greatly in size are to be formed, is not nearly as good as on the flat type. Consequently this type of tool is used almost exclusively on Cleveland automatics.

Machinery

used on the Cleveland automatic screw machine, because of the better side clearances obtainable. Circular forming tools

Spring Chucks and Feed Shells

The spring chucks used in the Cleveland automatics are of the push type as shown in Fig. 1; those up to 1 3/4 inch capacity are of the solid type as shown at *A*, and those larger

* For additional information on screw machine practice see "The Cleveland Automatic Screw Machine," in the April and May, 1914, numbers.
† Associate Editor of MACHINERY.

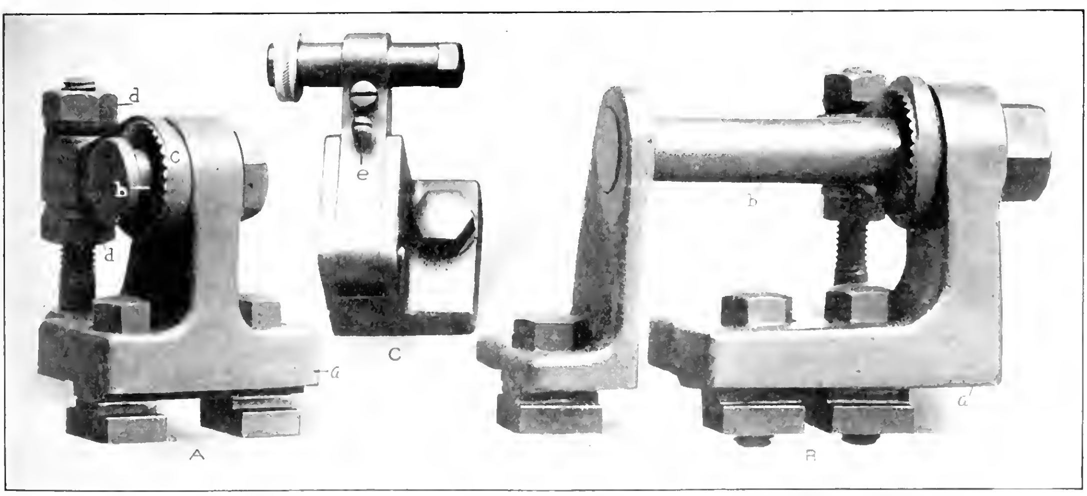

Fig. 2. Tool-holders for carrying Circular Forming and Cutting-off Tools and a Cross-slide Knurling Tool-holder

than this are of the type shown at *B*. The chuck at *B* carries pads which are held in the nose by screws, as shown, a pair of pads being illustrated at *C*. The feed shell used for pushing the stock through the chuck is of the spring type, as shown at *D* and *E* in Fig. 1, and on sizes up to 1 3/8 inch capacity the solid type of feed shell as shown at *D* is used.

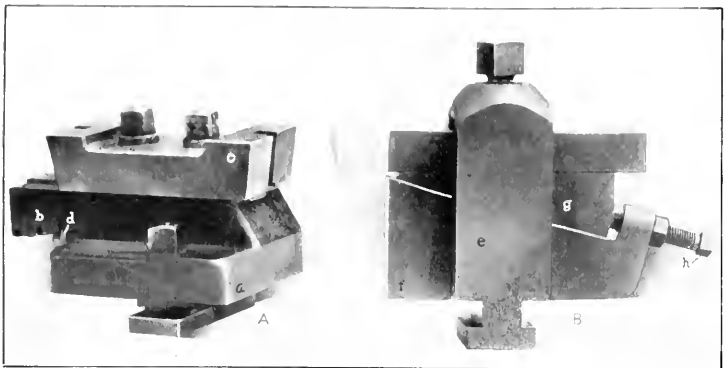

Fig. 3. Two Types of Flat Forming Tool-holders

For stock of larger diameter, the feed shell at *E* is used; this is provided with the pads shown at *F*, which are held by screws as illustrated. Both the spring chucks and feed shells, of course, are made to handle various shapes of stock; the chucks are ground 0.005 inch larger than the bar stock, and the feed shells are reamed 0.010 larger than the bar. This permits the chuck to get a better grip on the stock and hold it more securely while it is being operated upon. The hole in the chuck, of course, is made the same shape as the stock that it is intended to handle.

Toolpost for Circular Forming and Cut-off Tools

Two types of toolposts for holding circular forming and cut-off tools are illustrated in Fig. 2. *A* shows a toolpost known as the single type, which can be used for narrow forming tools or cut-off tools, whereas tool *B* is used principally for extra wide forming tools and is known as the double type. These toolposts are used either on the rear or front of the cross-slide, and they comprise a forging *a* which acts as a bracket for carrying the stud *b*. This stud fits in the hole in the tool and, as shown at *A*, is provided with a head which holds the tool up against the adjusting ratchet *c*. The outer face of this ratchet is provided with teeth which fit correspondingly shaped teeth in the inner face of the circular tool, holding the tool rigidly and at the same time making adjustment possible. This is secured by means of the adjusting nuts *d* which bear on cup-shaped washers fitting in similarly shaped holes in the extended arm of this adjusting member. Adjustment of the cutting edge of the tool is secured by moving these nuts up or down, as requirements demand. The forming toolpost shown at *B* is provided with an outer bracket which supports the extended bolt. This tool has three clamping bolts for securing it to the cross-slide of the machine. Adjustment for the circular tool is obtained in the same manner as for the type shown at *A*.

The accompanying table gives the dimensions for the circular forming type of toolposts for machines having capacities from 3/4 inch up to and including 3 1/4 inches. The 3 1/4-inch machine is about the largest size of Cleveland automatic on which the circular type of tool-holder is used. On sizes larger than this the flat type, which will be described later, is used almost exclusively. The upper portion of the table gives dimensions for toolposts which can be used on all three models A, B and C, having either single or double cross-slides; whereas the lower portion of the table gives toolpost dimensions applicable only to the model A machine. The spaces occupied by an asterisk indicate that the center of the tongue *b* is on the center line of the hole *c*. Hence, of course, dimension *C* is omitted.

Toolposts for Flat Forming Tools and Blade Cut-off Tools

The toolpost shown at *A* in Fig. 3 is the standard type of flat forming tool-holder that is used principally on machines having a capacity from 7/8 to 7 3/4 inches. This toolpost consists of a base *a*, the top face of which is beveled to an angle of about 15 degrees, which fits a beveled wedge *b*. The wedge *b* is provided with a tongue which fits into a corresponding groove in the top face of base *a*, and the top face of the wedge is provided with a groove that fits into a corresponding groove in the base of the flat forming tool *c*. Adjustment for height of the cutting edge of the forming tool is secured by means of a collar head screw *d*, which fits into a series of slots, depending on the height required, cut in the base of the wedge, and is screwed into the base *a*. The forming tool is held on the top face of the wedge by two clamping bolts as illustrated, and the entire toolpost is fastened to the cross-slide of the machine by bolts as shown.

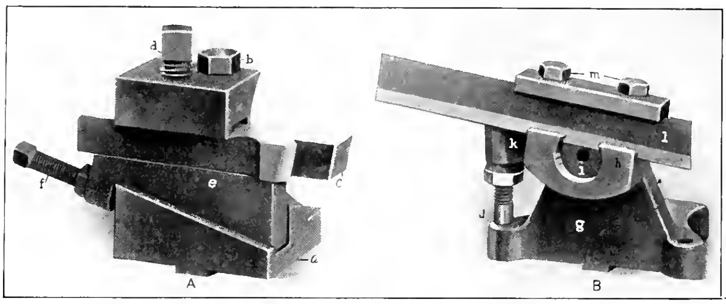

Fig. 4. Open-side Forming Tool-holder and Standard Universal Cut-off Tool-holder for Cut-off Tools of the Blade Type

B in Fig. 3 shows another type of toolpost used for light forming tools or for cut-off tools that are not of the blade type. This tool-holder is of simple construction as the illustration shows, and consists chiefly of three members, a clamping strap *e*, a base *f* and a tapered wedge *g*, the latter being adjustable to the desired height by a screw *h*. This holder, like those shown in Fig. 2, can be used on either the front or rear part of the cross-slide.

The tool-holder shown at *A* in Fig. 4 is known as an open-side forming toolpost for holding forming tools with square shanks. This toolpost comprises a block *a* which is fastened to the cross-slide by means of the bolt *b*, the lower end of which is screwed into a T-block. An additional clamping bolt in the base, not shown, is also used for clamping this

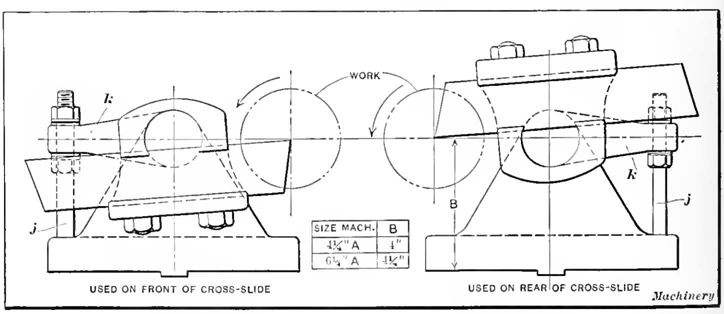

Fig. 5. Two Possible Combinations of the Universal Cut-off Tool-holder shown in Fig. 4

toolpost to the cross-slide. The forming tool c is held in the base by the set-screw d and is adjusted to the proper height from the cross-slide by the wedge e, the adjustment being secured by the screw f. The chief advantage of this type of toolpost is that a tool to be used in it can be made up very quickly and cheaply.

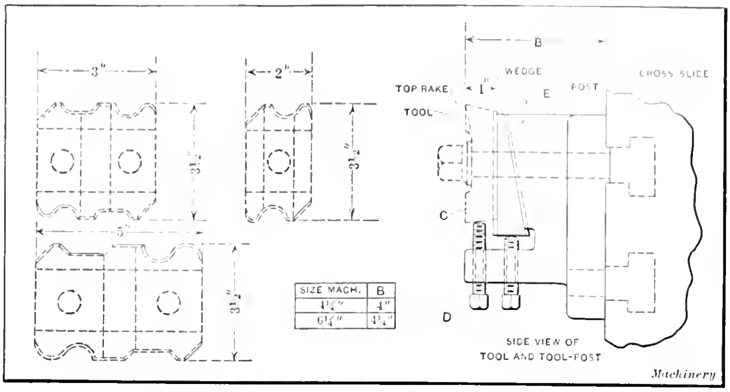

Fig. 6. Diagram illustrating Tool-holders for holding Large Flat Forming Tools and Proportions of Large Flat Forming Tools

The toolpost shown at B in Fig. 4 is known as a universal cut-off toolholder, and is adaptable for use on either the front or rear of the cross-slide, as clearly shown in Fig. 5. Referring to Fig. 4, the post g is so arranged that it may be clamped to either the front or rear of the cross-slide. The swinging tool-holder h is pivoted on the bolt i which also clamps the holder, ratchet and post together. A threaded stud j supports the ratchet k and this ratchet gives the adjustment to the tool-holder h. The blade type of cut-off tool l is clamped in place by two bolts m.

This toolpost can be used in various combinations, two of which are shown in Fig. 5. As shown to the left of this illustration, the cut-off tool blade is reversed with the cutting edge up, and in this position can be used on the front part of the cross-slide with the stock rotating in the direction indicated. It can be used on the rear of the cross-slide, as shown to the right of the illustration, with the cutting edge down and the spindle running forward as indicated by the arrow. It can be used on the rear of the cross-slide by reversing the blade and holder, cutting edge up, with the spindle running backward. Again, it can be used on the front of the cross-slide by reversing the position of ratchet k and threaded stud j, leaving tool-holder h in the same position that it formerly had, with the cutting edge up for the spindle running forward. It can also be used on the front of the cross-slide by reversing the tool-holder and blade, cutting edge down, and spindle rotating backward. Fig. 5 also includes a table giving the distance from the base to the center of the spindle on the 4¼- and 6¼-inch machines.

Fig. 6 shows the type of flat forming toolpost used on the larger sizes of machines from 4¼ inches up. The flat forming tool C is backed up by a set-screw D. This screw is not used for adjusting purposes, but simply to prevent any backward thrust of the cutter owing to a slight difference in the size of the hole and the diameter of the clamping stud. It also increases the rigidity of the tool.

The same illustration gives diagrams of the different sizes and proportions in which flat forming tools are made. The width in all cases is the same, but the length varies, depending on the work on which the tool is to be used. The angle E on the flat forming tool varies from 5 to 15 degrees, depending upon the material it is intended to cut. The top face of the tool is left flat as a rule, but on cutting cold-rolled steel and soft iron it has been found advisable in some cases to cut out the top; this is indicated by the dotted line in the end view, as top rake. Care must be exercised in doing this when the tool contour is of irregular shape. The peripheral speeds recommended for forming and cutting off various materials with cutting tools made from high-speed steel are as follows:

Material	Surface Speed in Feet per Minute
Brass	180–220
Cold-rolled steel	70–125
Tool steel	40–50

Drill, Reamer and Centering Tool Holders

Four different types of drill-holders are shown in Fig. 7. Type A is an ordinary drill-holder and is of simple construction, comprising a shank, the front end of which is drilled out to suit the tool, which is clamped by a set-screw located in a ring as shown. This holder will only retain drills of the size that it has been made for. B is a floating reamer holder. The holder shown at C is somewhat similar to that at A, but in this case the centering drill is held in position directly by the set-screw instead of depending on the spring of the metal. The holder at D is of the chuck type. The nose is bored taper, and a cone-shaped collet fits in it, which, when drawn back by the nut, holds the drill in position. A combination drill and chamfering tool-holder is shown at E in Fig. 7. This tool-holder, as the illustration shows, comprises a shank a, split on the front end and carrying the drill. Surrounding the front end of the shank is a holder b in which a chamfering tool c is held by a set-screw as shown. Holder b is clamped to the shank of the tool by a set-screw which, in addition to retaining the holder b in position, also clamps the drill.

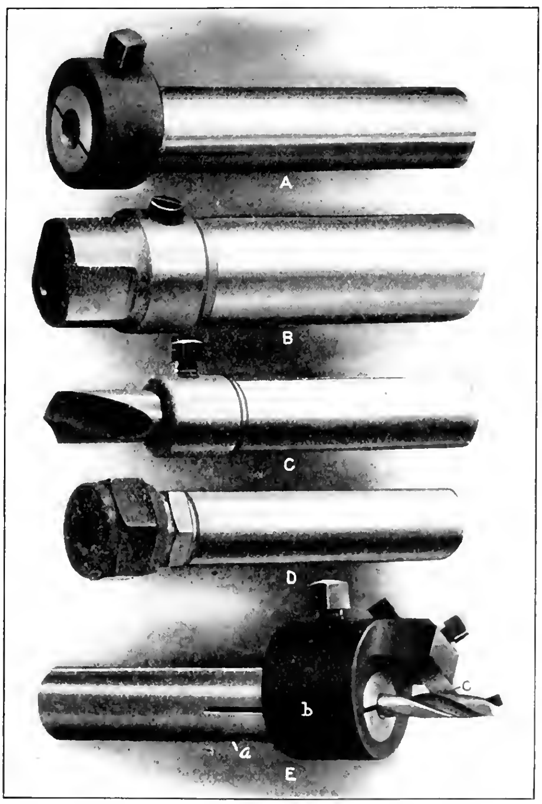

Fig. 7. Standard Drill, Reamer and Centering Tool-holders

The following gives the peripheral speeds recommended for drilling and counterboring operations when using tools made from high-speed steel:

DRILLING

Material	Surface Speed in Feet per Minute
Brass	180–250
Cold-rolled steel	90–100
Tool steel	40–50

COUNTERBORING

Material	Surface Speed in Feet per Minute
Brass	180–220
Cold-rolled steel	70–100
Tool steel	40–50

TUMBLER GEAR DESIGN*

BY S. C. B.

The accompanying illustrations will prove useful in calling attention to a number of points that are sometimes overlooked in tumbler gear design. In all the illustrations, the driving and driven gears are shown of the same diameter, and the force diagrams are drawn to the same scale. The force diagrams apply to involute teeth having a pressure angle of 20 degrees. The frictional losses in the bearings and between the teeth of the gears have been disregarded. In order to make the illustrations clear, only the pitch lines and base circles have been drawn. The outside circumferences of the gears have been omitted.

In Fig. 1, line *DE* represents to a given scale the force acting tangent to the pitch line of the driver, and *FE* is the resultant pressure normal to the tooth curve, and also the pressure on the bearings, *DF* being the component force acting to push the gears apart. The angle α is equal to 90 degrees minus the pressure angle of the gear teeth. Line *FE*, normal to the tooth curve, is tangent to the base circle and intersects the pitch lines on the line of centers.

Figs. 2 and 3 show the effect of changing the position of the tumbler gear with relation to the driving gear and also the effect of changing the direction of rotation of the driving gear with relation to the tumbler. Forces *EF* and reactions *GF* are determined as in Fig. 1. Completing the parallelogram of forces, we find *DF* to be the resultant force tending to move the tumbler gear. It should be noted that in each case *DF* passes through the center of the tumbler gear. The force *DF* multiplied by the perpendicular distance from *DF* (or *DF* extended) to the center *O* of the driving gear gives the turning moment acting on the tumbler arm *OH*. The great difference in the values of forces *DF* in Figs. 2 and 3 should be noted.

Fig. 4 shows a graphical method for obtaining the size and center of a tumbler gear in which there is no resultant force, due to the tooth pressure tending to rotate the tumbler arm *OH*. This diagram will also prove useful in designing idler gears carried on overhung studs, as it shows the theoretical size of an idler gear which would cause the resultant forces on the idler stud, due to the tooth pressures, to be reduced to a minimum. The center *H* is found at the intersection of the extensions of lines *KN* and *OR* which are drawn through the intersections of a common tangent to the base circles of the driving and driven gears with the pitch circles of the same gears. By construction, angle α equals 90 degrees minus the pressure angle, and the normal forces *FE* and *FG* oppose each other and have no resultant acting on the center *H* of the tumbler gear. There is, therefore, no tendency to rotate the tumbler arm *OH*.

It will generally be found that the theoretical tumbler gear thus determined will be too large, but the knowledge gained by an analysis of this kind will be a great help in arriving at a correct design. This article has been written with the hope of provoking further discussion upon this very interesting subject.

* For articles on tumbler gear design, previously published, see MACHINERY, December, 1907, "Tumbler Gear Design," and December, 1899, "Tumbler Gearing." See also MACHINERY'S Reference Book No. 14, "Details of Machine Tool Design," Chapter IV.

REMOVING PAINT AND ENAMEL FROM TIN

BY G. G.

It is sometimes required to remove paint or enamel from tin, iron or other metal surfaces. Under ordinary circumstances, this is a long and tedious job, especially if the surface under the enamel or paint is required to be left clean and bright. A method which I have used successfully to overcome this difficulty is described in the following. This consists of treating the surface from which the paint or enamel is to be removed with either metallic mercury or bi-chloride of mercury. If the pieces to be cleaned are small

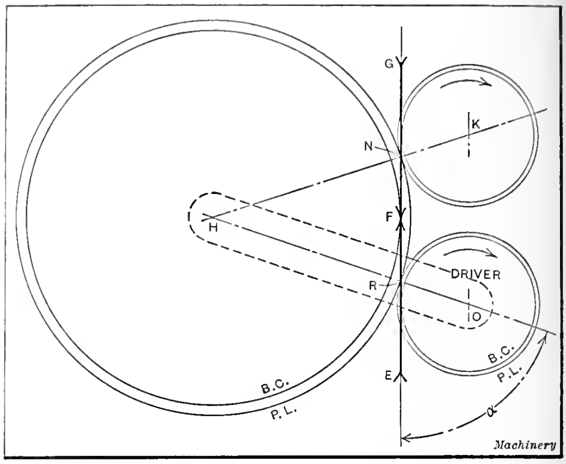

Fig. 4. Graphical Method of Tumbler Gear Design

enough in size, they may be placed in a receptacle containing a sufficient amount of mercury (quick silver) and held under the surface for about fifteen minutes. It will then be found that the paint or enamel may be easily rubbed off with the finger or a rag. If the pieces are too large to be treated in this way, lay them down so that the surface to be cleaned is horizontal, with the enameled or painted side up. Then cover these surfaces with metallic mercury and leave them for about fifteen minutes. The paint or enamel can then be rubbed off as previously described, leaving a clean surface. A typical application of this method is in the case of tobacco boxes, from which the enamel can be readily removed. When treated in this way, such boxes make attractive holders for small drills, reamers and other tools. If metallic mercury is not obtainable, bi-chloride of mercury will be found to answer the purpose nearly as well. A solution of this chemical is made by dissolving as much of it as possible in water. If this alternative method is used, great care must be exercised as bi-chloride of mercury is a deadly poison.

FILING YOUR OWN PATENT

BY BELL CRANK

In the February number of MACHINERY an article of this title was presented by Mr. Ford W. Harris, that should be particularly interesting to men who are developing ideas which they intend to patent. I have secured patents on several of my inventions and this experience has convinced me that it would be a distinct advantage for an inventor to make application for a patent without the aid of an attorney. In two cases I had my attorney make searches to see whether my inventions had been anticipated by others. He was an experienced and reliable man who was well-known to me, and he reported that there appeared to be no other patents that would prevent mine being granted. Yet when the patent office reported on them, they had found patents which so limited my claims that both patents were of but little more value than the expense to which I was put in securing them.

In another case I was so confident of the novelty of my device that, although I remembered the failure of his previous search, I instructed this attorney to go ahead. Again he reported favorably, but it was found by the patent office that my invention had been anticipated and so I lost the $15 fee charged by the government in addition to a $35 attorney's fee. In two other instances I secured patents without having a previous search made. This experience was the means of teaching me quite a little about the method of procedure in securing patents, and has given me a high regard for the thoroughness of the searches conducted by the patent office. As a result, I would not spend money to have a search conducted by an attorney because no attorney has facilities for making a search equal to that of the patent office. Even if he had such facilities and made a thorough search, he would charge so much for doing it that his fee would probably be more than the cost of an application for a patent.

There are a lot of "no patent no fee" attorneys who profess to make a free search to determine the patentability of an invention. It is extremely doubtful, however, if any of them do so; and if they report an invention non-patentable, which they very seldom do, it is not the result of a search but because they happened to know that the invention has been anticipated. When in doubt, they take chances and depend upon their skill and experience to "wriggle" through some sort of a patent, whether it is of any value or not, and thus obtain a fee. It is practically certain that if all patent attorneys prosecuted only such inventions as they honestly believed to be of any real value, about one-half of those now engaged in the profession would have to go out of business. It must not be forgotten that the usual attorney's search—for which the customary fee is $5—covers only United States patents. But there may be, and often are foreign inventions which interfere with the granting of a patent in this country. In the case of one of my own inventions, there were two foreign patents which prevented my obtaining two of the most important claims.

I feel sure that it is well worth while for an inventor of limited means to take the time and trouble to learn how to make application for a patent without employing an attorney. For the first fee of $15, the patent office makes an examination of the patentability of an invention that is far more thorough than any independent practitioner could conduct for such a fee. Unless an invention is entirely new, there are sure to be several previous patents cited by the patent office, which must be carefully considered in reference to the claims that are made. If the inventor believes that he has a very valuable device and the other patents do not seem to interfere materially with his claims, I would advise him to employ a reliable patent attorney to complete the prosecution of the patent. If, on the other hand, the invention is one of minor value and he feels sure that he is competent to carry the prosecution of the patent through to a satisfactory conclusion, the attempt may be made. Then, if the inventor finds it too difficult to go on with, he may still employ an attorney to complete the work. The inventor will find this very interesting work, and work which will increase his knowledge of the procedure of the patent office.

It is a common thing to hear people criticize the work of the United States patent office, but after an inventor has seen the facility with which the employes of this office find patents that interfere with the granting of his own, he is sure to have greater respect for their work. Even if he finds that his application cannot be granted because of previous patents, the knowledge which he has gained of the developments which have been made along the line of his own invention is usually worth all or more than the $15 fee which he has paid.

I believe that Mr. Harris' advice in regard to how an applicant for a patent should draw up his claims is about as clear as it could be made for the benefit of the novice. In this connection, I should like to earnestly advise those who have anything to do with applying for a patent to treat the examiners who have charge of their cases with the utmost courtesy, and to endeavor to make friends of them. The rules of the patent office are strict in regard to this matter and even a registered attorney may be disbarred for misconduct in prosecuting applications. You may think that the examiner is very strict in regard to a technical matter which appears of minor importance to you; but it pays to concede to his wishes in such things, for he is certain to know more about it than you do. The essential elements of the claims may easily be retained and still allow you to make the changes which the examiner suggests, as there is always more than one way of saying the same thing. The salaries paid the examiners are not as high as those paid to men of equal ability who are employed outside the government service. Those who continue in the patent office do so because of their interest in the work, for which they certainly deserve due respect.

In regard to the sort of attorney to employ, a contributor in the April number of MACHINERY—himself a patent attorney—lays great stress on the need of employing a practitioner, even though he is incompetent. In this contribution, the statement is made that the office registration of patent attorneys is a very strict matter and that the requirements are severely enforced. This may be so, but no satisfactory proof was offered to substantiate it. The rules of the office, as published, state that any citizen of the United States who is not an attorney may be registered, if he can satisfy the commissioner that he is of good moral character and possesses legal and technical qualifications to make him competent to render valuable services to applicants for patents, and to assist them in making their applications. It is well known that there are a large number of patent attorneys who were examiners in the patent office, and never studied any law except that which was incident to their work as examiners. There is also very little doubt that any inventor who has successfully prosecuted a few of his own applications would have little difficulty in getting registered as an attorney.

In regard to what the contributor in the April number of MACHINERY says about the value of patents, *i. e.*, that someone can usually be found who is willing to pay the attorney's fee for an interest in the patent, it may be observed that although many attorneys advertise their willingness to secure a patent or waive their fee if they fail, and offer numerous inducements in order to secure clients, you never hear of any of them advertising that they will assume all expenses of securing a patent for a part interest in it. This is a startling evidence of how lightly they value the patents which they prosecute for their clients. I once heard an eminent inventor say that he would not give $5 each for all the patents that are issued, if he had to take all of them. This is equivalent to saying that not one patent in each hundred is worth $500. There is little doubt that every patent attorney of any considerable experience knows that the majority of patents issued never bring as much to the inventor as they cost him.

* * *

At the present time there is one motor vehicle to every fifty-five inhabitants in the New England states. During the past year, the number of vehicles registered in these states increased by nearly 25 per cent. About one-tenth of the total number of automobiles in the United States is registered in New England, while the population in these states is only about one-sixteenth that of the whole country.

SPECIAL BORING MACHINE USED ON WILLIAMSBURG BRIDGE

MACHINE THAT ENLARGED PIN-HOLES FROM TEN TO THIRTEEN INCHES IN ONE PASSAGE OF THE CUTTER-HEAD

In the article on "Replacing Pins in the Williamsburg Bridge," in the June number of Machinery, mention was made of some of the problems connected with the strengthening of this bridge. As will be recalled by those who read this article, the work of reconstruction involved the replacement of the four hinge pins which connect the approach span trusses with those of the main span at points near the towers. The original pins were ten inches in diameter and it was necessary to rebore the holes to a diameter of thirteen inches for the new pins. In connection with this work a special boring machine had to be constructed, because of the unusual conditions which existed. A description of this machine and some interesting facts connected with its use are given in the following.

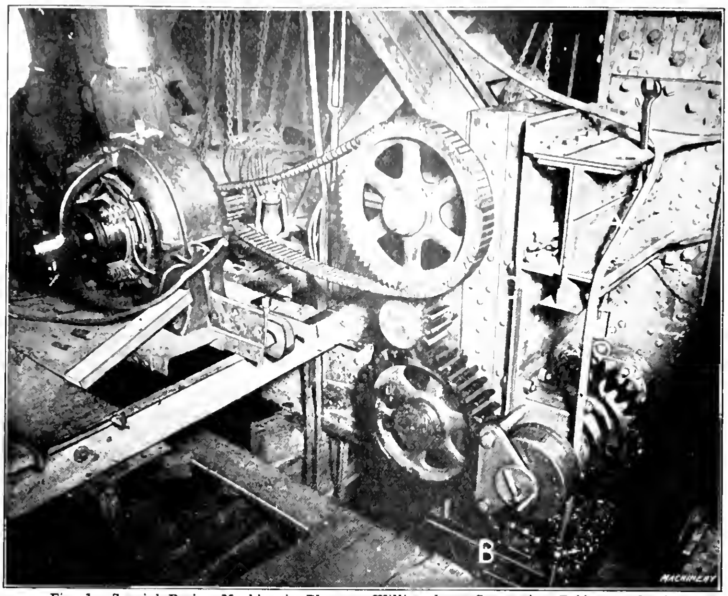

Fig. 1. Special Boring Machine in Place on Williamsburg Suspension Bridge ready for reboring Pin Hole from 10 to 13 Inches Diameter in One Passage of Cutter-head

As mentioned in the preceding article, the load carried by the old pins had to be transferred to a new girder erected transversely above the ends of the main span trusses close to the tower. In this way the pins were relieved of the dead load stresses, but part of the live and all of the "wind" loads were still transferred through these joints. Owing to this condition, it was impossible to rebore the holes while the railway and vehicular traffic continued across the bridge. As an interruption of this traffic during the day would cause great inconvenience, it was decided to do the boring at night, and nights of an even temperature and low wind were desirable, because, even under favorable conditions, it was considered hazardous to have a pin removed for more than two or three hours. Therefore, the time for the boring operation was limited, and even during this short time, the members held together by the pin were likely to move slightly and interfere seriously with the boring operation. Because of these conditions, it was apparent from the beginning that no ordinary boring-bar could be used, and it was decided to build a special boring machine; moreover, to prevent any relative movement of the members while boring, it was necessary to have them rigidly tied together. This was effected by an elaborate system of auxiliary members placed around the pin-hole. These were arranged so that they could be rigidly connected by bolts just before starting the boring operation, and be released as soon as the new pin was in place. The actual boring time was limited to a maximum of two hours, and a machine had to be designed to enlarge a hole thirteen inches for a distance of twenty-eight inches, in one passage of the cutter-head, and finish the hole to the required diameter within a limit of 1/64 inch.

In order to determine if a satisfactory hole could be obtained with roughing and finishing cutters working together, and to obtain the most efficient rate of feed, shape of tool, etc., a series of experiments were conducted in the shops of the Department of Bridges, and the data obtained were used in designing the machine. These preliminary tests showed that one of the most important points in the design was that of securing a rigid support, in order to avoid chattering. Among the special conditions that had to be considered were the ease of adjustment for centering the boring-bar as quickly as possible, the insertion and removal of the bar to permit placing the new pin in position, and the extremely limited space of only twenty inches between the center of the pin-hole and the side of the main tower. Furthermore, the machine had to be designed so that it

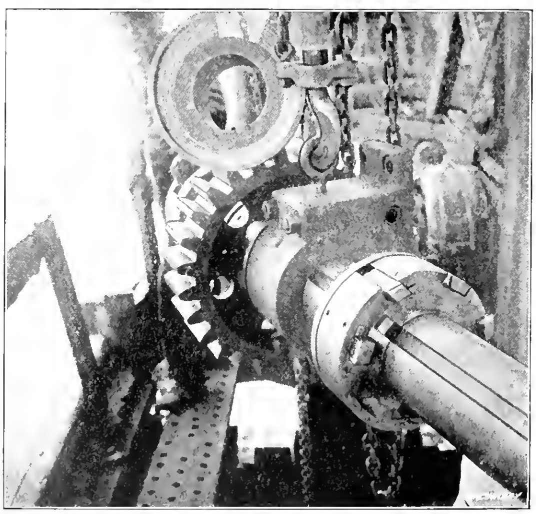

Fig. 2. Boring-bar and Cutter-head equipped with Seven Tools

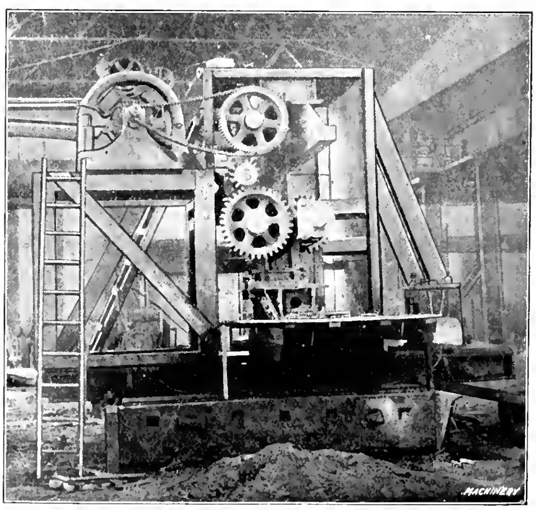

Fig. 3. Preliminary Test of Boring Machine

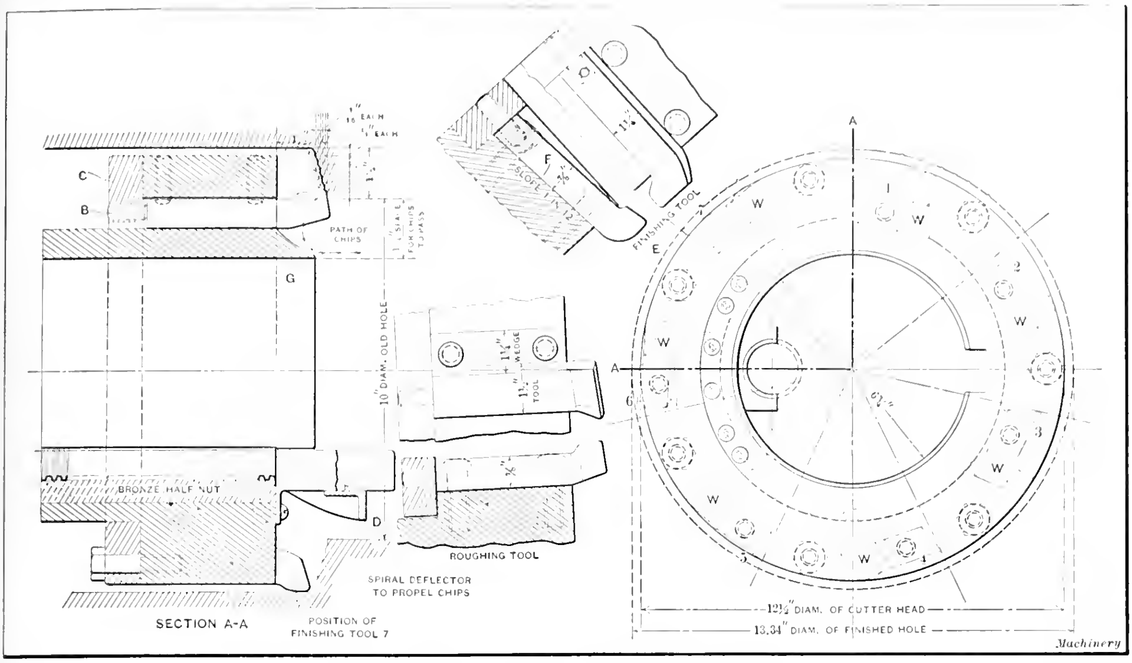

Fig. 4. Seven-tool Cutter-head used on Boring Machine

could be changed from right-hand to left-hand for boring the pin-holes on opposite sides of the tower. The most serious difficulty of all, however, proved to be the removal of the large quantity of chips without interference with the cutting tools, because in order to secure the necessary rigidity, the boring-bar was made 6¾ inches in diameter so that there was not much room between the bar and the ten-inch hole.

Owing to the importance and dangerous nature of this work, it would have been unwise to take any chances regarding the successful operation of the machine, and it was also imperative to know definitely the time required for the boring operation. To ascertain beforehand exactly what the machine would do a trial hole was bored, the conditions existing on the bridge being reproduced as nearly as possible. This preliminary test was made in the presence of representatives of the Department of Bridges at the shops of the Fawcus Machine Co. at Ford City, Pa., where the machine was built. Fig. 3 shows the machine assembled for testing. The post for this test was practically the same as the one on the bridge, and it was provided with members in the center arranged in the same slanting position that they occupied on the bridge members, so that the tools would work under corresponding conditions in each case. This test proved that the machine was entirely successful. The hole was enlarged from ten to thirteen inches in diameter in one hour four minutes, and a smooth surface obtained.

It was necessary to move the boring machine successively to four places on the bridge, but as the bridge construction in each place was similar, it was possible to utilize the framework of the bridge as a support for the machine. The connections of the roadway floor beams (the latter being detached to make room for the boring machine) were utilized for attaching the horizontal brackets *A* and *B* (Fig. 1). Bracket *A* held the upper end of the main post *C* of the machine, whereas bracket *B* supported the lower end. The open rivet holes of these connections located the supporting brackets in almost exactly the same position at all four points where the boring had to be done. The main post *C* rested on two taper adjusting blocks, which, in turn, were held by bracket *B*. These blocks gave both vertical and horizontal adjustment for post *C* and provision was also

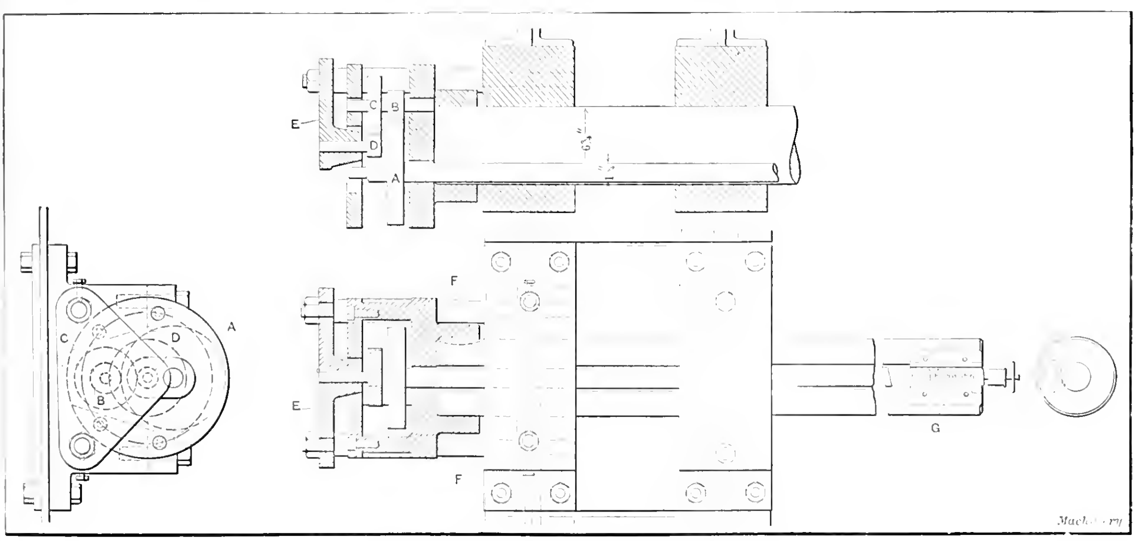

Fig. 5. Geared Feed Mechanism for Cutter-head

made for tilting this post transversely with relation to the bridge. The angle-plates connecting the post to bracket *A* were provided with slotted holes to permit of these adjustments. The post *C* consists of two built-up I-sections rigidly joined by plates. The driving gear on the bar (see Fig. 1) and its meshing gear enter between the two webs of this post. The power is transmitted from a 35-horsepower motor by a silent chain, and then through a train of gears giving a reduction of 49 to 1 from the motor to the bar. The journals for the gear shafts are attached to post *C*, which also carries the outer bearings of the bar. These outer bearings are bolted to finished surfaces on post *C*, so that the bar could readily be placed in position after the post was properly set. The rear end of the bar was supported by a journal clamped to the angles of the trolley track floor beams. This rear journal was so designed that it could be adjusted in all directions.

In order to center the journals of the bar, a piano wire was stretched through the small center hole of the old pin. The bearings for the bar, while attached to the main post

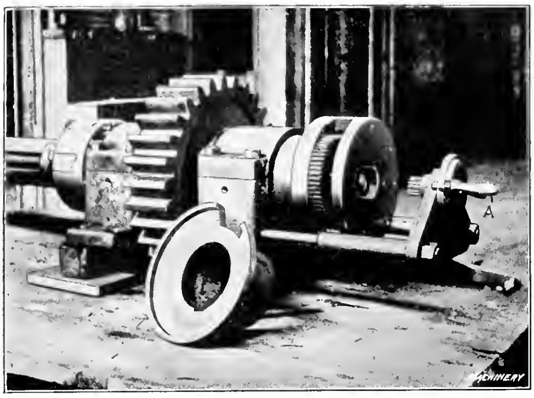

Fig. 6. Detail View of Feed Mechanism

of the machine, were then set central with this wire by adjusting the post, as required. The position of the bearings was checked by a gage consisting of a 1 7/16 inch bar which fitted the central hole of the old pin and carried three 6¾-inch removable collars which fitted the journals.

The cutter-head was fed along the bar by a feed-screw contained in a groove extending along one side of the bar. This feed-screw was operated by an epicyclic train of four gears, *A*, *B*, *C*, *D* (Fig. 5), located at the front end of the bar. These gears provided a reduction of 10 to 1, giving the cutter-head a feeding movement of 1/32 inch per revolution of the bar. The shaft of the central pinion *D* is journaled in the triangular plate *E* which is held by two studs *F* to the journal of the bar. To obtain an automatic feed, the pinion *D* was held stationary by the engagement of a pin in the handle shown at the right in Fig. 6, which engaged the plate shown. By withdrawing this pin, a hand feed of any desired rate could be obtained by turning the gear *D* in one direction or the other. For a quick return of the cutter-head, plate *E* was detached; then the feed-screw could be turned directly by a crank. The feed-screw was designed to be in tension during the boring operation, the axial thrust being taken by a stepped or collar bearing *G* (Fig. 5).

The forged steel cutter-head shown in Figs. 2 and 4 is 12½ inches outside diameter and six inches long. This cutter-head has seven cutters or tools, six being for roughing and one for finishing. Each of the roughing tools took a cut having a radial width of ¼ inch, the feed being 1/32 inch per revolution, as previously stated. The front edge of the inner cutter protrudes 1½ inch from the cutter-head, and the other tools are arranged in steps varying by 1/16 inch increments, toward the cutter-head, as shown in Fig. 4. The cuts were distributed between the different tools so that if one should break the following cutter could do the work of two tools. When boring one of the holes a tool did break, but this was not detected until the hole was successfully finished. The cutting speed for roughing was 45 feet per minute, and the speed for finishing was 51 feet per minute.

The four outer cutters are held in rectangular grooves cut across the edge of the cutter-head, whereas the three inner cutters are inserted into slots cut through the head. The roughing cutters are ⅞ by 1½ inch and are made of "Ultra Capital" high-speed steel. The rear edges of the tools are beveled and they are held by wedges *W*, which are forced downward by screws as shown. This method of holding the tools proved very effective. The position of all the tools can be adjusted longitudinally by means of set-screws *B* located in the back plate *C*. The finishing tool *E* rests in a seat *F* beveled axially so that the tool is not only adjustable in a longitudinal direction, but outward or radially to a limited extent. In this way, it was possible to regulate the diameter of the hole with considerable accuracy. The circular gage for setting the tools may be seen in the upper part of Fig. 2. It has a series of annular steps which represent the respective diameters to which the cutters must be set. The gage is partly cut away on one side and when it is placed on the bar, the steps or edges formed by this opening provide a simple but accurate means of setting the tools.

The removal of the chips presented a rather serious problem, as they had to pass forward through the long opening between the 6¾-inch bar and the wall of the ten-inch pin-hole. No chips could pass between the cutter-head and the thirteen-inch hole owing to the lack of room. This problem was solved by grinding the tools so as to produce chips in long curls not over 1½ inch in diameter, so that they could readily pass through the opening. As will be seen by referring to Fig. 4, the cutting edges incline backward in such a way as to curl the chips downward and cause them to follow the path indicated by the arrows. As the chips left the tool they were turned toward the front by the large fillet-like projection *G* on the cutter-head. To protect the feed-screw from the chips, a cover plate six inches long is attached to the front face of the cutter-head. On the face of this plate there is a spiral deflector *D* forming an angle of 45 degrees with the bar for propelling the chips forward. While boring the hole, the tools were cooled by a liberal supply of soap- and soda-water solution. Four barrels of this solution were placed on the top chord of the truss forty feet above the pin-hole, and the lubricant was directed onto the tools by the hose shown in Fig. 1.

All four of the pin-holes were bored without the slightest mishap. When boring the last hole, the old pin was removed at 10:30 P. M. and before midnight the boring-bar was ready for use. The traffic on the bridge was stopped at 12:15 A. M. Tying the members to be bored rigidly together, required fifteen minutes and the boring operation began at 12:30 A. M. The hole was enlarged to 13 inches by 1:30 A. M. While the machine was capable of finishing the hole in one cut, as originally planned, it was decided to take a 1/64-inch finishing cut in all cases, as there was time for a second cut. The latter required only forty-five minutes, as the motor ran faster under the light load. The new pin was in the hole and two new wind-chord members placed on it at 3:30 A. M. when the bridge was again ready for traffic after an interruption of only three hours fifteen minutes. That this work was done without a hitch was due to the careful planning of the Department of Bridges (F. J. H. Kracke, commissioner) and to the efficient design of the boring machine.

The power required to drive the boring-bar was calculated from the rules given by Taylor and Nicholson. The rule given by the former to allow as much power for feeding the tools forward as for turning the bar was adhered to. The ammeter and voltmeter readings taken at one minute intervals during the boring operation showed that nearly five horsepower was required for driving the machine when running without load, whereas the maximum power while boring was twenty-six horsepower. The calculated power was eighteen horsepower, but in this calculation no allowance was made for the friction caused by the chips in the hole, which proved to be quite high, as one horsepower less was required while boring the rear part of the hole from which the removal of chips could be assisted by hand. The weight of the boring machine frame is about two tons and that of the boring-bar, with the two main bearings attached, about 1400 pounds.

DRAWING A CIRCULAR BRASS CUP

The following outlines the experience which the writer had in drawing a brass cup made from stock 1/16 inch in thickness. The first operation was performed in a combination blanking and drawing die of the usual type, and resulted in the production of a cup of the form shown by dotted lines *A* in Fig. 1. With the work carried to this point, it was desired to complete the cup in two operations, and the first attempt in this direction was made with the punches and die shown in Fig. 1. These tools were used in the following manner: A blank was placed in the die and the punch for the second operation was intended to force it down into the die, turning up the flange about point *E* and bringing the cup to the form shown in cross-section in Fig. 1. The punch for performing the third operation was similar to that used for the second operation, with the exception that the working rim was 1/16 inch longer. The purpose of this punch was to upset the lower edge of the rim. The trouble with this process occurred in the second operation. After the flange of the cup had been turned up about half way, the work offered so much resistance to being compressed that the metal began to turn up from the body of the cup at the point *D*, and this made it impossible to force the stock down into the die.

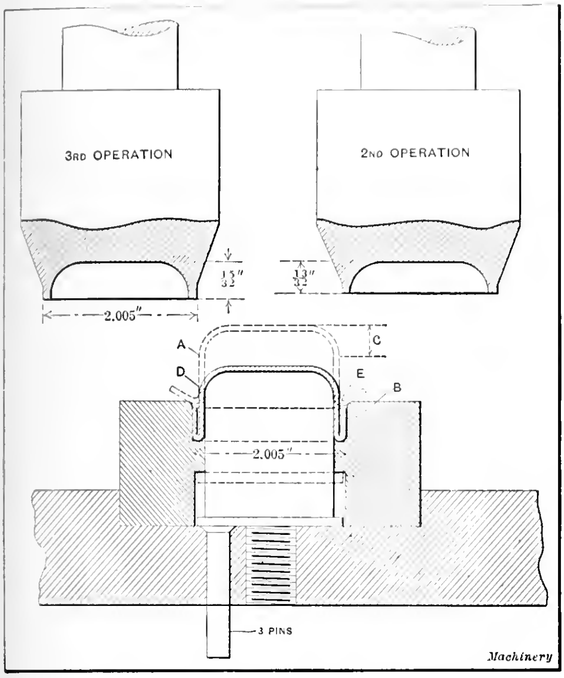

Fig. 1. Punches and Die that proved Unsuccessful for the Drawing Operation

To overcome this difficulty, the dies shown in Figs. 2 and 3 were designed. Fig. 2 shows the punch and die for performing the second operation, where it will be seen that the rim of the punch is extended in order to support the body of the cup at all points. The work is also supported from the inside by the spring plunger. When drawing the cup in this punch and die, deformation of the work is practically impossible. The design of the die provides for stripping the finished cup and also allows a free movement of the plunger, which is required to rise considerably above the die to facilitate locating the blank. The third operation is performed by the punch and die shown in Fig. 3, and the method of using these tools will be self-evident to any mechanic without a lengthy description. A blank upon which the second operation has been performed is inverted and forced down into the die. Great pressure is required to be exerted on the metal at *H* in order to upset it properly and produce a smooth surface. It was found necessary to taper the punch about 0.010 inch along the straight portion *J* in order to make it fairly easy to strip the cup from the die.

SETTING THE MILLING MACHINE TABLE AND KNEE

The method I am about to describe provides for locating a milling machine table and measuring the distance from the table to the center of the spindle, when it is desired to locate the table at a specified distance below the spindle. This method is rapid and accurate, and should be appreciated by milling machine operators who do a variety of work and are often required to bore or drill a hole at a certain distance from a finished face on the work, as in the case of a bearing bracket. The method of locating the table in a certain longitudinal position is also explained, this method being useful in cases where it is desired to locate the dividing head crosswise on the table and have it exactly opposite the spindle.

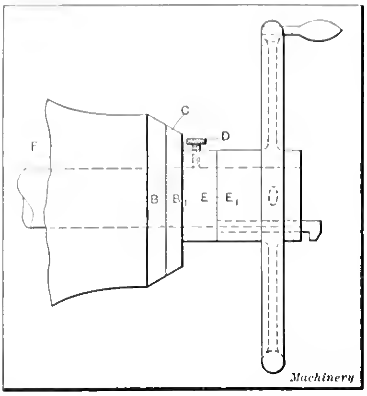

Fig. 1. Locating Height of Milling Machine Knee

Fig. 1 shows the knee handwheel, and a pair of angle plates for making the preliminary setting of the table relative to the spindle as shown in Fig. 2. The distance A is made any convenient length, and by the use of an indicator held in the spindle chuck the knee may be adjusted vertically until the spindle is centered on A. With this setting the table will be $\frac{A}{2}$ below the center of the spindle. Having proceeded thus far, a line is scribed on the column slide and knee, which serves as an approximate location. The zero line B_1 of the graduated dial C is next brought into coincidence with the zero line B on the boss of the knee, after which the dial C is locked to the feed-screw by means of the binding screw D. On the hub of the dial and the hub of the handwheel scribe zero lines E and E_1.

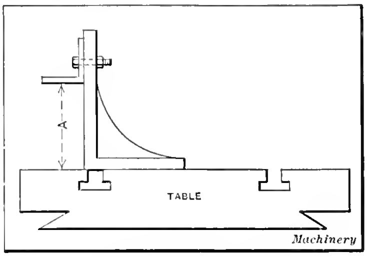

Fig. 2. Angle Plates for making Preliminary Setting

After the setting has been made in this way, the table may be returned to the starting point by first locking the dial C to the feed-screw F with the index lines E and E_1 in coincidence; then raise or lower the knee until the lines on the column slide and knee, and the index lines B and B_1 are both in coincidence. This shows that the table has been returned to the required point and the accuracy of the setting may be depended upon. Care should be taken that the tension of the screw is upward and that all of the table and knee locking screws are tight before the lines are scribed and the final adjustment is made. By locating the dial C with the index lines E and E_1 in coincidence, any location may be obtained by measuring with a scale from the line on the column slide and having the index lines B and B_1 correspond with the scale measurement.

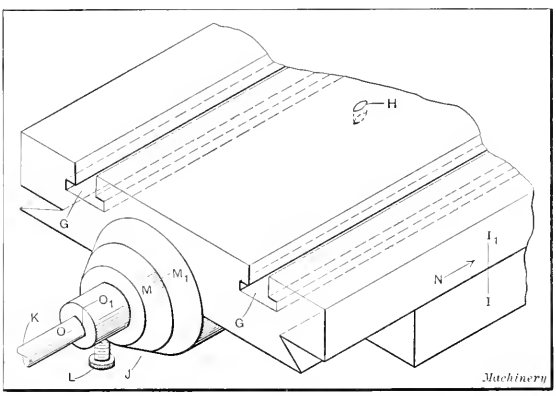

Fig. 3. Locating Longitudinal Position of the Milling Machine Table

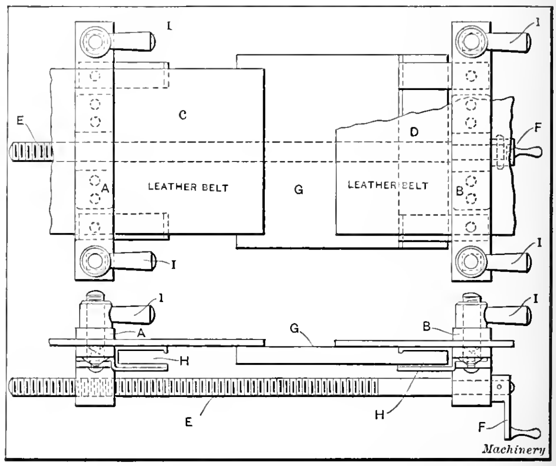
Most of the milling machines used in jobbing shops are provided with an auxiliary baseplate or jig for use in setting the dividing head crosswise on the table, so that it is in line with the spindle. The method of making this setting is illustrated in Fig. 3. The jig is first located on the table by tongues which fit in the slots G and a dowel-pin H. With the dividing head in place on the jig, use an indicator in the chuck of the machine spindle to set the dividing head spindle in line with the machine spindle. When this setting has been made, scribe the index lines I and I_1 on the slide and table. Next lock the graduated dial J to the table feed-screw K by means of the binding screw L, having the zero lines M and M_1 in coincidence. Care should be observed to have the tension of the table feed-screw in the direction indicated by the arrow N when the lines are scribed and the final adjustment is made, and the same precaution should be observed in resetting. The reading of the handwheel and the distance of the table below center should also be observed and a memorandum of these readings should be preserved. To relocate the table in this position, the first step is to lock the graduated dial J to the table feed-screw K, having the index lines O and O_1 in coincidence. Then feed the table in the direction of the arrow N until the index lines I and I_1, and also the lines M and M_1 correspond. Using this method and having the jig located by the dowel-pin H, an accurate setting is assured.

Denver, Col. STANLEY EDWARDS

DEVICE FOR ADJUSTING DRIVING BELTS

The accompanying illustration shows a very simple and convenient device for stretching belting preparatory to cutting and lacing. It is similar in design to the various devices of its kind on the market today, but is particularly easy to manipulate. In the past I have been using the Gardner & Miller patent belt clamp, which is operated by two feed-screws with turnbuckles. This necessitates the use of both hands in tightening. It is also minus the cutting-board arrangement, which has to be supported by hand while cutting; I therefore "hit upon" the accompanying design.



Device for adjusting Driving Belts, equipped with a Cutting Board

The clamps A and B are operated by handle-nuts I, which work up and down on bolts with square shoulders, thus fastening the ends of belts C and D. The belts are then ready to stretch by means of the screw E which has a crank F on its squared end. The crank F is replaced by a wheel with a corrugated rim, which is used in preference to the regular crank when adjusting small belts, as it does not get too much tension on the belts and leaves them in condition for a future adjustment. The cutting-board G is then inserted in compartment H, leaving the belt ready for cutting and lacing.

Bronx, N. Y. ERNEST SCHWARTZ

A USEFUL T-SQUARE

While visiting a drafting-room recently my attention was attracted by a T-square that was being used by one of the draftsmen. From various catalogues, etc., in which the desired data could be found there had been clipped tables of decimal equivalents, bolt-head and nut sizes, pitch of stand-

ard screw-threads, number and letter sizes of twist drills and many other tables of use to the draftsman. These tables had been arranged and pasted on the top sides of the T-square blades, after which they were given a coat of shellac. It impressed me that the usefulness and convenience of this system could be applied generally, as it is not necessary to even look away from the board to obtain data that is in common use. It is surprising to know how much printed matter can be placed on the blade of an ordinary T-square.

Denver, Col. STANLEY EDWARDS

OIL VAPOR IN COMPRESSED AIR

I notice an inquiry by the O. B. M. Co. in the May number of MACHINERY on how to remove oil vapor from compressed air. As I have had to do with the lubrication of a great many air compressors in the work in which I am engaged, I would say that very often more oil is used in the cylinders of compressors than is necessary. The compressed air is dry and there is no moisture to wash the oil off the surfaces as in the case of oil cylinders, and but very little oil is needed to afford good lubrication. The company probably is using more oil than is necessary and it is the vapor which arises from the large amount of oil in contact with the hot surfaces that is causing the trouble. A smaller amount, just enough to give good lubrication, would not give off an appreciable vapor. The oil used should be sufficiently high in flash point so that it will not give off an appreciable amount of vapor at the temperatures ordinarily obtained in air compressors.

Two years ago while reorganizing the lubricating practice of a large corporation, I found at one plant, where several air compressors were in use, that the chief engineer used no oil whatever in his air cylinders but used soapsuds as a lubricant. The suds were made by dissolving a bar of hard soap in about five gallons of water, and were fed into the cylinder the same as oil.

Boston, Mass. WILLIAM N. DAVIS

EXAMPLES OF BELT GUARDS

The accompanying illustrations show three examples of types of belt guards which have been adopted for use in the plant of the Norwich Pharmacal Co., Norwich, N. Y. This firm has devoted a great deal of time and money to the provision of safeguards and after a thorough investigation has found that this type of belt guard gives very satisfactory results. Referring to the illustrations it will be seen that Fig. 1 shows the guard used to cover the belts of a drill press, while Figs. 2 and 3 show the application of this type of guard on woodworking machines. Guards are particularly important on woodworking machinery owing to the high speeds

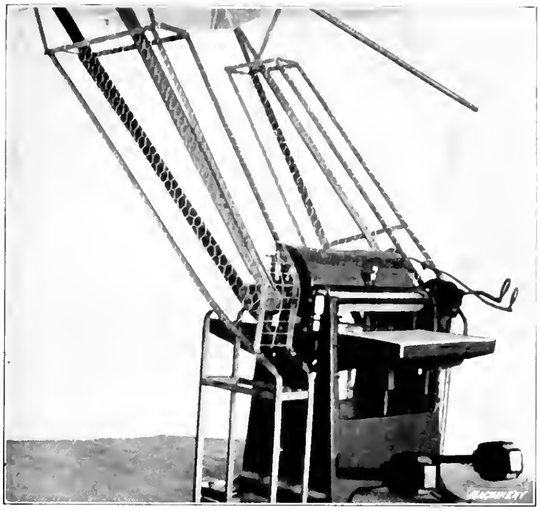


Fig. 3. Belts of a Wood Planer that are adequately guarded

at which such belts are customarily run. The construction will be evident from the illustrations.

ETHICS OF CONTRIBUTING TO THE TECHNICAL PRESS

Much has been written on the question of the general rights of progressive men in regard to publishing descriptions of up-to-date methods, knowledge of which they have gained in their general experience, and it is easy to see that the matter cannot be arranged satisfactorily to all. The manufacturer generally thinks he is being wronged if one of his employes, or former employes, makes public some of his general methods of manufacture. On the other hand, the employe must be allowed some rights in the matter.

Many a man may have ability and qualifications which his present employer does not recognize or appreciate, but the man often is possessed with a determination to be recognized and sits down and thinks over different ways of doing it. He desires to prove that he can do what he claims he can. What better way is there to do this than to write of what he knows for the technical journals pertaining to his particular line of business? In his experience as a workman he has seen and studied the various methods used by him and—if he has the ability to hold a position requiring brains—has either made or suggested improvements and money saving features in connection with such methods that may, or, as is often the case, may not have been accepted by the powers higher up.

So, in the desire to help others willing to study and at the same time help himself, he writes for the magazines describing his experiences and methods he has improved upon. They are published, the general trade is benefited, he gets a check which will help him in his battle for a fair living, and nobody is a loser by such publication. Of course, it will be understood that the stealing of a valuable drawing and the furnishing of the same to the

press or to a competitor is not morally right or legal, but if a man sees a machine and is then clever and competent enough to make a good drawing of it and its motions and write about it on his own time, there can be no reasonable objection sustained by anybody.

As a matter of fact, when a firm refuses to raise a man's wages above a living rate, and lets him go out of its employ, there certainly can be no claim on him or what he has learned while with this firm. If there is anything that this firm does not wish anybody else to use, and it is really an invention, the only legal protection is a patent or copyright. If such a method is not novel enough to be granted such protection there should be no objection to the publication of it. As a matter of fact there is nothing done today that could not be improved upon, and these same manufacturers who object to the publication of some insignificant improvement which may have been used by their own former employers years back will welcome the publication of an improvement if made at the works of their competitors.

Publication of a method causes no actual loss. As a general policy, any manufacturer reading of an improvement on a method that is better than his own, immediately sets to work to make a still better one and the general public is thereby benefited. Any suppression of information for the purpose of enabling a few men to make their money more easily is a menace to our national progress and should not be considered. Were it not for the books and magazines published at the present time, our national mechanical development—the highest of any country—would be seriously crippled.

Southbridge, Mass. WARREN E. THOMPSON

THE MAKING OF RACE CAMS

Some time ago the problem of cutting a race cam similar to the one shown in Fig. 1 arose. This cam had to be cut on short notice and at low cost. The standard method of doing such work required a large amount of time and money to be spent in making a master cam for the cam cutting machine. The difficulty was easily and economically overcome by making the cam as shown in Fig. 2.

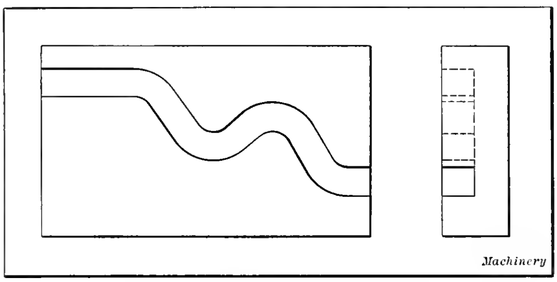

Fig. 1. Type of Race Cam to be made

Instead of using one casting, as is the usual practice, two castings were used. These were first machined so that the casting *A* in Fig. 2 had a thickness equal to the required depth of the raceway; and the other casting *B* was of such a thickness that when the two were fastened together they would have a combined thickness equal to that required for the cam. The piece *A* was cut with a surface on its upper edge which gave the outline of the lower side of the raceway. The other piece was then cut with a surface on its upper edge which corresponded to the upper side of the raceway. These two pieces were fastened together with countersunk machine screws and dowel pins, so that the two surfaces corresponded to the required surfaces of the raceway.

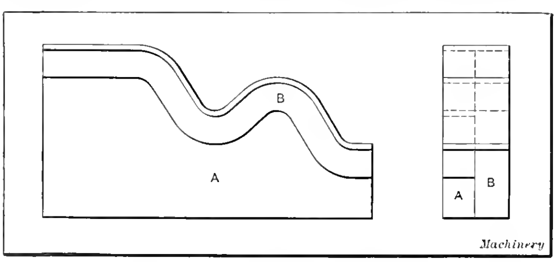

Fig. 2. How the Cam was finally made

A piece of sheet brass, 1/16 inch thick, and of a width equal to the thickness of the cam, was then bent so that it fitted perfectly with the surface of the upper side of the raceway. This piece was then fastened to the cam with countersunk machine screws. The result was a cheaper cam than could possibly have been produced by the old method, and an equally efficient one for the purpose for which it was required.

Philadelphia, Pa. SIDNEY K. EASTWOOD

DRILLING EQUI-DISTANT HOLES IN A STRAIGHT LINE

The method described in the following was used for drilling eighteen holes with a No. 48 drill through a piece of brass 7/8 by 1/8 by 24 inches in size. It was required to have the holes spaced exactly 1 inch apart and located in a perfectly straight line. Referring to Fig. 1, the edge *A* of the piece of brass *B* was filed true to a 24-inch standard steel straightedge, and the first hole *C* was then drilled 7/16 inch from the edge *A*. A 1-inch hardened scale *D* was next ground away at one corner so that it would not touch a drill in the hole *C* when the square *E* was placed against the drill with the head of the square on the edge *A*. The scale *D* was clamped to the work by means of a small hand clamp *G*.

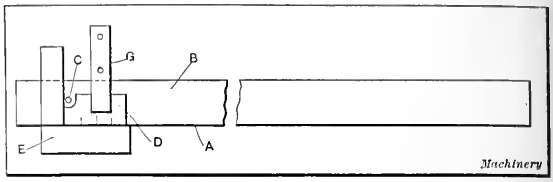

Fig. 1. One-inch Scale for obtaining Longitudinal Spacing of Holes

The work *B* with the scale *D* clamped to it was next placed against the 24-inch steel straightedge shown at *H* in Fig. 2, and a 1/16 brass strip *I* with a hole *J* drilled in it was clamped to the straightedge *H* by means of a hand clamp *K*, a thin strip *L* being placed between the strip *I* and the straightedge *H* so that the combined thickness of the straightedge and strip *L* was slightly greater than the combined thickness of the work *B* and the scale *D*. The straightedge *H* was next clamped to a board *M* by means of two parallel clamps *N*, after which the second hole was drilled in the work through the hole *J* in the strip *I*. In order to locate this hole, the drill was brought into contact with the end of the 1-inch scale *D*, this contact being determined by "sense of touch" as the drill revolved.

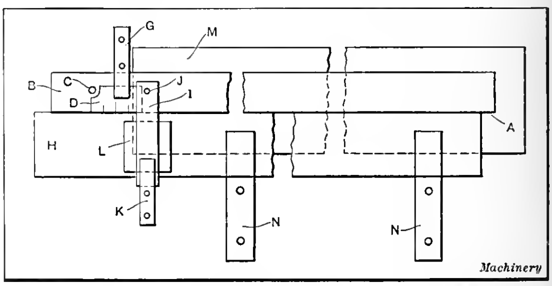

Fig. 2. Twenty-four-inch Scale and Jig for obtaining Transverse Alignment

The work *B* was next removed and the scale *D* unclamped and reclamped in the next position, while the drill was still in the hole *J*, the method of setting being the same as illustrated in Fig. 1. The work was then assembled once more—as illustrated in Fig. 2—and the third hole drilled. All of the hand clamps were so placed that they did not extend over the drilling machine table or interfere with the operation in any way. This sequence of operations was continued until eighteen holes were drilled, and when the work was completed the distance between the holes and their alignment was found to be quite accurate. G. L. C.

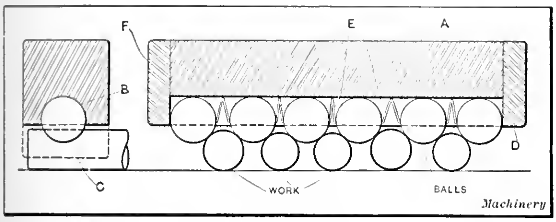
A MULTIPLE CLAMP

In certain operations where quick-acting tools are employed, a decided advantage is obtained by securing several pieces of work with a single clamp. The clamp illustrated herewith was designed with this object in view. Referring to the illustration it will be seen that the design is quite simple, there being none of the complicated floating parts which are often employed in tools of this kind.

The principle upon which this clamp operates is that of allowing the clamping members, which are hardened steel balls, to roll or slide between two fixed ends. Being free to move laterally, these balls adapt themselves to slight variations in the size of the work. The slight irregularity in the center distances caused in this way may produce corresponding inaccuracies in the work, but in most cases the error is negligible.

The main body of the clamp *A* may be made to suit the requirements of the work which is to be handled. This body is bored at *B* to receive the clamping balls. After boring the hole, the stock *C*, which is shown in the illustration by dotted lines, is milled away almost to the horizontal line passing through the center of the hole *B*. Just enough stock is left below the center to prevent the balls from dropping out. One end of the hole is next closed by a plate *D*, after which the balls are put in through the other end, spring spacing pieces *E* being used to maintain the required center distances. The plate *F* is then secured to the opposite end of the clamp.

In operation, the two end balls are held in position by the plates *D* and *F*, and the remaining balls are free to move laterally to adapt themselves to irregularities in the size of the work, the irregularity in size being considerably exag-



A Multiple Clamp which is adaptable for Differences in the Size of the Work

gerated in the illustration. When pressure is applied to the clamp, all of the pieces of work are held equally tight. Instead of using balls, a clamp of this kind could have a dovetailed slot milled in it and hardened rolls with tapered ends, or sliding dovetailed pieces, used for the clamping members.

Providence, R. I. C. KNOWLES

IMPROVED DOWELING METHOD FOR DIES

Blanks which have been punched from sheet metal are often perforated by a second operation performed in a piercing die. The blanking and piercing are sometimes accomplished in a single operation, using a gang punch and die, but when accuracy is essential a more common method is to perform the blanking and piercing operations separately.

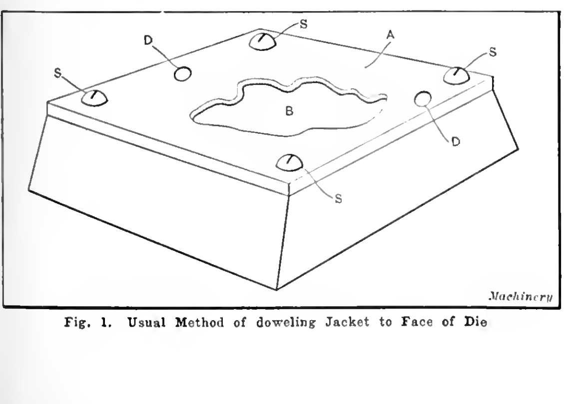


Fig. 1. Usual Method of doweling Jacket to Face of Die

The blank is usually located on the piercing die by means of a gage or "jacket" which consists of a sheet metal piece with a hole through it of the shape and size of the blank. The works fits closely into this gage, which is depended upon to locate the blank and bring it into exactly the desired position for piercing.

The gage is securely held to the die with screws, but screws cannot be depended upon to keep it accurately located; consequently the use of dowel pins is resorted to. The dowel-pin holes are drilled with the gage in place and close fitting dowel pins are driven through it into the die. This method of securing the gage is shown in Fig. 1, where *A* represents the gage with the locating hole *B* cut in it. The screws holding the gage to the die are shown at *S* and the dowel pins at *D*.

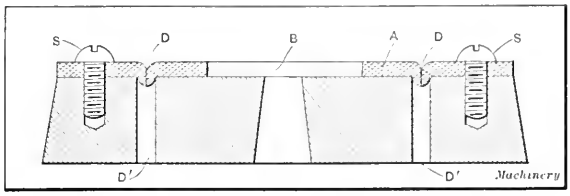

Fig. 2. Improved Method of doweling Jacket in Place

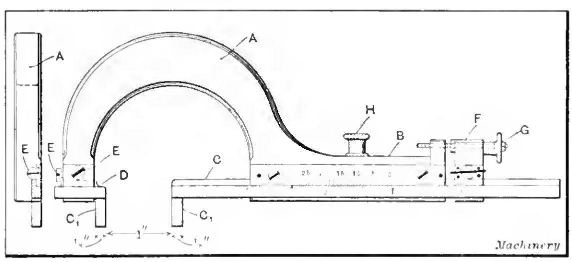
A better method of securing the gage or jacket to the face of the die is shown in Fig. 2. With the gage *A* in position, holes are drilled through it into the die at the points where the dowel pins should be. Two holes 1/16 inch in diameter are drilled in this way. The gage is then removed and the holes *D'* in the die are enlarged to a diameter of 1/8 inch. After hardening the die, the gage is replaced, and after locating it and fastening it in the required position with screws *S*, the point of a center-punch is placed in the 1/16-inch holes and the metal is driven downward into the larger holes in the die. In this way metal plugs *D* which take the place of the dowel pins project from the under side of the gage into the die. It does not take long to locate the gage in place in this way, and, as the plugs are part of it, they will always remain securely in place. F. E. C.

OUTSIDE AND INSIDE VERNIER CALIPER

The accompanying illustration shows a two-inch vernier caliper which is suitable for making both outside and inside measurements. These measurements may be made by using the tool directly or by setting ordinary outside or inside calipers. The following notation is used in marking the different parts of the instrument. *A* is the bow frame which has an extension *B* that supports the guide for the bar *C*. This bar has a projecting jaw C_1 which corresponds with the



A Two-inch Vernier Caliper for Outside and Inside Measurements

projecting jaw on the fixed jaw *D*. The fixed jaw is adjusted by means of the screws *E*. The projecting jaws C_1 are finished circular on the outside to provide for measuring internal sizes, while the inside jaws are made flat and are capable of measuring on the outside of either flat or round parts.

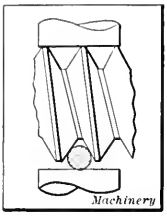
The bar *C* has forty graduations per inch, as usual, with a graduated margin extending beyond the two-inch line to cover a vernier reading in thousandths of an inch. The vernier plate is not made in accordance with the usual method, but is graduated twice the length of the ordinary plate made for a scale with forty graduations per inch. The reason for this is that the vernier plate cut to correspond with each alternate line is easier to read and also provides for getting

dimensions to 0.0005 inch. The adjusting head F is provided with a screw G for regulating the bar C, and H is a binding screw which holds the bar in place after the caliper has been set. A valuable feature of the instrument is that it is of rugged construction and not likely to get out of order. The total outside measurement of the jaws C_1 when together is 0.250 inch, so that in setting for inside measurements the vernier reading is 0.250 inch less than the true dimension. A vernier caliper of this kind could be made in different sizes to meet the requirements of various classes of work.

Springfield, Mass. FRANCIS W. CLOUGH

ONE-WIRE SYSTEM FOR MEASURING THREADS

The pitch diameter of screw threads may be measured with ordinary micrometers and one wire arranged as indicated in the accompanying illustration. If the outside diameter of the screw is large or small, allowance must be made for this in measuring. If it is over-size, one-half of the amount that it is over-size must be added to the dimension for the standard outside diameter in the formulas below. If it is under-size, one-half of the amount that it is under-size must be deducted. One wire is much easier to handle than three wires, and when the thread is of very coarse pitch, the end of the micrometer spindle will not reach from one thread to the next as is necessary with the three-wire system. If M = micrometer reading over wire, when pitch diameter is correct, then the formulas for measuring with micrometers and one wire are:



For V-thread,

$$M = 1.5 \times \text{diam. of wire} - \frac{0.866}{\text{no. threads per in.}} + \text{std. outside diam.}$$

For U. S. standard thread,

Machinery

$$M = 1.5 \times \text{diam. of wire} - \frac{0.7577}{\text{no. threads per in.}} + \text{std. outside diam.}$$

For Whitworth thread,

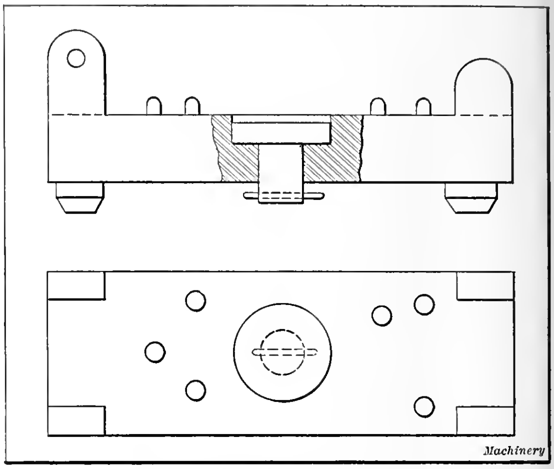
$$M = 1.583 \times \text{diam. of wire} - \frac{0.8004}{\text{no. threads per in.}} + \text{std. outside diam.}$$

The size of the wire used is governed by the pitch and form of thread. The best size to use is that nearest to two-thirds of the pitch. Mistakes can easily be made if too large a wire is used. A wire smaller than 0.6 or larger than 0.9 of the pitch should not be used. The accompanying table gives values of constants which are used in the formulas for measuring pitch diameters of screws by the one-wire system. This method of measuring the threads, of course, presumes that the thread has been cut on centers, so that it is certain to be concentric with the outside diameter of the screw.

Belvidere, Ill. IRVING BANWELL

EJECTING DEVICE FOR USE ON JIGS

The accompanying illustration shows an attachment designed for use on jigs where it is necessary to have the work a tight fit on locating pins. Where this practice is employed and the work has a flat surface in contact with the jig, difficulty is often experienced in removing the piece after the machining operation has been completed. This difficulty is easily overcome by adopting the ejector illustrated herewith. It will be seen to consist of a shoulder pin which is counterbored into the jig and pinned at the opposite side to prevent the shoulder pin from being lost. After the machining operation is completed, the pin is simply tapped up under the work, and in this way the latter is easily knocked off the locating pins.

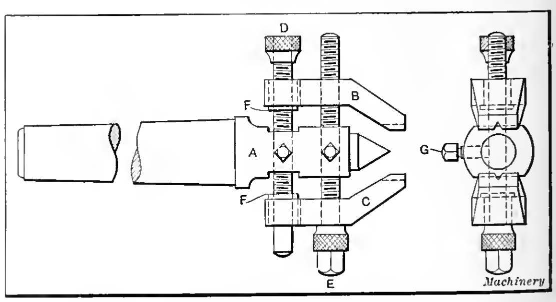


Plug for ejecting Work from Jigs and Fixtures

Montreal, Canada. HERCULES SMART

DRIVER FOR USE IN MILLING MACHINE INDEX HEAD

In the accompanying illustration is shown a driver for use in the milling machine index head for short pieces or for such work as requires to be milled on centers and close to the shank, as for example a short machine tap. Usually, the dog or driver is too much in the way on short work and this tool was made to overcome this trouble. The shank A is of tool steel and machined all over, after which the point is hardened, tempered and ground the same as any center. The jaws B and C are of machine steel, slotted at the ends to



Driver for Short Work where a Regular Dog interferes

receive the shouldered nuts. Jaw *B* is drilled and tapped for the screw *E*, while jaw *C* is drilled and reamed for the same screw. Both jaws are carbonized and hardened. Screw *D* has right- and left-hand threads with the middle portion plain, and the knurled head is a separate piece screwed and pinned on after complete assembly. The screw *E* is of one piece, with a right-hand thread of sufficient length for the extreme adjustments. Nuts *F* are drilled and tapped left and right to an easy fit on the screw *D* and are milled to an easy fit in the slots in the jaws *B* and *C*, having shoulders to take the thrust of the screw *D*. In use, the work is placed on the centers as with regular methods of driving, and the jaws *B* and *C* are brought into contact with the work; the jaws are adjusted the same as a parallel clamp is, and given the final "squeeze" with a wrench on the squared head of screw *E*. Then set-screws *G* are tightened lightly. It will be observed that the jaws are free to "float" until the set-screws have been tightened, which prevents cramping the work.

Hartford, Conn. ERNEST A. RUNGE

BABBITTING MANDRELS

The writer has given considerable time and study to the design of babbitting mandrels, and in the following article three mandrels are described which have been found satisfactory for use in babbitting bearings on a piece-work basis. The operation is satisfactory, very little defective work being produced. Fig. 1 shows assembly and cross-sectional views of a fixture for babbitting bearings of the type shown at *A*. The body of these bearings is made of malleable iron; they are rough-bored, turned and faced, and the bore recessed as shown. A very coarse feed is taken in order to produce a rough surface to which the babbitt will adhere firmly. There were a large number of these bearings to be lined and on this account it was found desirable to use a multiple fixture, the design finally developed being equipped with four mandrels as shown in the illustration. The mandrels are set in a cast-iron base *B*. It will be seen that the mandrel consists of two parts, the body *C* and a dovetailed piece *F* which has a small block *G* mounted in it. This block forms the oil groove in the bearing. The base of the fixture is bored in such a way that the mandrel and bearing are held concentric, and after the work has been set up as shown in the cross-sectional view everything is ready for pouring the babbitt. After the babbitt has been poured and given time to set the lever *D* is struck a sharp blow; this loosens the main part of the mandrel and enables it to be readily removed by inserting a wire in the screw-eye *E*. The dovetailed piece *F* is next removed by giving it a slight tap toward the center of the bearing. The bearing can then be removed from the fixture, and another casting set up in its place ready to be babbitted.

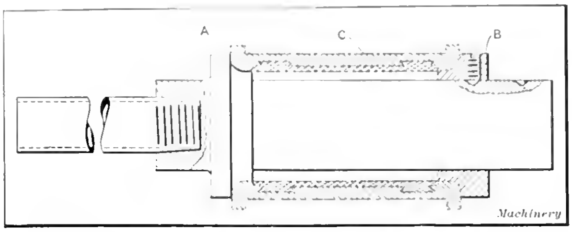


Fig. 3. Adjustable Mandrel for babbitting Plain Half Bearings

Fig. 2 shows a mandrel for babbitting bearings in which the oil grooves are set at an angle to each other as shown at *A*. This mandrel was made similar to the one shown in the preceding illustration and can be used in connection with the same base *B*.

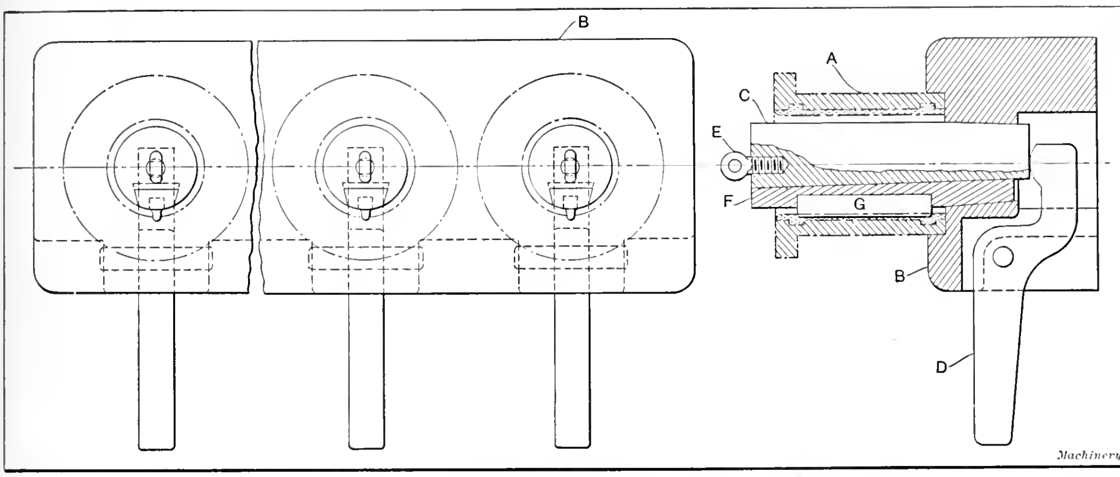

Fig. 1. Fixture equipped with Four Mandrels for babbitting Bearings with Straight Oil Groove

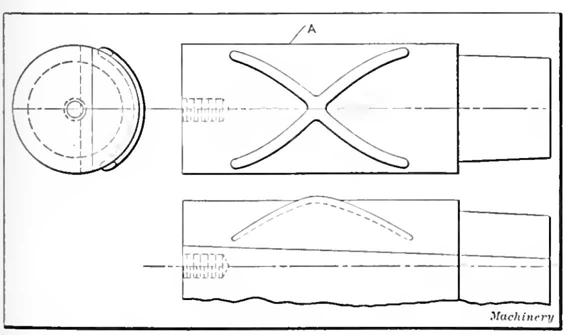

Fig. 2. Mandrel for babbitting Bearings with Crossed Oil Grooves

A mandrel is shown in Fig. 3 that is used for babbitting half bearings of the type shown at *C*, these bearings having no oil grooves. The mandrel consists of a center piece *A* which is provided with a handle made of ½-inch pipe at one end and a sliding collar *B* at the opposite end. The position of this collar can be adjusted for different lengths of bearings of a given diameter. It will be evident that the collar is held in position by a set-screw. The collars are turned to a close fit in the bearing castings so that they will not allow the metal to run out. These particular bearings were made of bronze castings and babbitted in the rough. The bearings were made in several different lengths, and by making the mandrel to suit the longest it may be used with equally good results for the shorter ones.

All three styles of bearings were babbitted on a piece-work basis with entirely satisfactory results. We generally had three or four of these fixtures set up on the bench, and by having a boy assemble the fixtures while the man did the pouring, a very satisfactory rate of production was attained. The best results are obtained by having all parts of the fixture and work at the same temperature. A good method is to lay as many of the bearing castings as possible around the top of the furnace in which the babbitt is melted.

G. E. P.

SPRING LATCH FOR JIG COVER

A hinged jig cover may be conveniently held in place by means of a spring latch of the form shown in Fig. 1, which is semi-automatic in its action. In this illustration, the body of the jig is shown at *A* and the hinged cover at *B*. This cover swings on the pivot *C*, and drops onto the latch *D* which takes the place of the locking screw arrangement shown in Fig. 2. In cases where the cover is merely used to carry bushings, a latch of this kind is entirely satisfactory, although it is not recommended for use on jigs where screws for holding down the work are carried by the cover. The method of using is evident from the illustration. To swing the cover clear of the work in the jig, the latch *D* is pushed back in the direction of the arrow. After the cover has been raised, the latch springs back into place ready to catch over the top of the cover, when it is dropped back onto the jig. When the cover is dropped, the latch catches it automatically, requiring no attention from the operator.

STRADDLE MILL KINK FOR CAST IRON WORK

When facing off the edges of a cast-iron piece with straddle mills, it will be noticed that the last corner at the end of the cut almost invariably breaks off. This condition is more marked if the edge at an angle to the face being milled has already been machined. The rounded corners on rough castings do not break as easily. Various remedies are used to avoid this difficulty, among which may be mentioned filing the corners of the work off on a bevel, supporting the work close up to the cut, or reducing the cut and feed. All of these methods, however, are but partially successful. The best "stunt" that the writer knows of is to take off the sharp corners of the cutter, *i. e.*, grind the corner off to an angle of 45 degrees, making a flat of about 1/16 inch. When this practice is followed the breaking and chipping of the work will be practically eliminated.

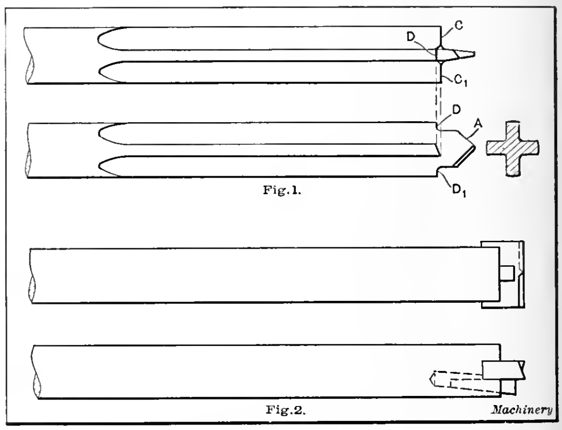
Middletown, N. Y. DONALD A. HAMPSON

[In facing a piece of work with straddle milling cutters, the stock left on the work at the time the cutters are approaching the completion of a cut is in the form of two cantilever beams. We know that the greatest stress in a cantilever is at the point of support, and by grinding off the corners of the cutters, as recommended, the cross-sectional area of this point of support is greater than that of any other cross-section. The additional strength provided in this way is sufficient to prevent the corner from breaking off.—EDITOR.]

DRILL AND BORING-BAR FOR PULLEYS

A drill for drilling holes in solid hubs of pulleys is shown in Fig. 1. The hole for which this particular drill was used is ¾ inch in diameter, which is too small to core and true by boring. We tried twist drills and flat drills, but if the drill encountered a blowhole in the casting, it would run out of true. The tool now being used is made of high-speed steel and it has drilled about one thousand pulleys and is still doing business. As the illustration shows, it is milled to a cross-shaped section which makes it very stiff.

The point of the drill *A* is ground like an ordinary flat drill and it makes a smaller hole than the main drill body. The two ends *D* and D_1 are ground below the cutting edges *C* and C_1 so that the stock left by the point *A* is removed by these two edges. Obviously, the ends *D* do not cut. If the drill is started true and fed in until the two corners *C* have entered, the hole acts as a bushing and the drill cannot run out, even though it enters a blowhole. Of course, the point *A* must be ground centrally and the edges *C* must be ground so that they both cut and do not make the hole larger than the drill body. This drill is 11/16 inch in diameter and is used in a lathe.



Figs. 1 and 2. Drill and Boring-bar for Pulleys

After a hole is drilled in a pulley, a boring-bar like the one shown in Fig. 2, is used for truing the hole. The corners of the cutter are ground square and the cutter, which is of high-speed steel, is held by a half-round key. The hole for this key is drilled on a slight angle before the slot is milled for the cutter. When a new cutter is to be inserted, the old one is driven out, which causes the key to fall out. The hole in the pulley is finished by reaming.

* * *

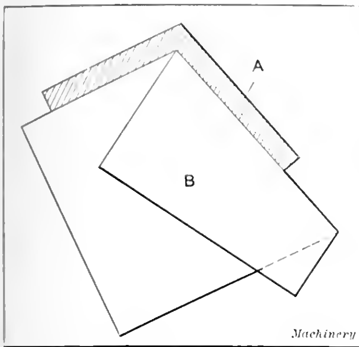
Persons who look upon the increase in gold production as chiefly responsible for the increased cost of living will regret to hear that important new deposits of gold have been found in Siberia (already one of the leading gold-producing regions of the world), and that these will rank among the richest fields in Siberia. According to that school of economists who put the blame on gold, if nature had made it as common as iron, we would all be starving.

SHOP AND DRAFTING-ROOM KINKS

INGENIOUS MEANS AND SHORT CUTS FOR SAVING LABOR AND MATERIALS

AN ANGLE BENDING KINK

It frequently happens that the machinist is required to bend a piece of sheet iron, brass or other stock to a certain angle, but the draftsman has omitted to give this angle on the drawing from which the machinist is working. In such cases, the time-honored method of bending a piece in the vise and then trying it on the drawing is often employed. Owing to greasy hands and to oil on the stock, the drawing soon becomes so dirty that it is unreadable.



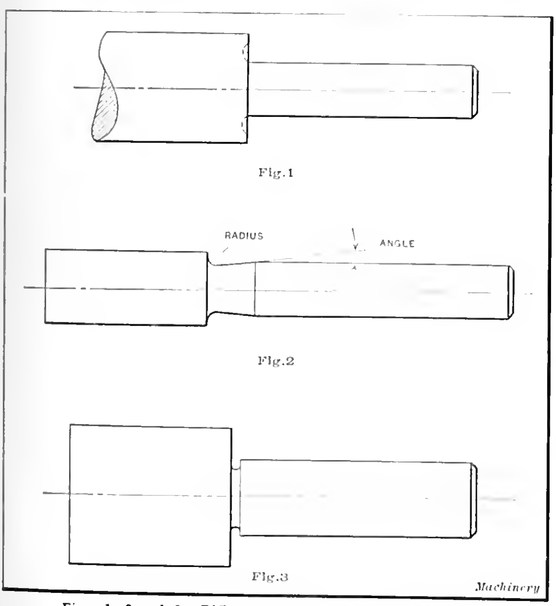
Paper Templet for bending Angles

A much cleaner method, which the writer has employed on a variety of work, consists of laying a piece of paper over the drawing with one edge coinciding with one side of the required angle. The paper is then folded as shown in the accompanying illustration, so that a templet of the required angle is formed. The stock is now bent in the usual way until it fits accurately against the templet. In the illustration, the cross-sectional view *A* represents the angle, as shown on the drawing from which the machinist is working, and *B* represents the paper templet.

East Orange, N. J. GEORGE GARRISON

A NECKING KINK

The accompanying illustrations show different methods of necking an arbor preparatory to grinding it. When there is a large shoulder at the end of the arbor, the most satisfactory method of necking is that shown in Fig. 1. Where the shoulder is relatively small, the method illustrated in Fig. 2 will give very satisfactory results. The method shown in Fig. 3 is in quite general use, but this is decidedly poor practice. It weakens the shaft or arbor very materially owing to the fact that the neck is cut in such a way that it reduces the cross-section at the point where the greatest strain is likely to be experienced.



Figs. 1, 2 and 3. Different Methods of necking an Arbor preparatory to grinding

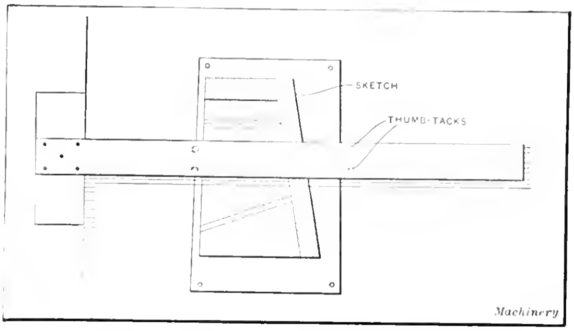
PROTECTING DRAWINGS

A method by which drawings may be protected against the smudging action of the T-square consists of sticking four thumb-tacks in the under side of the blade so that it will not come into contact with the portion of the drawing that it is desired to protect. This method will be found particularly useful where a pencil drawing is made, as it will prevent the pencil lines being rubbed by the T-square. It will also guard the drawing against being soiled by a dusty square, and the same arrangement will be found effective in preventing the ink from running under the edge of the square.

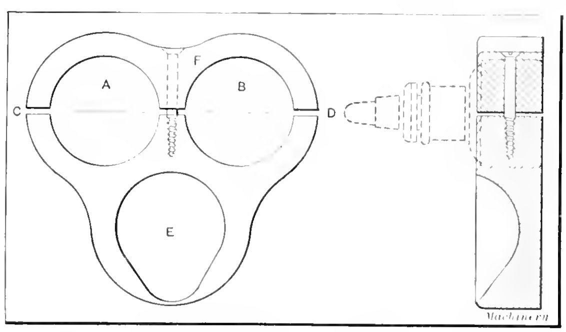


Method of raising T-square from Surface of Drawings

Washington, D. C. A. P. CONNOR

HOLDER FOR THUMB-TACKS AND INK BOTTLES

The illustration presented herewith shows a holder for a draftsman's ink bottles and thumb-tacks which can be easily made if the instructions are carefully followed. The outline, the holes *A* and *B* for the ink bottles and hole *E* for the thumb-tacks are laid out on a piece of one-inch board with the grain of the wood running parallel to the line *CD*. The holes are then cut out with a fine band-saw, the saw being first run along the line *CD*, after which the semi-circles are cut out. The hole *E* for the thumb-tacks is next made with a spoon gouge. The hole is then drilled for the screw *F* which holds the back in place, after which the parts are sandpapered and shellacked. When the shellac has dried the bottles are put in position and the back screwed up tight against them.



Tray for holding a Draftsman's Thumb-tacks and Ink Bottles

The Massachusetts Institute of Technology has erected an aero-dynamic laboratory and has also instituted courses in the study of this science. It is the first technical institution in the country fitted to instruct students thoroughly in the subject of aeronautics.

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

LIMITS IN SPECIFYING BAND, BAR AND PLATE IRON AND WIRE

A. S. H.—We have a large drafting-room, and the following questions often come up during the day. There seems to be a difference of opinion on the practice of specifying the materials mentioned and we would appreciate an opinion from the readers of MACHINERY as to limitations of these products. 1. What are the limits within which to specify band or bar iron? 2. Is there a correct thickness for specifying bar iron where the thickness of band iron stops and bar iron starts? 3. Where does the diameter of wire stop and rods begin? 4. In specifying plate how wide does iron have to be before it becomes a plate?

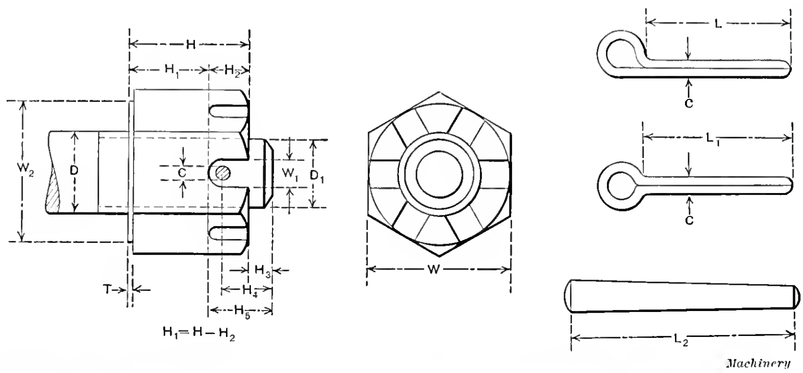
The questions are submitted for opinions of the readers.

DIMENSIONS OF CASTLE NUTS ADOPTED BY A. R. M. M. ASSOCIATION

A. L. D.—What are the dimensions of castellated nuts and thin castellated nuts adopted by the American Railway Master Mechanics' Association?

A.—Dimensions of castellated nuts and thin castellated nuts recommended by the American Railway Master Mechanics' Association at the Atlantic City meeting June, 1912, are given in the accompanying tables compiled by the Brightman Mfg. Co., Columbus, Ohio. Table II on the following page gives the dimensions of castle nuts and thin castle nuts as derived by the formulas, being closely in agreement, of course, with the data in Table I.

TABLE I. DIMENSIONS OF CASTLE NUTS AND THIN CASTLE NUTS*



Recommended Dimensions, Inches

Nut	D	Diameter of screw	1/2	5/8	3/4	7/8	1	1 1/8	1 1/4	1 3/8	1 1/2	1 5/8	1 3/4	1 7/8	2	2 1/4	2 1/2	2 3/4	3	3 1/4	3 1/2

Machinery

THE SOCIOLOGICAL SIDE OF INDUSTRY

Evidence accumulates that America is awakening to a better sense of social justice and the need of economic reform. Great trusts and private monopolies of public utilities are being dissolved or regulated by public commissions, and while competition in business may be wasteful, the need of equal opportunities for all requires the strengthening of laws aimed at methods which interfere with freedom in trade and manufacture.

For many years the unfair and inadequate "fellow servant" rule in law made society practically helpless in many states to protect labor from the risks of life and limb incident to railroading, mining, building and manufacturing. The labor compensation law passed by the New York State Legislature last year is but one of several enacted by the states to place the burdens on the industry affected, making it responsible for the maintenance of its injured and the families of its killed. The ultimate effect should be to reduce preventable accidents to a minimum. Machinery will be safeguarded and dangerous manufacturing conditions eliminated. Much progress has already been made, and men are being taught to be careful of themselves and of their fellow workmen.

Another source of encouragement to the social worker is the more liberal spirit of employers toward labor. The example of the Ford Motor Co., unwise perhaps in some respects, must have a tremendous influence on the betterment of relations of capital and labor. Libraries, free and otherwise, are useful to inform the mind and stimulate ambition; but better food and clothes and houses as a result of faithful daily toil are of still greater value to the mass of workers.

Welfare work pays when rightly directed. Decent living conditions are necessary for the healthful condition of mind and body essential to good working efficiency. In places where very little in the way of healthy recreations and amusements is available to the people, it is decidedly to the interest of local manufacturing concerns to provide them in such manner as to conserve the independence and self-respect of those benefited. The whole modern movement tends to elevate the ideals of society and to place labor on a higher plane by recognizing human rights and abolishing injustices rooted in antiquated legal practices. That the conditions which have developed in America during the past thirty years are out of place in, and probably dangerous to, a democratic form of government, the thoughtful and unprejudiced observer will admit. A brighter day has dawned for industry. The new social spirit and the new freedom will give heart to American inventors and workers generally, and will encourage the enterprising spirits on every level to make for themselves a place in the industrial and commercial world.

* * *

In experiments undertaken by the Technical Institute of Berlin, Germany, it has been ascertained that the most suitable angle of clearance back of the cutting edge on twist drills, for drilling steel and cast iron, is 6 degrees at the circumference of the drill, this angle increasing, in general, to from 20 to 24 degrees toward the center of the drill. Such an angle can generally be obtained by commercial twist drill grinding machines.

ANNUAL CONVENTIONS M. C. B. AND A. R. M. M. ASSOCIATIONS

The forty-eighth annual convention of the Master Car Builders' Association and the forty-seventh annual convention of the American Railway Master Mechanics' Association were held in Atlantic City, June 10-12 and June 15-17, respectively. Simultaneously, the Railway Supply Manufacturers' Association exhibited machinery and tools covering an area on Young's New Pier of nearly two acres or 82,000 square feet. The exhibits comprised railway supplies in general, including locomotive, car, track and shop materials, tools, machines, etc. The machine tool exhibit was an important part of the show and it attracted much attention. Each year this showing of machines, tools, cutters, etc., for locomotive repair shops becomes of greater and greater diversity and importance. Railway shops in general are large potential markets for machine tools and allied products, and the growth in size and power of locomotives requires the best and most efficient machine tools.

The Master Car Builders' Association convention program was made up, as usual, of technical papers, topical discussions and reports of committees, being in part as follows:

June 10. Revision of Standards and Recommended Practice; Train Brake and Signal Equipment; Brake Shoe and Brake Beam Equipment; Car Wheels.

June 11. Coupler and Draft Equipment; Safety Appliances; Rules for Loading Materials; Interline Inspection; Car Trucks; Train Lighting and Equipment; Tank Cars.

June 12. Damage to Freight by Unloading Machines; Specifications and Tests for Materials; Car Construction; Retirement of 40,000 and 50,000 Pound Capacity Cars from Interchange Service.

The following officers were elected for the Master Car Builders' Association: F. F. Gaines, president; E. W. Pratt, first vice-president; William Schlafge, second vice-president; F. H. Clark, third vice-president; Angus Sinclair, treasurer; C. F. Giles, M. K. Barnum and John Purcell, executive committee.

The program of the American Railway Master Mechanics' Association included the following technical papers and discussions:

June 15. Mechanical Stokers; Revision of Standards; Safety Appliances; Dimensions for Flange and Screw Couplings for Injectors, by O. M. Foster; Motors for Railway Shops, by B. F. Kuhn.

June 16. Locomotive Headlights; Design, Construction and Maintenance of Locomotive Boilers; Standardization of Tinware; Superheater Locomotives; Use of Special Alloys and Heat-treated Steel in Locomotive Construction; Review of the Work done by Other Mechanical Organizations, by Dr. Angus Sinclair.

June 17. Smoke Prevention; Revision of Standard Efficiency Tests of Locomotives; Revision of Air Brake and Train Signal Instructions; Train Resistance and Tonnage Rating; Fuel Economy; Tests of Schmidt Superheater and Brick Arch, by H. W. Coddington.

The following officers were elected for the American Railway Master Mechanics' Association: D. F. Crawford, president; D. R. MacBain, first vice-president; R. W. Burnett, second vice-president; C. E. Chambers, third vice-president; John S. Lentz, treasurer; R. E. Smith, J. C. Fritts and H. T. Bentley, executive committee.

The exhibitors comprised two hundred and sixty-nine concerns, among whom were the following showing machine tools, taps, cutters, steel and other machine shop supplies:

Acme Machine Tool Co., Cincinnati, Ohio. Cincinnati-Acme 3¼-inch by 36-inch flat turret lathe; 18-inch geared head universal turret lathe.

Alston Saw & Steel Co., Folcroft, Pa. Alston hacksaw blades.

American Tool Works Co., Cincinnati, Ohio. "American" 36-inch heavy pattern, high duty lathe; 16-inch tool-room lathe; 6-foot radial drilling machine; 2-foot radial drilling machine; 24-inch crank shaper.

Armstrong-Blum Mfg. Co., Chicago, Ill. "Marvel" high-speed hacksaw machines.

Baker Bros., Toledo, Ohio. Baker high-speed, heavy duty drilling machine.

Baush Machine Tool Co., Springfield, Mass. New design 5-foot radial drilling machine; Lassiter staybolt turning and threading machine; automatic staybolt drilling machine.

C. H. Besly & Co., Chicago, Ill. Besly patternmaker's disk grinder; motor-driven disk grinder; forged taps; pressed steel ring wheel chucks; spiral circles; etc.

Hermann Boker & Co., New York City. "Novo" and "Novo Superior" high-speed steels, etc.

W. L. Brubaker & Bros., Millersburg, Pa. Screw plates, taps, dies, reamers, etc.

C. & C. Electric & Mfg. Co., Garwood, N. J. Electric arc welding outfit in operation.

Carborundum Co., Niagara Falls, N. Y. Carborundum and aloxite wheels and abrasives.

Cayuta Mfg. Co., Sayre, Pa. Ball bearing screw jacks, etc.

Celfor Tool Co., Buchanan, Mich. "Celfor" drills, reamers, countersinks, cutters, etc.

Cincinnati Bickford Tool Co., Cincinnati, Ohio. "Cincinnati-Bickford" 24-inch upright drill with tapping attachment; 5-foot plain radial drilling machine.

Cincinnati Milling Machine Co., Cincinnati, Ohio. "Cincinnati" high power milling machine equipped with stream lubrication; high power vertical milling machine; cutter and tool grinder.

Cincinnati Planer Co., Cincinnati, Ohio. "Cincinnati" 36-inch by 36-inch by 8-foot heavy pattern planer with four heads and reversible motor drive.

Davis Boring Tool Co., St. Louis, Mo. Boring bars for car wheels and boring tools and reamers.

Duff Mfg. Co., Pittsburg, Pa. Hydraulic jacks, etc.

Eagle Glass & Mfg. Co., Wellsburg, W. Va. Steel oil cans, oilers, oil carriers, etc.

Earle Gear & Machine Co., Philadelphia, Pa. "Lea-Simplex" cold saws.

Electric Controller & Mfg. Co., Cleveland, Ohio. Lifting magnets and automatic machine tool controllers and starters.

Goldschmidt Thermit Co., New York City. Thermit and samples of thermit welding.

Edwin Harrington Son & Co., Inc., Philadelphia, Pa. Multiple-spindle drilling machine, hoists and travelers.

Hollands Mfg. Co., Erie, Pa. Machinists' vises.

Independent Pneumatic Tool Co., Chicago, Ill. "Thor" pneumatic tools.

Ingersoll-Rand Co., New York City. "Little David" pneumatic tools.

International Oxygen Co., New York City. Oxy-hydrogen welding and cutting equipment.

Jones & Lamson Machine Co., Springfield, Vt. Flat turret lathes.

Landis Machine Co., Waynesboro, Pa. Motor-driven bolt cutters, die heads, etc.

Landis Tool Co., Waynesboro, Pa. Self-contained plain grinding machine.

R. K. LeBlond Machine Tool Co., Cincinnati, Ohio. Motor-driven 25-inch heavy-duty engine lathe; heavy-duty plain milling machine; 21-inch quick change engine lathe, three-step cone and double friction back gears; universal cutter and tool-room grinder; 16-inch portable fitting lathe for locomotive roundhouses.

Lodge & Shipley Machine Tool Co., Cincinnati, Ohio. 16-inch selective head universal tool-room lathe; 18-inch selective head universal manufacturing engine lathe; 30-inch heavy forge lathe; 48-inch selective head engine lathe.

Lutz-Webster Engineering Co., Inc., Philadelphia, Pa. Lutz universal compression ratchet, compression lathe dog, drilling press or "old man" with fixed and swivel arms.

Newton Machine Tool Works, Inc., Philadelphia, Pa. Locomotive link grinding machine; cold metal sawing machine.

Niles-Bement-Pond Co., New York City. Niles combined journal turning and axle turning lathe; P. & W. 10-inch vertical shaper.

R. D. Nuttall Co., Pittsburg, Pa. Cut gears and pinions and demonstration of heat-treatment of steel.

Henry Pels & Co., New York City. Punching and shearing machines for I-beams, channels, angles, etc.

Reed Mfg. Co., Erie, Pa. Machinists' vises, etc.

Reliance Electric & Engineering Co., Cleveland, Ohio. Adjustable speed and constant speed direct current motors and alternating current constant speed motors.

Joseph T. Ryerson & Son, Chicago, Ill. "Ni-chrome" steel and high-speed twist drills.

William Sellers & Co., Inc., Philadelphia, Pa. Car wheel boring machine with automatic chuck; lineshaft hangers and bearings.

Warner & Swasey Co., Cleveland, Ohio. Universal hollow hexagon turret lathes.

Watson-Stillman Co., Aldene, N. J. Hydraulic jacks, etc.

Wiener Machinery Co., New York City. "Oeking" combination punch, shear and bar angle cutter; universal radial drilling machines.

Wiley & Russell Mfg. Co., Greenfield, Mass. Taps, dies and screw cutting tools and machinery.

T. A. Wilson & Co., Reading, Pa. Safety glass spectacles for machine shop and foundry works, etc.

Wilmarth & Morman Co., Grand Rapids, Mich. "New Yankee" drill grinders.

Yale & Towne Mfg. Co., New York City. Hoists, chain blocks, trolleys, etc.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

SCHUCHARDT & SCHUTTE ENGRAVING MACHINE

Schuchardt & Schütte, Cedar and West Sts., New York City, are now building a machine for engraving trademarks, name-plates, letters, numbers, etc., on steel stamps, dies and other products. The machine operates on the pantograph principle; a pattern of the required design is slipped into a slot in the pattern table and strapped in place. At one end of the pantograph there is a guiding point which is brought into contact with the pattern and run over it; and the engraving tool is carried by a spindle at the opposite end of the pantograph. The movement of the guiding point over the pattern, causes the engraving tool to follow exactly the same course. Three of the arms on the pantograph are provided with scales by means of which the relation between the lengths of the arms can be adjusted to obtain any desired size for an engraved design, the limit of the machine being from a ratio of 1 to 1 between the size of the work and the pattern down to a ratio of 1 to 10 between the work and the pattern. Where only a few pieces are to be engraved, the design drawn on Bristol board can be used for a pattern.

In addition to having the engraving tool guided over the work by means of the pantograph, it is necessary to have the tool rotated. A brief consideration will suffice to show that the movement of the tool by means of the pantograph makes it necessary to provide a flexible system for supporting the driving pulleys. The way in which this is arranged by three sets of pivoted arms is very clearly shown in Fig. 2. One of the difficulties which has been experienced with en-

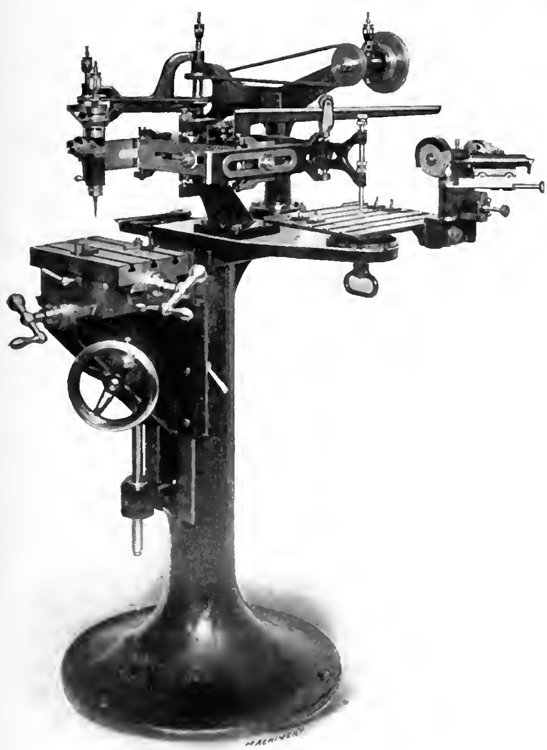

Fig. 1. Schuchardt & Schutte Engraving Machine

graving machines working on the pantograph principle, is that the bearings supporting the tool spindle become worn through the belt pull, thus causing a serious inaccuracy in the work produced by the machine. In the new Schuchardt & Schütte engraving machine, this difficulty has been overcome by employing the extended sleeve construction which has been successfully applied in various classes of machine design, for eliminating unnecessary strain on the bearings. This sleeve extends up from the main spindle housing, between the spindle and the driving pulley so that the belt pull is supported by the sleeve rather than the spindle bearing, and, in this way, unnecessary wear of the bearing is avoided.

In Fig. 1 a small grinding attachment is shown bolted to the pattern table. This attachment is used for grinding the

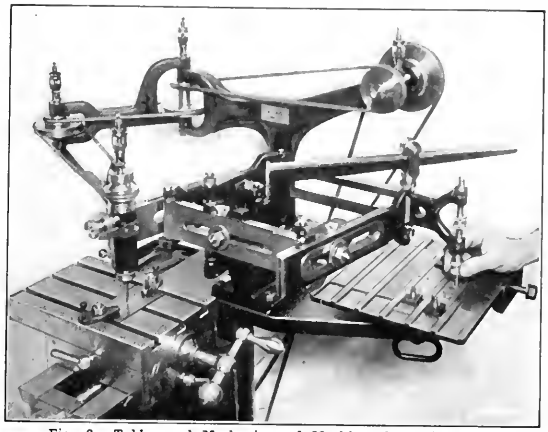

Fig. 2. Tables and Mechanism of Machine shown in Fig. 1

engraving tool. It will be seen that there is a two-step cone pulley at the right-hand side of the machine, which is not shown with a belt running over it. One of the steps on this pulley is connected to the source of power which drives the machine, and the other is used for carrying the belt which transmits power to the grinding attachment. One of the engraving tools is shown set up in the horizontal chuck, with its point in contact with the grinding wheel. In setting up this tool ready for grinding, the first step is to have it accurately centered. This is done by bringing the point of the tool into contact with an index point on the end of a pin, which is set up in the bed of the grinding attachment. The engraving tool is cylindrical in shape, and for about 1½ inch at its lower end a flat is ground which removes about one-half of the metal. The tool is not ground, however, by merely rotating it about its axis, with the tool in contact with the wheel. Experience has shown that the best results are obtained by having the ground surface of the tool of an elliptical section instead of circular, and this special form is obtained by controlling the motion of the tool when in contact with the grinding wheel, by means of a cam located at the far end of the tool-holder. The grinding attachment is bolted to a lug on the under side of the pattern table and may be quickly removed by simply loosening one bolt.

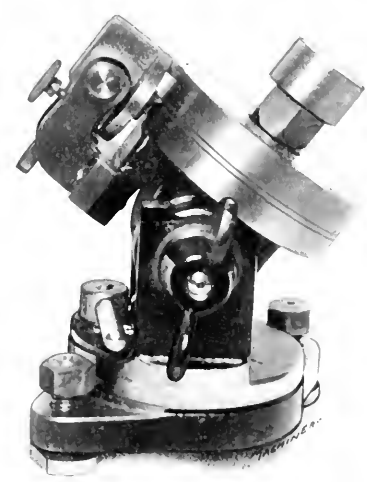

Fig. 3. Dividing Head for Use on Schuchardt & Schutte Engraving Machine

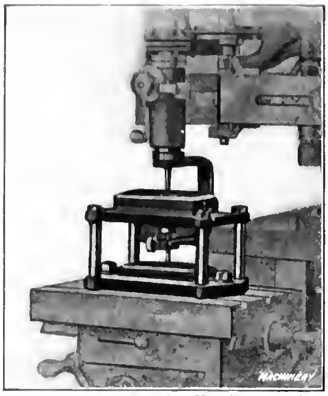

Fig. 4. Attachment for Use in engraving on Convex or Concave Surfaces

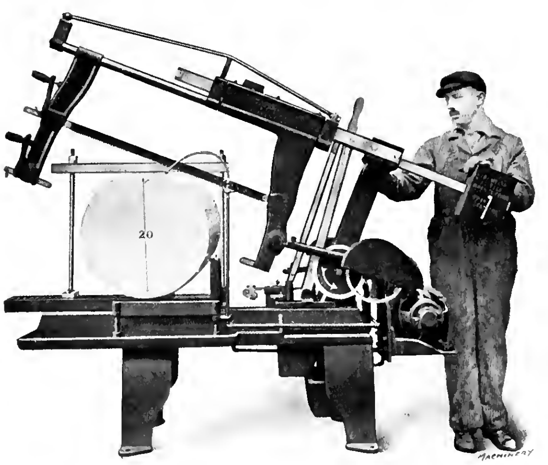
Fig. 3 shows an attachment for use on this machine, which provides for engraving on cylindrical or conical surfaces, or on flat dials on which it is required to engrave at equal intervals. This attachment consists essentially of an arbor on which the work can be mounted, and the provision of means for rotating this arbor through any required angle between successive engraving operations. For engraving on cylindrical or conical surfaces, it is obviously necessary to have the element of the surface on which the engraving is to be done held in a horizontal position. This is done by loosening the wing nut and then swinging the arbor down to the required angle. In most cases, where engraving is to be done on such surfaces, the pattern itself is flat and strapped to the pattern table in the usual way.

Another useful attachment for use on this machine is illustrated in Fig. 4. This attachment is for use in engraving on concave or convex surfaces. For work of this nature, it is necessary to have the engraving tool work to a constant depth, but the tool must also follow the contour of the work. This is done by having a master blank of the required form located on the lower support of the attachment. A guide point runs over this master blank and controls the movement of the engraving tool, which is in contact with the work carried on the upper support of the attachment.

The design of the machine has been carefully worked out to give it the necessary rigidity for withstanding hard service. When desired, three different styles of pattern letters and pattern numbers can be supplied with the machine. Many manufacturers, however, prefer to use some other style of patterns, and these can be made direct on the machine. Of course, the same statement applies to the production of patterns for trademarks, name-plates and similar designs. The operation of this engraving machine is so simple that it has been found that a boy or girl of average intelligence can be taught to use it and to do very satisfactory work.

ROBERTSON 20-INCH HACKSAW

In the May, 1914, number of MACHINERY, the No. 7 power hacksaw built by the W. Robertson Machine & Foundry Co., 32 Greenwood Place, Buffalo, N. Y., was illustrated and described. Those who read this description will remember that the capacity of the No. 7 machine is for work up to 10 inches in diameter. Since that time, a machine of quite similar design has been brought out by this company, the change consisting of the application of a special saw frame which increases the capacity up to work 20 inches in diameter.



Robertson Hacksaw for cutting Stock up to 20 Inches in Diameter

In order to cut work of the maximum size which comes within the range of this machine, without raising the frame to an extreme angle, the first ten inches of the cut is made by inserting a blade in the middle of the frame, as shown in the illustration. When the first half of the cut has been completed in this way, the blade is mounted at the bottom of the frame, after which the cut is completed.

BESLY DOUBLE-SPINDLE, MOTOR-DRIVEN GRINDER

A recent product of Charles H. Besly & Co., 120-B N. Clinton St., Chicago, Ill., is the double-spindle, motor-driven ring-wheel grinder, front and rear views of which are shown in the accompanying illustrations. This machine is equipped with 21-inch vitrified wheels and is driven by direct-connected motors. The double-spindle design brings the two grinding wheels into contact with the work so that two parallel surfaces can be ground simultaneously.

The motors are bolted onto sub-plates which are mounted on ways planed on the main bed casting and clamped in position, the arrangement being similar to that of the head- and tailstocks of a lathe. The left-hand head of the grinding machine is stationary while the right-hand head can be moved along the bed by means of a rack and pinion, and clamped to grind the work to any desired length or width within the capacity of the machine. The motors are rated

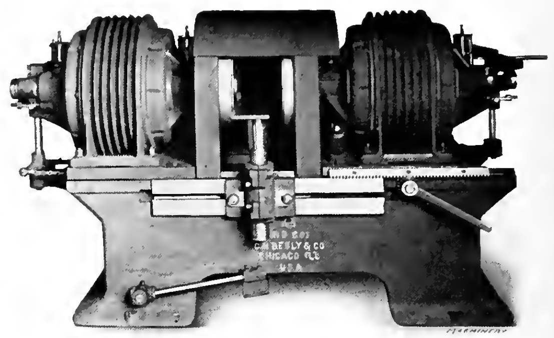


Fig. 1. Front View of Besly Double-spindle Motor-driven Ring-wheel Grinder

at 10 horsepower, run at 900 revolutions per minute, and are intended for operation on 60-cycle alternating-current circuits. When motors are provided for operation on 25-cycle circuits, the machine is equipped with ring wheels 24 inches in diameter, in order to get the required peripheral speed when running at 750 revolutions per minute. Each motor is controlled by a starting compensator with low voltage and overload release; these starting compensators are mounted on the back of the grinder. Grinding machines of this type are not built to operate on direct-current circuits.

The ring wheels are held in "Helmet" pressed steel, ring wheel chucks which are so constructed that the ring wheels may be adjusted to compensate for wear. The design has been worked out in such a way that this adjustment may be made without removing the chuck from the spindle of the grinder. To bring the grinding wheels into contact with the work, the rotor shaft or spindle of each motor has a longitudinal feed of 1 inch. This feed is actuated by a hand lever or foot treadle, the motion being transmitted through a pinion and rack on each of the outer bearing bushings. The spindles are geared together by a connecting-rod at the back of the machine, so that their motion toward and away from the work is simultaneous and uniform. Either spindle may be thrown out of gear and locked so that the opposite wheel may be moved toward the work by means of the hand lever or foot treadle. This causes the rotor of the motor to be displaced ½ inch from magnetic balance during

the grinding operation. Careful tests have shown that this displacement only reduces the motor efficiency from 1 to 2 per cent, while the maximum output remains approximately the same as when the motor is running in magnetic balance. The longitudinal movement of each sliding spindle is limited by an adjustable micrometer stop which is graduated to read to 0.001 inch, so that the work may be accurately ground to size and duplicate pieces produced at high efficiency.

The work-rest has a vertical adjustment and is supported from a slotted pad on the front of the bed casting. The regular equipment includes nine work-rests of varying widths from 7/16 to 5 15/16 inches. An automatically telescoping dust hood is provided, which is hinged at the back in order to provide access to the ring wheels for changing them when necessary. This hood has an air-tight connection at the back of the machine to provide for exhausting the grindings. It will be noticed that the motor rotors are mounted directly on the grinding spindles which are of hard machine steel and supported in inserted bearing bushings lined with bearing metal. The motors are equipped with special end castings to receive the inserted bearing bushings, and the end thrust on the spindles is taken by hardened and ground tool steel thrust collars. The end play of each spindle is controlled by an adjustable collar which is held in place by a lock-nut at the end of the spindle. Both bearing bushings slide with the spindle and completely encase it so that it is thoroughly reinforced when under load and adequately protected from damage by emery dust.

The geared hand lever on the sliding spindle affords a leverage of 36 to 1, so that the operator may force the machine to the limit of its driving power without undue effort. The lever is clamped to the pinion stud, which is a desirable feature of the grinder because the lever may be clamped to

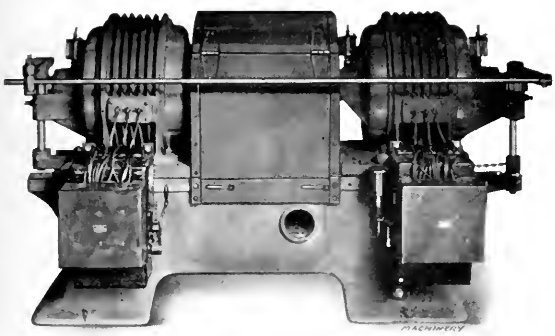

Fig. 2. Opposite Side of Machine shown in Fig. 1

this stud in the position which makes it most convenient for the workman. The principal dimensions of the machine are as follows: Diameter of spindles at inner bearings, 3 inches; diameter of spindles at outer bearings, $2\frac{1}{2}$ inches; height of the machine to the center line of the spindles, 38 inches; combined length of four bearing bushings, 42 inches; maximum opening between ring wheels, 11 inches; floor space occupied by the bed casting, 28 by 72 inches; shipping weight of the machine, 6000 pounds.

DRILL SPEED REGULATOR

The Drill Speed Regulator Co., 516 Free Press Bldg., Detroit, Mich., is placing a device upon the market which provides for driving different sizes of drills at approximately the correct speed. In addition to the obvious advantage of securing the most suitable speed, the device is provided with a quick-change chuck so that different sizes of drills which are required may be inserted and removed with a very small loss of time. A different collet is provided for each different size of drill which is used, and this makes it impossible for the most inexperienced operator to use the wrong speed for a given size of drill. It is merely necessary for the operator to insert the drill in the chuck and it will be driven at the right speed.

The speed changes are accomplished by having the drivers

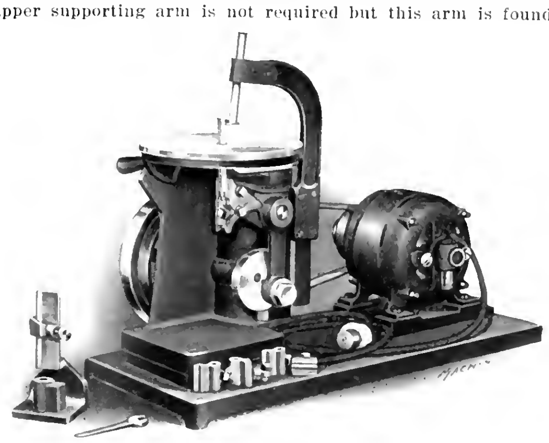
Device for obtaining Proper Speed for Different Sized Drills

on each different collet located in a different position so that each one engages the proper gears in the head. This device also increases the power of the drill press, as large drills are driven through back-gears; and it can be used for tapping when applied to drill presses equipped with a reverse mechanism. The illustration shows the complete speed regulator and also two collets; one of these collets has a 5/16-inch taper shank drill in it and the shank of the collet is No. 1 Morse taper. The other collet carries a ¾-inch taper shank drill and its shank is No. 2 Morse taper. Two pieces are also shown in this illustration which are typical of the classes of work for which this speed regulator is particularly useful. These speed regulators are made to fit any drill press of standard design.

COCHRANE-BLY PORTABLE FILING MACHINE

In shops where large numbers of dies, gages, templets and similar parts are made, there is a lot of light filing to be done at different benches. For handling work of this kind the Cochrane-Bly Co., Rochester, N. Y., has been making a belt-driven bench filing machine. In order to adapt this machine for portable service, an aluminum motor base to support a ⅛-horsepower standard type, General Electric motor has been added. A motor for use on either alternating or direct current of 110 or 220 volts can be supplied and the entire equipment weighs only 75 pounds, so that it can be easily moved about from bench to bench. The motor is provided with a chord and plug for connection with an ordinary lamp socket.

One of these motor-driven equipments is shown in the accompanying illustration where it will be seen that the motor and filing machine are equipped with two-step cone pulleys. The slower speed is for use in filing and the higher speed is employed for lapping operations. As a general rule, the upper supporting arm is not required but this arm is found



Cochrane-Bly Motor-driven Filing Machine for Portable Service

particularly valuable in cases where lapping stones are used, and also for classes of work where rather coarse files are required. The file holder is for round file shanks, and a fixture is provided for babbitting ordinary file shanks to fit this file holder. The principal dimensions of the machine are as follows: Height from bench to top of table, 11 inches; diameter of table, 8 inches; face width of pulleys, 1¼ inch; speed of pulleys for filing, 500 R. P. M.; speed of pulleys for lapping, 600 R. P. M.; stroke, ¾ or 1½ inch.

SELLEW ADJUSTABLE DRILL HEAD

The accompanying illustrations show an adjustable spindle drill head which is a recent product of the Sellew Machine Tool Co., Pawtucket, R. I. Fig. 1 shows the head with the gear guards in place ready for use; and in Fig. 2, the guards are removed in order to show the gearing and construction of the head. Referring to this illustration, it will be seen that there is a ring or plate located at the top of the head, and an interchangeable sleeve for connecting the head to the quill of the drilling machine is bolted to this ring. Different sleeves may be bolted to the ring to provide for mounting the head on different drill presses. There is a circular T-slot on the under side of the ring which receives the T-bolts for clamping the intermediate gear sleeves which support the spindle heads after the spindles have been adjusted to the required positions.

The construction of the spindle heads—alternating short and long, as shown in the illustration—provides for making close adjustments with ease and rapidity. Each alternate spindle can also be brought directly under the clamping bolt of the spindle head nearest to it, either inside or outside of the intermediate circle. The gears supported by the intermediate spindle sleeves are driven by a central gear which has a taper shank entering the drilling machine spindle. All of the gearing and spindles are of heat-treated nickel steel, and the spindles have bronze-bushed bearings. Ball-thrust bearings, mounted outside of and below the spindle bearings, carry the end-thrust. Ample provision is made for lubricating each spindle bearing by means of individual grease chambers. The head shown in the illustrations is fitted with adjustable chucks, but sleeves for taper shank drills can be provided, if so desired. These heads are made in three sizes which range from a head having five spindles which can be distributed over a 1½-inch circle to twelve spindles which may be distributed over a 15-inch circle.

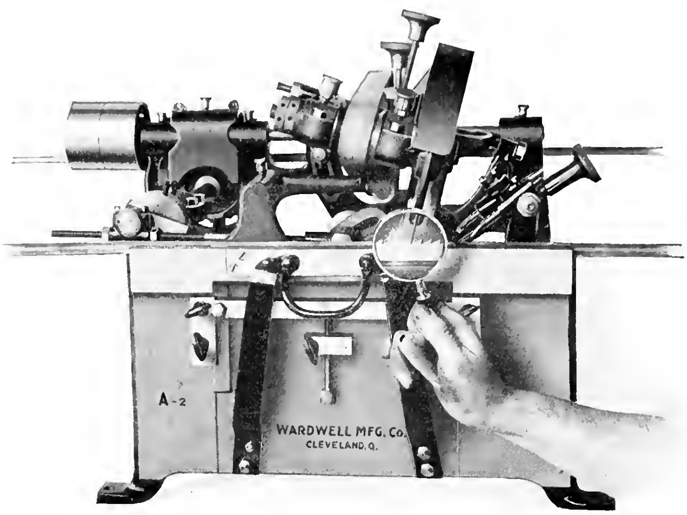
Fig. 2. Sellew Drill Head with Gear Guards removed

WARDWELL BAND-SAW SHARPENING MACHINE

The development of band-saw machines for cutting metal has been followed by a serious loss in certain plants, where it has been the practice to throw away the saws used for this purpose, after they have become dull. As such saws cost from $0.90 to $1.25 each, it will be readily understood that a serious "leak" results from this practice. In order to provide for resharpening metal cutting band-saws, the Wardwell Mfg. Co., Cleveland, Ohio, has recently designed and placed upon the market a grinding machine which is described in the following. By using this machine it is possible to resharpen saws at a cost of from 3 to 5 cents each.



Wardwell Grinding Machine for resharpening Metal-cutting Band-saws

The operation of the machine is extremely simple. From the main driving shaft, which extends across the back of the machine, a belt transmits power to the shaft which drives the grinding wheel. This shaft is supported on a pivoted arm which swings over a segment, and the adjustment provided in this way enables the grinding wheel to follow the face of a tooth no matter what its angle may be. After the grinding wheel has reached the bottom of the tooth, a cam causes it to move up the back of the tooth, this cycle being repeated over and over for each tooth on the saw. Power is taken from the main shaft through a worm and worm-wheel, to a shaft at the left-hand side of the machine, on the end of which there is an eccentric which governs the feed of the band-saw.

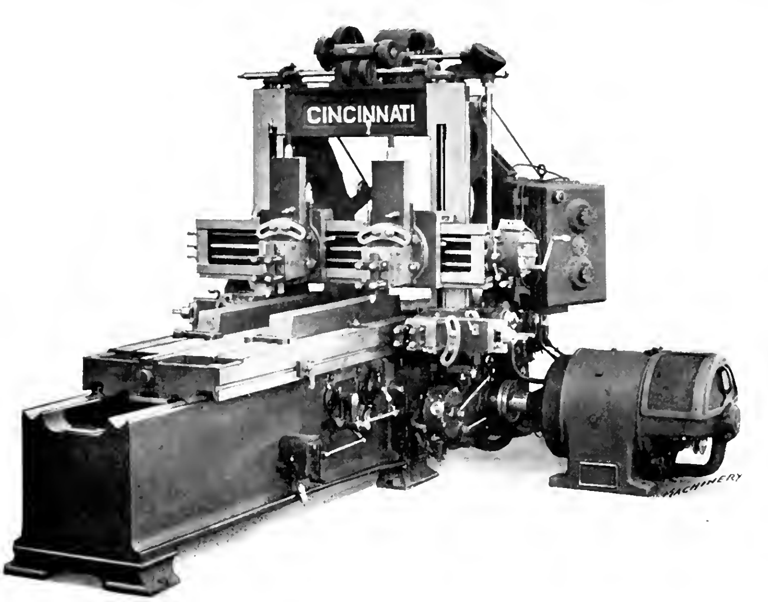
A secondary adjustment provides for making a more delicate regulation of the feed. An adjustment at the right-hand side of the machine permits the saw to be fed in such a way that the grinding wheel cuts exactly the required amount of metal from the face of each tooth. The proper combination of these adjustments enables the grinding wheel to be perfectly timed so that when the wheel has traveled all the way down the face of the tooth, the cam comes into action and raises the wheel as it travels up over the back of the tooth.

The operation of the machine is so

precise that saws having teeth as fine as twenty to the inch can be accurately resharpened. It will be understood from the preceding description that the machine is automatic in action, and after it has once been started it requires no further attention until the saw is completely sharpened. The saw is positively fed through the machine at the rate of from fifty to sixty teeth per minute. There is an adjustment on the front of the machine for raising the saw in the vise, thereby permitting a slightly heavier cut to be taken without changing the other adjustments. All of the adjustments are provided with lock-nuts, so that when they are once set and the nuts tightened, they cannot work loose. Band-saws resharpened on this machine are said to cut with practically the same efficiency as when they were new.

CINCINNATI HEAVY PATTERN PLANER

The Cincinnati Planer Co., Cincinnati, Ohio, is now building a 36 by 36 inch by 8 foot heavy pattern planer which is equipped with four heads and reversible motor drive. There are ten cutting speeds which cover a range of from 25 to 60 feet per minute and ten return speeds, the maximum return being 100 feet per minute. To adapt the machine for heavy classes of work, all the gears and also the rack under the table are of steel. A noteworthy feature of the design is the rapid power traverse to the heads, which relieves the operator and is the means of making a material increase in production. The mechanism is extremely simple, absolutely "fool proof" and ready for use at any time. The motor shown at the top of the arch delivers power through spur gears to the rail elevating device and thence to the horizontal rapid traverse shaft. This shaft carries a bevel gear meshing with a gear on the vertical rapid traverse shaft at the side of the housing. This shaft transmits power to a pair of spur gears located at the end of the rail.



Cincinnati 36 by 36-inch by 8-foot Heavy Pattern Planer

The regular feed is transmitted to the heads in the usual way from a friction on the end of the pinion shaft to the trigger or feed gears at the end of the rail, power being transmitted through a segment and rack. The feed and rapid power traverse gears on the rail screws and rod are free to revolve until clutched by a spool located between them. There is a neutral position in which neither of the gears is engaged. This arrangement makes it impossible to engage both the rapid power traverse and feed at the same time. Provision is also made to protect the mechanism against all accidents, making the entire control absolutely "fool proof." The three small handles at the end of the rail control the clutch spools while the handle just below them engages the rapid power traverse. Moving this handle to the right causes the heads to follow in the same direction, and *vice versa*. The rail and side heads are taper gibbed throughout and the heads on the rail are provided with micrometer adjustment. The housings are extended right to the bottom of the bed, to which they are securely bolted, doweled and locked. All gears are covered to prevent the operator from being injured.

SCHUCHARDT & SCHUTTE SCREW TESTING MICROSCOPE

The demand for a high degree of accuracy which has followed in the wake of interchangeable manufacture has led to the development of many ingenious methods for insuring the attainment of a high degree of precision. One of the latest of these is the Schuchardt & Schütte precision measuring and screw testing microscope which forms the subject of the present article. This instrument is intended for making absolutely accurate measurements of small objects, and it is particularly adapted for measuring and checking micrometer screws, dividing scales, standard gages, dies and a great variety of other parts where precision is a prime requisite. An idea of the accuracy of the instrument may be gained from the fact that it will give the length and pitch of a screw to within 0.00004 inch; the maximum and minimum diameters, and depth of the thread to within 0.0004 inch; and the angle of the thread to within 5 minutes. In making any or all of these measurements it is unnecessary to change the position of the screw after it has been set up.

The illustration shows a screw set up in the instrument where it will be seen that the object to be examined is held in a chuck *A*. In the field of the microscope there are cross hairs which are used as reference points. In measuring the pitch of the screw, the vertical cross hair is first brought exactly over the high point of the thread, after which the reading of the scale *D* and micrometer head *E* is taken. The screw *C* is then manipulated to move the object across the field of the microscope until the cross hair comes into contact with the next point on the thread, after which the reading of the scale *D* and micrometer head *E* is taken again. The difference represents the pitch of the thread. Similarly, in measuring the depth of the thread, a horizontal cross hair is first brought into contact with the top of the thread, after which the reading of the scale and vernier *G* is taken. The screw *F* then moves the work until the horizontal cross hair reaches the bottom of the thread, after which the reading is again noted, the difference being the depth of the thread.

The field of the microscope can be rotated to provide for measuring the angle between the lines or surfaces on the work. For making such measurements the field is rotated to bring one of the cross hairs into contact with one of the angular sides, after which the reading of the scale and vernier *K* is noted. The field is then rotated until the same cross hair comes into contact with the opposite angular side, after which a reading is again taken. The difference represents the included angle between the sides and the result is accurate within 5 minutes. The field is rotated by screw *H*.

The object under examination may be inclined to the optic axis of the instrument and the angle of inclination read on the scale and vernier *M*. As the object remains in the same plane as the axis of rotation, it is not thrown out of focus owing to the inclination of the instrument. In measuring the pitch of a screw it should be inclined the same number of degrees as the angle at which the thread crosses it. This angle can be approximated or else accurately measured by

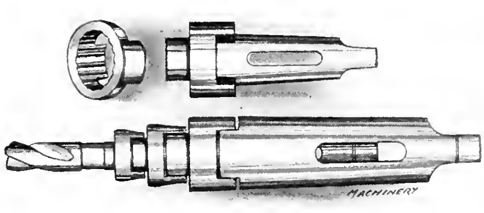
the scale provided for that purpose. The microscope is focused by means of the usual rack and pinion for coarse adjustment and a micrometer screw is provided for making fine adjustments. The dividing head *N* of the micrometer screw is used for obtaining the correct position for viewing the profile of the screw thread or other object which is being examined. This is accomplished by focusing the top of the thread on the cross hairs in the field of the microscope and then lowering the body by means of the fine adjustment an amount equal to the secant of the angle through which the screw is tilted multiplied by one-half the maximum diameter of the thread. The object under examination is illuminated by means of a mirror which will be seen near the base of the instrument. The iris diaphragm used in connection with the mirror can be quickly swung aside or brought back into position, according to the requirements of individual cases. For measuring large objects such as milling cutters, hobs, etc., a special bracket with adjustable centers is provided. This instrument is sold by Schuchardt & Schütte, Cedar & West Sts., New York City.

Schuchardt & Schutte Precision Measuring and Screw Testing Microscope

"DRIVE-EM-ALL" DRILL SOCKET

As its name implies, the "Drive-em-all" drill socket made by the Dazie Mfg. & Supply Co., Inc., 103 Park Ave., New York City, is applicable for driving all styles of taper shank drills and other taper shank tools. Referring to the illustration, it will be seen that there is a serrated ferrule which is driven over the shank of the drill. This ferrule constitutes one member of a clutch, the corresponding clutch member being formed by the end of the socket; and in this way a positive drive is secured. As the socket will drive drills either with or without a tang, one of its important advantages is for using up drills with broken tangs.

In using this socket, the first step is to press the ferrule down onto the shank of the drill. If the drill has a tang, the ferrule is placed in such a position that the tang enters the slot in the socket. The ferrule should be forced far enough onto the shank so that there is a small opening between the ferrule and the socket, the purpose being to provide for wear which may develop when the tool has been in use for some time. When a drill is worn out, the ferrule can be removed from its shank and used on another tool. These sockets and ferrules are made in twelve different styles for various combinations of inside and outside tapers.



"Drive-Em-All" Drill Socket

TUCKER OIL HOLE COVERS

Four styles of oil hole covers which constitute a recent addition to the line of W. W. & C. F. Tucker, Hartford, Conn., are illustrated herewith. These are known as Styles D, E, F and G, and they are so marked in the illustrations in order to provide a ready means for reference. Fig. 1 shows each style of oil hole cover open ready for oil to be introduced into the port, while the covers are shown closed in Fig. 2, these illustrations making the design so clear that only a brief description will be necessary.

It will be seen that the Style D cover is threaded at the bottom in order to be screwed into the oil hole which is tapped to receive it, and that there is a slot for a screwdriver at the top of the cover. The port is normally closed by means of a sleeve which is held down through a compression spring. In order to open the cover to give access to the port, this sleeve is raised with the point of the oil can, which is then pushed into the port and the necessary amount of lubricant supplied. These covers were particularly designed to meet a demand for an oiling device provided with means for excluding dirt and grit from the bearing. They are particularly adapted for use in connection with spring hinge bolts and other parts of motor cars, and can be mounted in a horizontal or vertical position or at an angle. A little experience will enable the oiler to raise the sleeve over the port with the point of his oil can so that only one hand is required for the purpose. It will be seen that the Style G cover is quite similar to the Style D, except that a flat is provided on each side of the body to enable the wrench to be used in screwing the cover down into the tapped oil hole instead of having a slot to be engaged by a screwdriver.

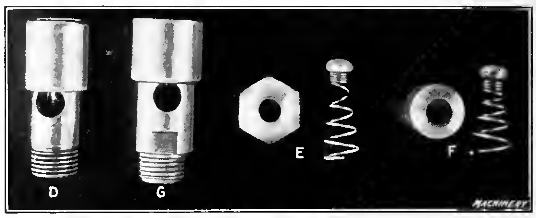


Fig. 1. Styles D, E, F and G of Tucker Oil Hole Covers shown Open

It will be seen that the Styles E and F oil hole covers are the same in general respects, the point of difference being that the Style E is threaded at the bottom to be screwed into a tapped oil hole, while the Style F is tapered so that this cover is driven into the hole. The top of both covers is slightly rounded so that a clean wiping surface is provided, and there are no sharp corners to hold the dirt. It is claimed that the valve or ball check which closes the port of these covers is exceptionally small, thus providing a greater open space for the oil to enter. In the illustration Fig. 1, the spring and ball which keep the port closed is shown beside the cover.

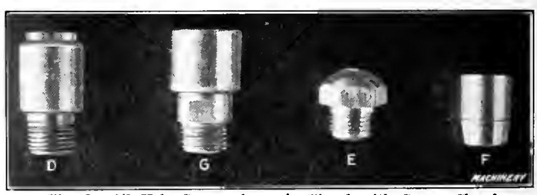

Fig. 2. Oil Hole Covers shown in Fig. 1 with Covers Closed

SCHUCHARDT & SCHUTTE GAGE STANDARDS

For machining work where a very high degree of accuracy is required, the use of gage blocks as the ultimate standard to which all of the gages and measuring instruments used in the shop are referred has come to be recognized as one of the most satisfactory methods of securing the desired degree of precision. Schuchardt & Schütte, Cedar and West Sts., New York City, are now making gage standards of

this type in several different sets, one of which is shown in the accompanying illustration. The No. 9 set, which is the most complete, is intended for use in checking the accuracy of measuring tools such as standard gages, limit gages, micrometer calipers, etc. The blocks may be combined to give intervals of 0.0001 inch and the individual blocks are so accurate that any combination of four or five blocks will have a total error which does not exceed 0.00004 inch. The No. 8 set of gage blocks is similar to the No. 9 except that there are not as many blocks in this set, and it is only capable of combinations for intervals of 0.001 inch. For shops where the English system of fractions is used on work requiring great accuracy, three sets of gage blocks known as Nos. 6, 7 and 7A are provided. The blocks in these sets are graded in 1/16-inch steps, 1/32-inch steps and 1/64-inch steps, respectively. While there is a smaller number of blocks in these sets, they are of the same accuracy as the more complete sets previously referred to.

By referring to the illustration, it will be seen that these gage blocks are prismatic in shape and the distance is marked between the parallel surfaces of each block. It is a well-known fact that hardened steel products are subject to variations in their shape and dimensions for some time after conducting the heat-treatment. This difficulty is eliminated in the Schuchardt & Schütte gage standards through the use

No. 8 Set of Schuchardt & Schutte Gage Standards

of a special tempering process which relieves the excessive internal strains without softening the metal. The gages are non-magnetic when they leave the factory and particular care should be exercised to prevent them from becoming magnetized. If this precaution is not observed, very fine particles of metal will be picked up by the gages, and although these particles may be too small to be visible, they will introduce appreciable errors when several gage blocks are used in combination. In using the blocks the surfaces are first wiped with a piece of chamois leather to remove any grease or dirt, after which the gages which are to be in contact are placed edge to edge and the contacting surfaces slid across one another with the application of a moderate pressure. The surfaces are so smoothly finished that molecular attraction causes the blocks to be held together. As the size is stamped on each block, all the knowledge a workman requires in using these gage standards is the ability to make a simple arithmetical addition in order to determine when he has obtained the required dimension. This is done by adding the size of each gage block as it is combined with the blocks already selected, until the required combination is obtained.

AUTOMATIC DRILL CHUCK

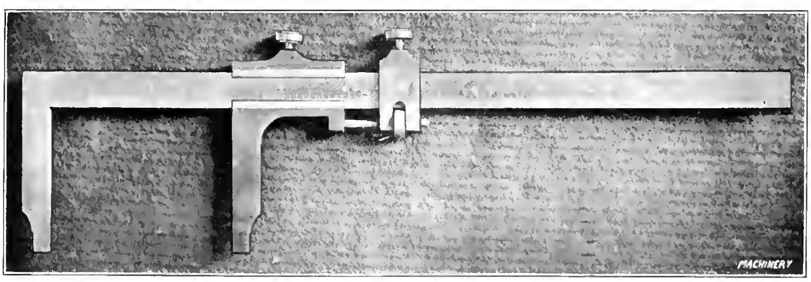
The "Quictite" drill chuck, which forms the subject of this article, is the latest product of the Automatic Drill Chuck Corporation, Majestic Bldg., Detroit, Mich. The most important feature of this chuck is the rapidity with which drills can be inserted or removed. For this purpose it is merely necessary for the operator to grasp the knurled collar and hold it back against the rotation of the drill-press spindle. This opens the jaws of the chuck so that the drill may be pushed up until it comes into contact with a hardened thrust plug. The knurled collar is then released and the jaws spring forward and take a firm grip on the shank of the drill. These chucks are made in three different sizes. The illustration shows the No. 6 size which has a capacity for drills from No. 40 up to 3/8 inch; this chuck can be opened by hand when the drill-press spindle is running at speeds up to 4000 R. P. M. This type is also made in a No. 8 size which has a capacity for drills ranging from 3/16 to 1/2 inch in diameter, and in a No. 5 size having a capacity for drills from ½ to 1 inch in diameter. All sizes of drills operate in the same way.

The "Quictite" Automatic Drill Chuck

The two most important features of the rotary cam type of jaws used in these chucks are the powerful gripping action which is secured and the smooth contact surface which is provided. The driving power provided by the chuck jaws increases in direct proportion to the resistance offered by the cut, and there is no tendency for the jaws to damage the shank of the drill. There are three jaws, each of which has a triple set of grips, so that a total of nine contact points engage the shank of the drill. The action of the jaws is self-centering, no matter what the size of the drill, so that all drills are always accurately centered in the chuck. Particular attention has been paid to the construction of the chuck along lines which provide ample strength and durability.

SMITH OPEN-FACE CALIPER

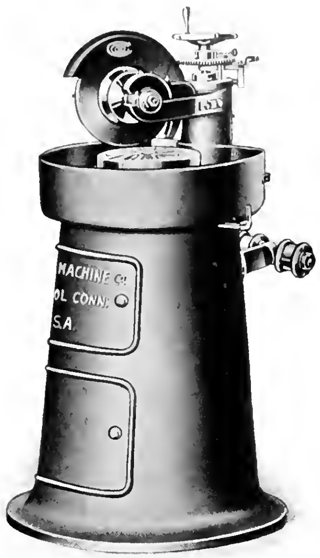
A vernier caliper of the beam or sliding type, which is a recent product of E. G. Smith, Columbia, Pa., is illustrated herewith. This tool differs from the general style of Columbia sliding calipers in that it has a so-called "open face" which is a great convenience in reading the measurement. At present this tool is only made in the 8-inch size, with the lower scale graduated to fiftieths and provided with a vernier to read to 0.001 inch; and with the upper scale graduated in sixteenths, with a vernier to read to 1/128 inch. The construction and shape of the jaws provides as much strength as in other styles of Columbia calipers. The jaws are hardened and accurately ground.



Smith Open-face Caliper with Scales reading to 0.001 Inch and to 1/128 Inch

GARRIGUS PRECISION GRINDER

The C. G. Garrigus Machine Co., Bristol, Conn., is now building a 12-inch rotary surface grinder which is particularly adapted for precision work. The design of this machine is marked by its simplicity and durability, and as the grinding operation is continuous, the rate of production is very satisfactory. The range is from very small pieces up to anything that will come within a 12-inch circle, and pieces can be finished within 0.0004 inch of the required dimension.



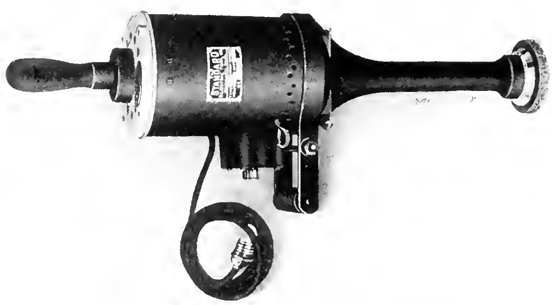
C. G. Garrigus 12-inch Rotary Surface Grinding Machine

The head is supported on a vertical oscillating column which is attached to the feed-shaft and actuated by a ratchet and pawl. Each tooth of the ratchet lowers the grinding head 0.000125 inch. The magnetic chuck is mounted on a spindle that is operated by a cone clutch pulley and connected by gearing to the cam which operates the wheel column. The stroke of the oscillating wheel is regulated by the adjusting cam roll. The movement of the head and rotation of the chuck are controlled by the action of a lever at the side of the machine.

When this grinding machine is equipped for grinding cast-iron parts, such as piston rings, a special wheel cover with an opening to which a flexible tubing is connected, is mounted on the machine. A different style of pan is also used which makes the machine more accessible for the operator when grinding single pieces. For wet grinding, a tank connected with a pump affords a continuous supply of water to the work held on the chuck. The chuck has two speeds and is operated by hardened steel gears. The principal dimensions of the machine are as follows: Size of grinding wheel, 12 by ¾ inch; greatest distance from center of wheel to top of chuck, 12 inches; vertical adjustment of head, 8 inches; diameter of magnetic chuck, 12 inches; and weight of machine, 1400 pounds.

STANDARD UNIVERSAL ELECTRIC GRINDER

The Standard Electric Tool Co., Cincinnati, Ohio, has placed a new grinder on the market which is intended for such work as surfacing rough castings and also for performing buffing operations. This tool is provided with a universal motor which operates on either alternating or direct current with equal efficiency. It is especially adapted for use on low-frequency circuits of 25, 30 or 40 cycles. The motor is form wound and impregnated with "Bakelite," which effectually prevents short circuits, grounds and other troubles incident to high-speed operation.



Standard Grinder equipped with a Universal Motor

The motor is designed to run at 6000 revolutions per minute, and the armature spindle is extended and has a 4-inch emery wheel mounted directly upon it. Imported ball bearings are employed throughout the tool. The motor has a capacity for ½ horsepower and is said to be exceptionally durable. The efficiency is unusually high when operating on alternating current, owing to the high speed at which it is required to operate. The grinder is equipped with a spring for suspending it from the ceiling and it can be used in connection with a traveler and counterbalance. The motor may be attached to either a lamp socket or a power circuit.

AURORA 20-INCH DRILLS

Two improved 20-inch drills which are recent products of the Aurora Tool Works, Aurora, Ind., are illustrated in Figs. 1 and 2. These machines are of exceptionally heavy construction, with the column and base well ribbed and the head fitted on the column with a tongue and groove joint, and securely bolted by three ½-inch cap-screws. Power is transmitted to the spindle by four-step cone pulleys which carry a 2½-inch belt. The tight and loose pulleys are 9 inches in

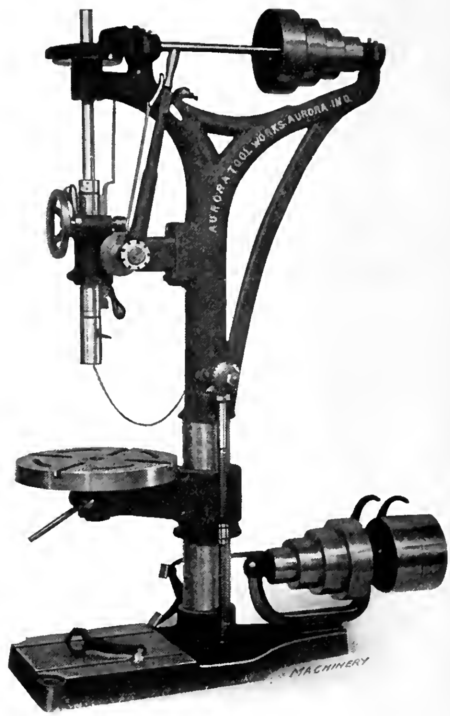


Fig. 1. Aurora 20-inch Drill equipped with Wheel and Lever Feed

diameter and carry a 3-inch belt; these pulleys run at from 550 to 600 revolutions per minute. Ample power is provided for driving a 1½-inch drill to the limit of its capacity.

The table rests on a large flat bearing in addition to being supported by the usual pivot bearing, this construction insuring perfect alignment even when holes are being drilled at points near the edge of the table. The spindle is fitted with a ball-thrust bearing and has a travel of 8 inches. On the plain wheel and lever feed drill, shown in Fig. 1, the worm is engaged or disengaged by means of an eccentric bushing. The feed lever is operated by a ratchet and pawl which automatically disengages when in the vertical position. On the drill equipped with power feed, which is illustrated in Fig. 2, the feed gears are of hardened steel and run in an oil-tight case. Three changes of feed can be instantly obtained without requiring the machine to be stopped. Each change of feed is clearly marked so that there is no excuse

for the operator making a mistake. The spindle sleeve is graduated and equipped with an automatic stop collar which disengages the feed when the tool has reached any required depth. The table and also the base of the machine are furnished with T-slots. The weight of the plain wheel and lever feed drill is 735 pounds, while the drill equipped with power feed weighs 900 pounds.

Fig. 2. Aurora 20-inch Drill equipped with Power Feed

HARRINGTON MULTIPLE-SPINDLE DRILLS

Edwin Harrington, Son & Co., Inc., Philadelphia, Pa., are now building a line of multiple-spindle drill presses which includes machines with circular heads ranging from 15 to 36 inches in diameter; and with rectangular heads ranging from a spindle area of 15 by 24 inches up to a spindle area of 20 by 40 inches. The number of spindles varies from 12 to 32, depending on the size of the head and the size of the drills which are to be used, the design of each machine having been worked out in such a way that it may be equipped with any size of spindle unit. The smaller machines are built to provide for movement of the head on the column by hand, but in the three larger sizes, the movement of the head is controlled exclusively by a power-driven screw. The illustrations show three different sizes of these machines from which an idea of the general design may be obtained.

No. 51-A and 51-B Machines

These are the smallest sizes of the Harrington multiple-spindle drills and the design of the two machines is essentially the same. They are made with two sizes of heads, each of which has a different spindle area and maximum number of spindles. The maximum area covered by the spindles of the head of the No. 51-A machine is over a circle 15 inches in diameter, and the machine has a capacity for driving twelve ½-inch drills. The No. 51-B machine is equipped with a head whose maximum spindle area is a 20-inch circle, and this head will drive sixteen ½-inch drills. Provision is made in the gear chest of each size head for the maximum number of spindle pinions so that the machine purchased with less than the full complement of spindles can be brought up to a full equipment at any time. Both machines have sufficient power for driving the rated number of drills in cast iron, at a peripheral speed of 65 feet per minute and a feed of 0.010 inch per revolution.

The head frame is cast in one piece with the saddle and is provided with heavy gibs and a long bearing on the column. A full counterbalance weight inside the column is connected to the head by two chains. There are two T-slots in the lower flange of the head for clamping the cast steel radius bars in which the bronze spindle sleeves are carried. The adjusting screw is arranged so that the spindle sleeves can be regulated up and down for different lengths of drills without moving the positions of the radius arms; the spindles have a long bearing in bronze sleeves and are provided with steel and bronze thrust washers. A telescopic shaft with universal joints at each end connects each spindle and its pinion. The drive is through a quarter-turn belt from a pulley mounted on the base of the machine to a pulley carried by a bracket at the top of the column; this drives the splined vertical shaft. A pinion on the lower end of this shaft transmits power to the upper gear of a pair of spur gears; and the lower gear of this pair drives the spindle pinions. All gears are made of heat-treated alloy steel except in cases where one gear of a pair is steel and the other bronze. All the gears have cut teeth. In belt-driven machines, a four-step cone pulley is driven from an overhead countershaft, and in motor-driven machines the lower cone pulley is replaced by a spur gear which meshes with a rawhide pinion on the motor spindle.

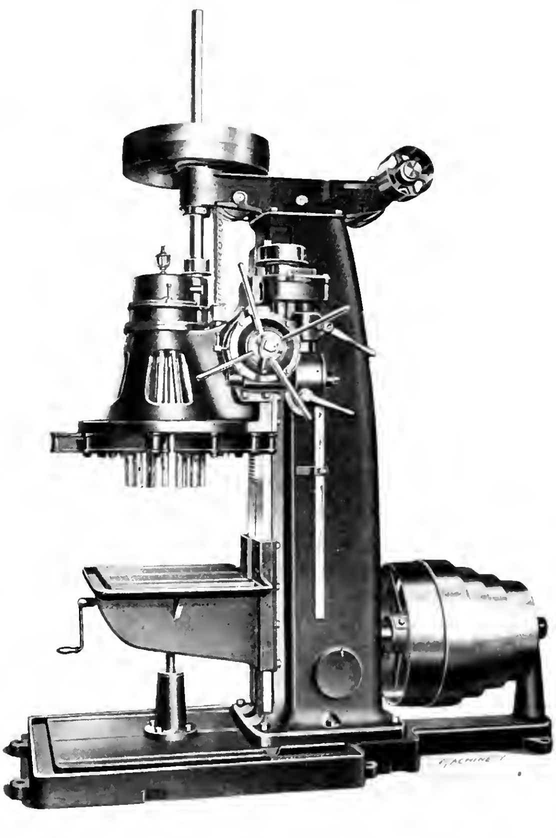

Fig. 1. Harrington No. 51 Multiple Spindle Drilling Machine

Power for the feed is taken by belt from the vertical shaft and thence through spur gears. The motion is then transmitted through bevel gears to a horizontal worm and worm-wheel. The planetary train of spur gears between the worm-wheel and rack pinion reduces the strain on the worm-wheel teeth. Both hand and automatic trip are provided on the worm in addition to a saw-tooth disengaging clutch. The frame of the machine is exceptionally massive, the base being

heavily ribbed and provided with T-slots, an oil channel, and a settling tank. An extension is bolted to the rear of the base and the cone pulley or motor is mounted on this extension. The table has a long bearing on the column and an elevating screw under the center of the drilling area. If desired, three T-slots can be planed in the table. In addition to the dimensions already given, the following figures give an idea of the capacity of both the 51-A and 51-B machines, to both of which these dimensions apply. Shortest distance between spindles, 1⅜ inch; vertical adjustment of each individual spindle, 1¼ inch; vertical traverse of head, 24 inches; vertical movement of table, 15 inches; floor space occupied, 7 feet 6 inches by 3 feet 2 inches; weight of No. 51-A machine, 5000 pounds, and weight of No. 51-B machine, 5400 pounds.

Fig. 2. Harrington No. 62 Multiple Spindle Drilling Machine

No. 62-A and 63-A Machines

These machines are of the same design except for the heads, which are of different sizes. The maximum area covered by the spindles of the head of the No. 62-A machine is a circle 20 inches in diameter, and this head has a capacity for driving twelve 1-inch drills. The head of the No. 63-A machine has a capacity for driving sixteen 1-inch drills and the maximum area over which the spindles can be distributed is a circle 25 inches in diameter. They have a powerful drive and easily operated rack feed. Provision is made for the full rated number of spindle pinions so that if purchased with less than the full complement of spindles, the remainder can be added at any time. All spindle dimensions refer to regular equipment of 1 inch capacity. Lighter spindle units for smaller drills can be used or the machine can be equipped with a smaller number of spindles of greater capacity than 1 inch, depending on the size. The driving power is sufficient to handle the rated number of drills in cast iron at a peripheral speed of 65 feet per minute.

The head is a solid casting rigidly braced to prevent springing and is fully counterbalanced, being connected by two chains. The radius bars are cast steel, clamped to the head by bolts through the flange. Each spindle runs in a bronze bushing, is driven by a heat-treated pinion, two hardened universal joints and a telescoping shaft, and has ball thrust bearings. Quick vertical adjustment for different drill lengths is made in any layout without moving the radius arms. The drive is by belt and bevel gears to the head, with a compact train of spur gears driving the spindles. The top shaft is mounted on roller bearings and the provision for lubrication is complete. Belt driven machines, with 7-inch or wider belts, are provided with an eccentric sleeve within the lower cone for decreasing the center distance when shifting the belt. In motor driven machines, a variable-speed motor drives directly to the upper pulley. Belt drive can be provided through a change gear box when required.

The feed is driven by belt from the vertical shaft, and there are three geared changes. A strong planetary train of spur gears on the rack pinion shaft reduces the strain on the worm gear teeth. The worm has both hand and automatic trip, besides a quick operating clutch for rapid hand movement of the head. The frame of this machine is very heavy. The base is heavily ribbed and provided with T-slots, oil gutter, and settling tank. An extension is bolted to the rear of the base for the cone pulley bracket or the motor as required. The table is of the open box type with large planed top surface and has three T-slots. An oil pump with distributing piping can be provided, and is driven by belt from the cone shaft. The principal dimensions of these machines are as follows: Minimum distance between spindles, 2¼ inches; vertical adjustment of individual spindles, 1¾ inch; vertical traverse of head, 34 inches; area of table, 24 by 24 inches for the No. 62-A machine, and 28 by 28 inches for the No. 63-A machine; weight of the No. 62-A machine, 8200 pounds, and weight of the No. 63-A machine, 8800 pounds.

No. 71-A, 72-A and 72-B Machines

These machines are all of the same type but vary in the size of frame and drilling area. Movement of the head in both directions is exclusively by power, the return stroke being automatically controlled. The drive is very simple but extremely powerful, and all of the feed and quick return control mechanism is carried in the bracket on top of the column. Provision is made in the gear chest of each for the maximum number of spindle pinions so that a machine purchased with less than the full complement of spindles can be brought to full equipment at any time. All machines have sufficient power to handle the rated number of drills in cast iron at a peripheral drill speed of 65 feet per minute and a feed of 0.010 inch per revolution. The head frame is

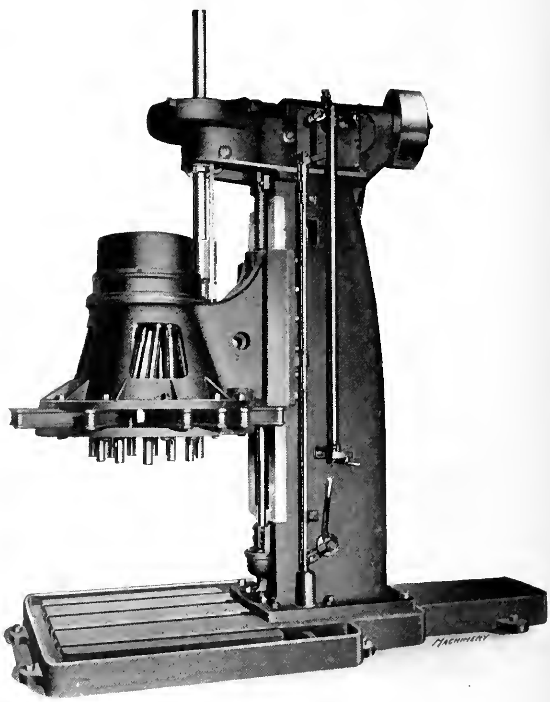

Fig. 3. Harrington No. 72 Multiple Spindle Drilling Machine

cast in one piece with the saddle and has heavy gibs and a long bearing on the column. A counterbalance weight inside the column, connected to the head by two chains, relieves the pressure on the feed-screw. Bolts through the head flange and the slots of the radius bars hold them in position. These radius bars are steel castings, in the inner end of which is a bored hole, carrying the bronze spindle sleeve.

The adjusting screw is arranged so that this sleeve can be regulated up and down for different lengths of drills without moving the position of the radius arms. The spindles have a long bearing in the bronze sleeves and are provided with ball thrust bearings. A telescopic shaft, with universal joints at each end, connects each spindle and its pinion.

The drive is by vertical belt to the pulley on the top bracket, which is provided with a roller bearing and mounted on an extended sleeve so that the belt strain does not come on the driven shaft. A pair of bevel gears transmits the power to the vertical shaft which carries a pinion on its lower end meshing with the upper of a pair of spur gears in the top of the gear chest, the lower gear, in turn, driving the spindle pinions. All pinions are made of heat-treated alloy steel. All have accurately cut teeth and bearings at both ends of their shafts, with ample provision for constant lubrication. The type of drive recommended is from a variable speed motor on the rear extension of the base, by belt to the pulley overhead. Regular belt drive from an overhead countershaft can be provided, in which the lower cone is mounted on an eccentric shaft to slacken the belt when shifting. For belt drive without the use of a countershaft, or for constant speed motor drive, a change speed gear box is placed on the rear base extension. Both the feed and return of the head are obtained from a large screw in the face of the column and a unit gear box in the top bracket. The screw is in tension and has a ball thrust bearing at the bottom. Three changes of feed by positive gearing are provided, and quick movement of the head in either direction is obtainable through a friction clutch. The clutches are so arranged that when the drills have reached full depth, the head automatically returns to the top of the stroke ready to be started on the next drilling operation. The frames of these machines are very heavy and the base is heavily ribbed and provided with T-slots, oil gutter and settling tank. The table is of the open box type with large planed top surface having three T-slots and gutter. An oil pump with distributing piping can be located on the rear of the column, and is driven by belt from the shaft below.

Fig. 1. Improved Type of "Old Man" or Drilling Post made by Lutz-Webster Engineering Co.

The principal dimensions of the No. 71-A machine are as follows: Capacity, for drilling sixteen 1¼-inch holes; maximum area covered by spindles, a circle 25 inches in diameter; shortest distance between spindles, 2½ inches; vertical adjustment of individual spindles, 1½ inch; vertical traverse of head, 31 inches; weight, 22,000 pounds. The dimensions of the 72-A machine are: capacity, for drilling twenty 1¼-inch holes; maximum area covered by spindle centers, a circle 32 inches in diameter; shortest distance between spindles, 2½ inches; vertical adjustment of individual spindles, 1½ inch; vertical traverse of head, 40 inches, and weight of machine, 28,000 pounds. The dimensions of the No. 72-B machine are: capacity, for drilling twenty 1½-inch holes; maximum area covered by spindle centers, a circle 36 inches in diameter; shortest distance between spindles, 2½ inches; vertical adjustment of individual spindles, 1½ inch; vertical traverse of head, 40 inches; and weight of machine, 29,000 pounds.

LUTZ-WEBSTER "OLD MAN"

The drilling post or "old man," as it is commonly called in the shop, has been successfully used for many years in certain classes of drilling which cannot be handled on a drill press. Various forms of these tools have been made by different manufacturers, each of which has certain points of merit. The Lutz-Webster Engineering Co., Inc., 31st St. and Gray's Ferry Road, Philadelphia, Pa., has recently added to its line the equipment which forms the subject of the present article. This tool, used in connection with the Lutz compression wrench, makes a particularly serviceable outfit. It will be seen that two arms are shown, one of these being a plain arm while the other is a swivel arm, which provides for drilling holes at an angle. A detail of the swivel arm is shown in Fig. 2, from which the construction will be readily understood.

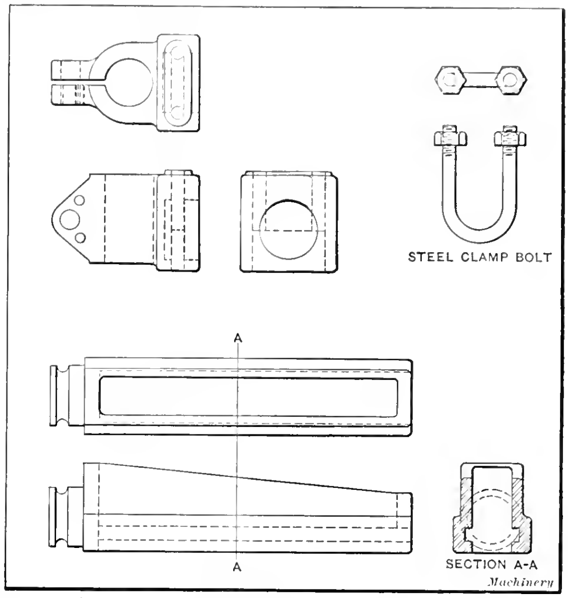

Fig. 2. Detail of Adjustable Arm for Lutz-Webster "Old Man"

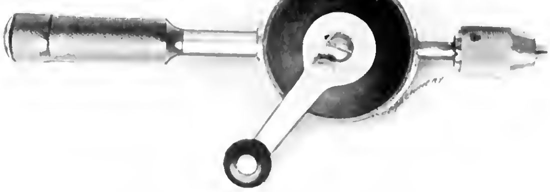
The features of this improved style of "old man" may be briefly outlined as follows: The ratchet is a single piece, and even a straight shank drill may be used in place of the ratchet, where the Lutz compression wrench is used to drive the drill. Under such conditions, the wrench affords the necessary grip for turning through part of a revolution, and it may then be released and moved back to secure a fresh grip ready for the next forward movement. In addition to the usual feed arrangement, an auxiliary feed movement can be obtained by means of a pin fitting in the hole in the supporting screw which is turned by means of this pin. These drilling posts are made in 16-, 20-, and 26-inch sizes and can be made entirely of steel or of malleable iron.

MILLERS FALLS HAND DRILL

One of the recent products of the Millers Falls Co., Millers Falls, Mass., is a No. 353 hand drill which is made entirely of metal with the exception of the enameled wood crank handle. The knurled handle at the top of the drill is provided with a screw cap which may be removed to give access to the socket in which extra drills can be carried. It will be seen that there are two pinions engaging the driving gear, the purpose of this double pinion arrangement being to support the gear on both sides, thus relieving the bearing from

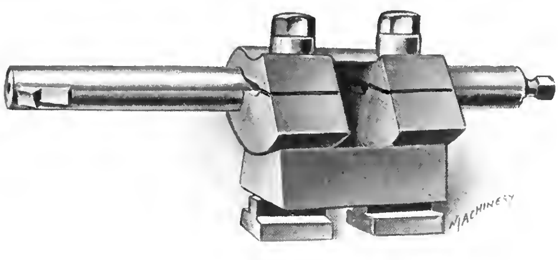


No. 353 Hand Drill made by the Millers Falls Co.

undue strain. The small knurled knob on the crank controls a ratchet which may be set to work either right- or left-hand, or to provide positive drive in both directions. The spring pawl connected to the knurled knob engages square holes in the driving gear. The pawl is tapered on one side and may be set so that the taper engages the holes to run back either right- or left-hand; and by setting the pawl edgewise with the holes, positive drive in both directions is secured. This ratchet mechanism is particularly convenient for use in cramped places. The capacity of the three-jawed chuck is for drills up to 3/16 inch in diameter.

RED-E BORING-BAR HOLDER

A recent addition to the line of tool-holders manufactured by the Ready Tool Co., 654 Main St., Bridgeport, Conn., consists of a boring-bar holder for supporting bars of the larger sizes. Reference to the illustration will make the method of using this tool clear without requiring an extensive description. It will be seen that the bar is mounted on the lathe by



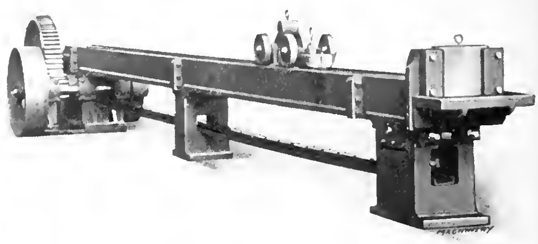
Ready Tool Co.'s Heavy Boring-bar Holder

first removing the toolpost and then inserting the T-bolts which secure the holder, in the T-slots in the carriage. Tightening up two nuts on the end of these bolts not only clamps the holder in place but also serves to secure the boring-bar in the holder. By rocking the upper part of the holder on the base, it is possible to adjust the bar for various heights that are required in different makes of lathes.

WATERBURY-FARREL CHAIN DRAW-BENCHES

For use in the manufacture of tubing, solid bars and similar products, the Waterbury-Farrel Foundry & Machine Co., Waterbury, Conn., has brought out a line of chain draw-benches which supersedes preceding machines for the purpose, built by this company. The new machines are built in three sizes having pulling capacities of 10,000, 20,000 and 30,000 pounds on the chain. Several noteworthy improvements have been made in their construction. The chain drive is of the "two-in-one" type, having drop-forged center links, and the outer links are made of bar stock; this gives exceptionally good wearing properties, a feature which is accentuated by the fact that there is a large wearing surface between the chain and the sprocket. The hook and chain are so designed that there is less danger of accidents resulting from the refusal of the hook and chain to disengage at the end of the drawing stroke, than was the case in some of the older type machines. The compact and self-contained drive is arranged with an outboard bearing on the sprocket shaft which maintains the alignment of the gears while setting up or erecting the machine. This makes the labor and expense of manufacture, installment and up-keep less than it would otherwise be. The main pinion is also mounted between bearings on the shaft instead of being overhung, and this is a feature which gives additional rigidity. The improved type of wheel tongs is used which has been applied on chain benches built by the Waterbury-Farrel Foundry & Machine Co. during the past three years. These tongs relieve the operator of a fatiguing part of the work and they are returned more quickly than the sliding type of tongs, so that an increase in output is effected through their use.

These draw-benches are adapted for motor drive. The ratio of the gearing and the pulley sizes is so worked out that an ordinary commercial motor can be belted to the driving pulley without requiring any alteration in the design of the bench. As a rule, but little variation is required from the standard motor pulley size. These draw-benches are designed so that they may be assembled either right-hand or left-hand, as desired, without requiring any change in castings or any special machine work. Another useful feature is that the bed is so constructed that it may be lengthened



Waterbury-Farrel Chain-driven Draw-bench for Tubing and Solid Stock

out at any time to suit the requirements of special work. Sight-feed oil cups are provided on all bearings in the driving mechanism, and the cut teeth of the drive and main sprockets do away with the majority of the noise incident to operating machines of this type. A steel channel is provided underneath the bed for supporting the chain instead of allowing it to drag on the floor. In addition to the three sizes of machines previously referred to, four small sized machines are built which have pulling capacities of 1000, 2000, 3500 and 6000 pounds, respectively; two larger machines are also built, which have pulling capacities of 40,000 and 60,000 pounds. These six machines provide for handling the same class of work as the three standard machines, but their capacities make them particularly well suited for exceptionally large or small work.

BEMIS WORK-HOLDING HEAD

Edgar W. Bemis, 92 West St., Worcester, Mass., is the manufacturer of a work-holding head for use on the milling machine, lathe or drill press. This head consists of a frame in which a hollow spindle is mounted. Inside the hollow

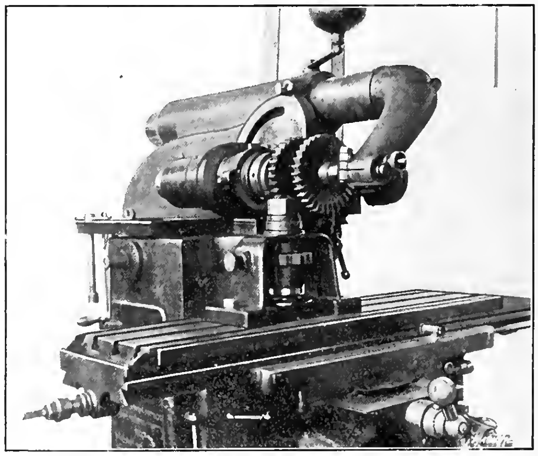


Fig. 1. Bemis Auxiliary Head set up on the Milling Machine

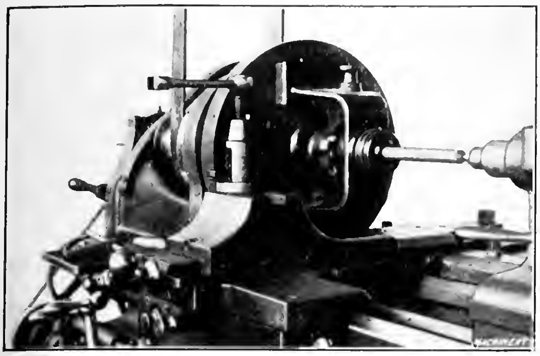

Fig. 2. Application of Bemis Auxiliary Head to Lathe Work

spindle there is a sliding spindle in which different sized collets can be mounted. At the opposite end from the collet, the sliding spindle is threaded into a handwheel which provides for drawing in the collet to grip the work. An index wheel is keyed to the outer or so-called hollow spindle. This index wheel has notches cut in its periphery which provide for indexing angles of 45 and 60 degrees, a spring plunger

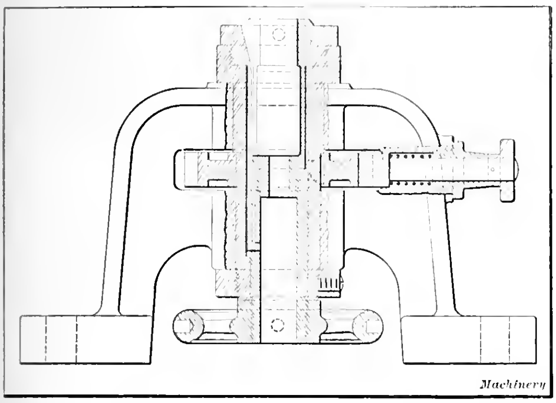

Fig. 3. Type A Bemis Work-holding Head

fitting into the required notch to locate and hold the spindle and work in the required position.

This head is made in two different styles which are known as the Type A and Type B heads. The Type A head, which is illustrated in Fig. 3, is equipped with a draw-in collet of standard design for holding pieces from 1/64 to 7/8 inch in diameter. Type B head is provided with a plug adapter on which threaded pieces can be mounted. These heads can be used on a milling machine for use in straddle milling such work as nuts of all kinds, and for various classes of tool-room and model work. The head is shown in Fig. 1 set up for milling a hexagonal nut. Fig. 2 shows the application of this head to the faceplate of a lathe, where the work is held by a draw-in collet. A typical application of the head for lathe work consists of cutting a multiple thread. After the first thread has been cut, it is required to index the work through 180 degrees (in the case of a double thread) ready for starting the next thread, and this can be easily done with the work held in this type of head. A particularly convenient feature is that after a piece has been put in the chuck, the head can be transferred back and forth between the lathe, drill press and milling machine for performing successive operations, without any serious loss of time in resetting the work, which would otherwise result in making such change.

VOLCANO NO. 3-C HAND TORCH

The Volcano Torch & Mfg. Co., Erie, Pa., is now making a No. 3-C hand torch which has an unusually high heating capacity for an equipment of this type. Instead of depending upon an air pump for generating the pressure, an auxiliary burner has been applied for this purpose, which heats the gasoline in the containing cylinder to give a pressure of from 125 to 250 pounds per square inch. In addition to the increased pressure secured in this way, the necessity for maintaining the required pressure by pumping at frequent intervals is avoided.

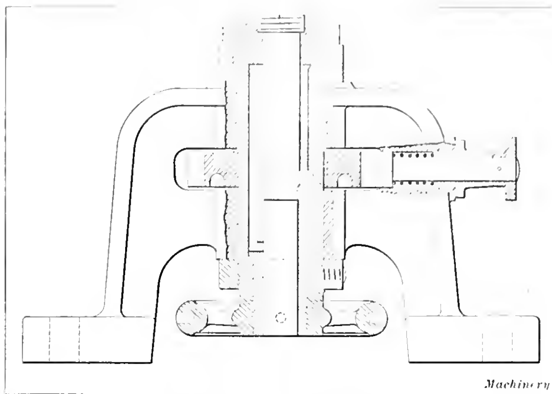

Fig. 4. Type B Bemis Work-holding Head

Referring to the illustration of the torch Fig. 1, the throttle or main valve which feeds the nozzle is controlled by the handle seen at the extreme right. The smaller handle below and to the left, is used for controlling the auxiliary burner which develops the pressure in the cylinder. This auxiliary burner is located inside the outer cylinder below the perforated section. A gaging device, seen on the right-hand side of the cylinder in Fig. 2, provides for regulating the amount of gasoline delivered to the auxiliary burner for use in pre-heating the gasoline in the main reservoir to generate the required pressure. A relief valve is provided for reducing the pressure when required, and there is also a safety valve to guard against the pressure being raised beyond a safe limit. Fig. 2 shows the pressure gage which enables the workman to see at a glance just what pressure has been developed in the cylinder.

One of the features of this torch is that it is unnecessary to stop the heating operation when it is required to replenish

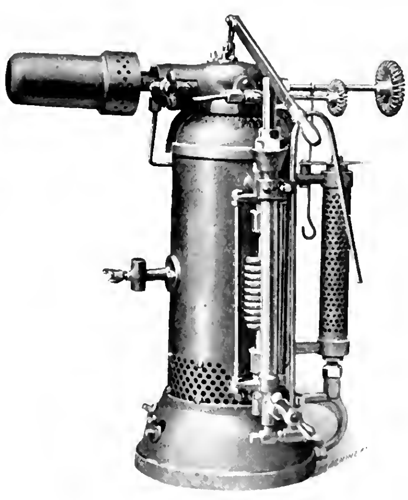

Fig. 1. Front View of Volcano No. 3-C Hand Torch

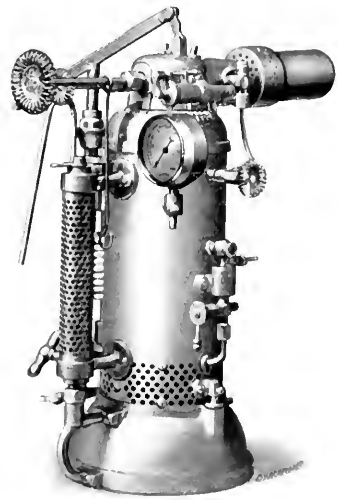

Fig. 2. Opposite Side of Torch shown in Fig. 1

the supply of gasoline in the main reservoir. It will be seen that there is a horizontal lever pivoted at the top of the torch and this lever operates a pump secured to the side of the torch. The small bent tube extending from this pump is provided for making connection with the supply of gasoline from which the required amount is pumped into the reservoir. The shut-off for the gasoline pump will be seen at the bottom of the pump in Fig. 1. The nozzle can be set in any required direction by means of an adjustment and then locked by a wing nut. An idea of the heating capacity of this torch may be gathered from the fact that a 9-inch solid round shaft can be heated red-hot for a distance of 12 to 16 inches in 30 minutes or to a brazing temperature in 1 hour 15 minutes, assuming that the heat is properly confined. This does not represent the maximum capacity of the torch, however, as larger work can be heated with it. The torch can be used out-of-doors in any kind of weather, and it will work with equal satisfaction in any position.

HEALD MAGNETIC CHUCKS

In the October, 1913, number of MACHINERY, rotary and planer types of magnetic chucks made by the Worcester Magnetic Chuck Co., were illustrated and described. This business has recently been taken over by the Heald Machine Co., 20 New Bond St., Worcester, Mass., and a number of noteworthy improvements have been made in the design and construction. In addition to incorporating refinements which make the chucks more efficient, new sizes and types have been brought out to cover a wider range of work. Two sizes of rotary chucks are illustrated in Fig. 1; the chuck shown at the left-hand side of this illustration is the 8-inch size, while the one to the right is a 12-inch chuck. The Heald Machine Co. is also making rectangular or planer type

Fig. 1. 8- and 12-inch Sizes of Heald Rotary Magnetic Chuck

chucks as shown in Fig. 2, which are particularly designed for use on planers, milling machines, surface grinders and similar tools.

The most important feature of these new chucks is their great holding power, which exceeds one hundred pounds per square inch. The holding power is also very uniform over the face of the chuck, the claim being made that the variation does not exceed 5 per cent over the entire faceplate. The design is so worked out that the body of the chuck is free from magnetism, and this is a point of considerable importance as it eliminates the tendency to magnetize the machine on which the chuck is used. The poles are closely spaced with very little dead surface between them; and this enables a great range of work to be handled. Small and large pieces are held with equal efficiency. The chucks are water-proof and non-heating, all the coils being carefully proportioned and thoroughly protected from dampness. The faceplate is of unusual thickness which gives long life and provides for frequent truing. It is an easy matter to replace the faceplate, however, when it is worn out. The unit coil system is adopted, which makes each coil independent of other coils in the chuck, so that the failure of one or more coils does not put the entire chuck out of commission.

A cross-sectional view of the rotary type of chuck is shown in Fig. 3, from which the construction will be readily understood. Referring to this illustration, it will be seen that the chuck is composed of a steel body *A* to which the faceplate *B* which carries the pole pieces is attached. The body has projections *C* cast integral with it which receive the coils *D* and carry the magnetism to the pole pieces *E* in the faceplate of the chuck. The coils slip over the projections and the top faces of these projections are finished even with the sides or walls of the chuck body. The pole pieces, one of which is indicated at *E*, are insulated from the remainder of the faceplate by means of non-magnetic metal, this insulation being shown at *F*. The faceplate casting is also insulated from the main body of the chuck by means of a ring of non-magnetic metal *G* which prevents the magnetism from passing into the body of the chuck.

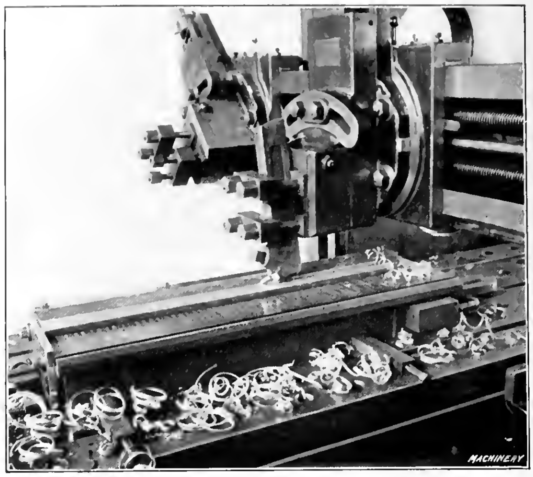

Fig. 2. Rectangular or Planer Type of Magnetic Chuck

In the rotary type of chuck, the current is delivered to a set of brushes which contact with two rings *H* and *I* of conducting metal, which are attached to the lower side of the chuck body. These rings are insulated from the body of the chuck by non-magnetic rings. A consideration of this cross-sectional view will show that the coils and wiring are readily accessible by simply removing the faceplate of the chuck. This plate is held in position by fillister head screws that pass up through the body and enter the under side of the plate. This construction eliminates difficulty arising from grinding away the heads of the screws, which results when these heads are placed in the faceplate of the chuck. The construction will be better understood by referring to Fig. 4 which shows the under side of the chuck with the fillister head screws in place.

A rotary chuck is shown in Fig. 5 with the top plate removed so that the inside of the chuck and the unit system of coils are plainly visible. The individual coils used for different sizes of Heald magnetic chucks have been stand-

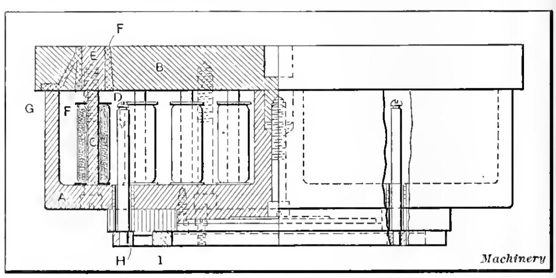

Fig. 3. Cross-sectional View of Heald Rotary Magnetic Chuck

ardized and can be supplied on short notice; they are easily inserted without making it necessary to return the chuck to the factory for repairs. After winding, the coils are carefully taped and thoroughly impregnated so that they will resist water and operate satisfactorily under temperatures as high as 500 degrees F. The insulation is so thoroughly protected that it is claimed the coils will operate when immersed in water.

It has already been stated that the holding power of these chucks is uniform within 5 per cent at all points on the faceplate. This uniformity has been determined by the use

of two one-inch steel cubes, one of which is placed near the center of the chuck and the other close to the periphery, a 16-inch chuck being used for the purpose. Two spring balances were then used to determine the holding power of the chuck, the balances being secured to rings on the upper side of the steel cubes. It was found that the holding power was the same at both places on the face of the chuck, and that the intensity was 112 pounds per square inch. This was by no means a record, however, as many of the chucks tested have shown a holding power as high as 125 pounds per square inch. It is claimed that this high power is due to the unit system of coils that is employed, and to the fact

Fig. 4. Rear View of Chuck showing Method of securing Faceplate from Back

Fig. 5. Chuck with Faceplate removed to show Arrangement of Windings

that the chucks are made of steel instead of cast iron. As the current is delivered direct to each coil in the chuck, it works at maximum efficiency.

Another important feature which was briefly referred to in a preceding paragraph, is that the body of the chuck is entirely free from magnetism. This result is secured by the perfect insulation of the body from the faceplate of the chuck. Referring to the cross-sectional view shown in Fig. 3, it will be seen that a ring of non-magnetic metal *G* is placed between the top of the chuck body and the faceplate, which effectually prevents the magnetization of the body of the chuck and the machine on which it is mounted. This

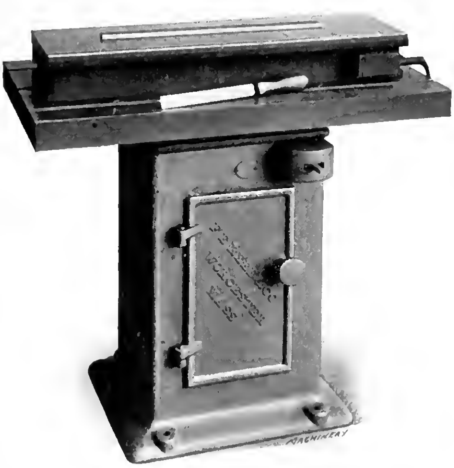

Fig. 6. Application of Heald Chuck for Scraping Operations

does away with the annoyance frequently caused by having particles of metal adhere to the body of the chuck and to the machine, due to their magnetic attraction.

One of the strong objections to magnetic chucks has been due to the fact that, as they were not perfectly insulated, the electric current passed down into the machine itself and resulted in the operator frequently receiving a shock. The Heald chuck is carefully insulated so that this source of annoyance is avoided. Freedom from residual magnetism is another feature. Upon shutting off the current from the chuck, it is almost entirely demagnetized, making it easy to remove the work from the faceplate of the chuck without requiring the use of a demagnetizing switch for this purpose. This result is obtained by perfect insulation as well as the use of carefully selected material for each member.

The arrangement of the poles in these chucks makes it possible to hold all classes of work from small washers up to pieces of sufficient size to cover the entire faceplate of the chuck. The arrangement of the poles is such that there is very little "dead" surface on the faceplate, so that when used for grinding small washers or other comparatively small parts, there is no need of using special devices for locating the pieces on the chuck. It is only necessary to cover the chuck with the washers and they will all be held securely in place. The water-proof feature is obtained by having all joints so tight that it is practically impossible for water to find its way into the windings. In fact, there is only one chance for water to get through, which is at the edge of the faceplate, and that chance has been made practically nil through having the joint ground to a very close fit. Even if moisture should get into the chuck, the coils are so thoroughly taped that they are practically water-proof.

These chucks may be used on either 110 or 220 volt current. Alternating current cannot be used, and in plants where only alternating current is available, a small generator may be installed to furnish the required current. An idea of the current consumption may be gathered from the fact that a 1/4 horsepower generator will supply sufficient current to run

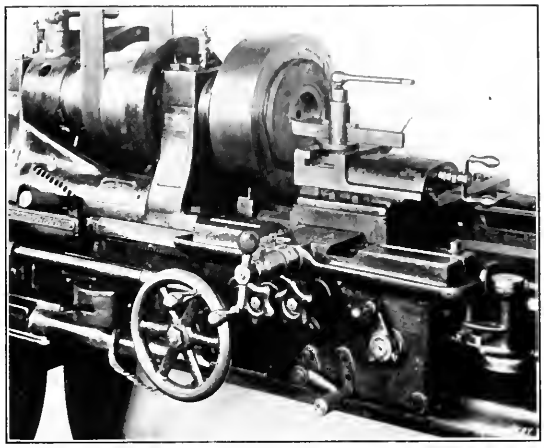

Fig. 7. Rotary Chuck set up on a Lathe

six of the 8-inch rotary chucks. An idea of the current required for different sizes of chucks may be gathered from the fact that a 12-inch rotary chuck requires only 0.6 ampere of current and the 8-inch rotary chuck requires 0.4 ampere. The 10 by 32-inch rectangular chuck takes 1.2 ampere.

The convenience of operation of the Heald magnetic chuck has led to its use in other classes of work than those for which it was originally designed. A typical example is shown in Fig. 6 which illustrates a 10 by 22-inch chuck which is being used as a scraping stand. The chuck is demagnetized for the removal of the work and the method is said to be far superior to that of holding the piece on a scraping stand. Fig. 7 shows a chuck mounted on a lathe and holding a cast-iron flange without the use of a center stud or side blocks. A facing cut 3/32 inch deep is being taken with a feed of 0.027 inch per revolution. The most striking application of the use of these magnetic chucks is illustrated in Fig. 2, which shows the chuck set up on a planer. A strip of machine steel is being held while a cut 5/16 inch deep is being taken with a feed of 5/32 inch. The cutting speed is 60 feet per minute and there is no tendency for the work to lift or move. The only support which the work received, aside from the holding power of the chuck, was from the guide strips at the end and on one side of the chuck. The same chuck was used on a milling machine for holding a cast-iron plate on which a 1-inch end milling cutter was fed to a depth of 5/16 inch, at a feed of 6 7/8 inches per minute.

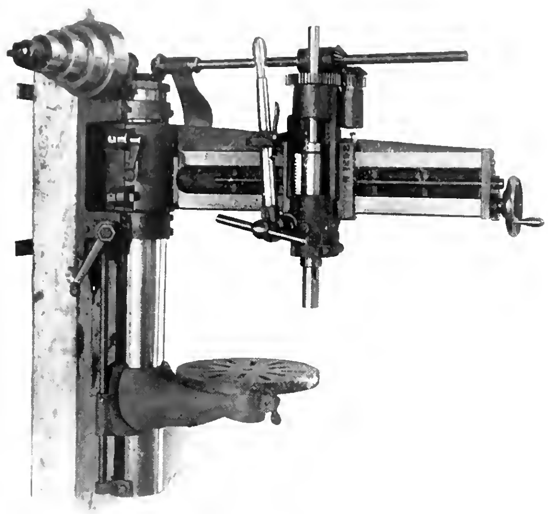
CANEDY-OTTO RADIAL DRILL

To meet the requirements of shops where a radial drill is needed, but where the price of a standard equipment of this type is prohibitive, the Canedy-Otto Mfg. Co., Chicago

Heights, Ill., has brought out the post type radial drill which is illustrated herewith. This is a powerful and accurate machine which is particularly adapted for use in machine shops, garages, blacksmith shops and bridge and boiler shops, where a wide range of drilling is done.

The drive is from a countershaft equipped with a four-step cone pulley and self-oiling bearings. This countershaft is customarily attached to the ceiling. The arm can be swung against the wall and it may be securely tightened in any position. The spindle head is traversed along the arm by means of a screw and handwheel. When the head has been brought to the desired position, means are provided for clamping it in place. The spindle has quick return by means of a hand lever, in addition to the regular hand feed which is provided by an independent lever.

The principal dimensions of the machine are as follows: Height, 56 inches; capacity for drilling to the center of a circle outside of the column 64 inches in diameter; maximum distance from center of spindle to column, 32 inches; minimum distance from center of spindle to the column, 7 inches; maximum distance from spindle to table, 18 inches; traverse of spindle, 9 inches; capacity for drills up to $1\frac{1}{4}$ inch in diameter; and net weight of machine, 800 pounds.



Canedy-Otto Post Type Radial Drill

UNION TWIST DRILL CO.'S GROUND HOBS

For several years makers of gear cutting hobs have been trying to manufacture one-piece ground hobs, that is, those on which the sides and tops of the teeth are ground accurately to shape. Only by grinding hob teeth all over is it possible to eliminate all the changes of shape developing in the hardening operation. The Union Twist Drill Co., Athol, Mass., succeeded in solving the problem commercially some time ago and is now prepared to furnish hobs with all faces accurately ground to shape.

The ordinary commercial hob is ground only in the bore except, of course, grinding on the faces of the teeth in the gashes, to sharpen them. The grinding of the bore, however, does not take care of any of the errors due to hardening except the distortion of the hole. At best, it merely averages the total errors, of which there are four classes, namely: changes of lead, distortion of individual teeth, varying distance between gashes, and distortion of the hob to an out-of-round shape. The Union Twist Drill Co. states that the shortcomings of the unground commercial hob cannot be fully realized until the corrections made by the all-over grinding process are observed.

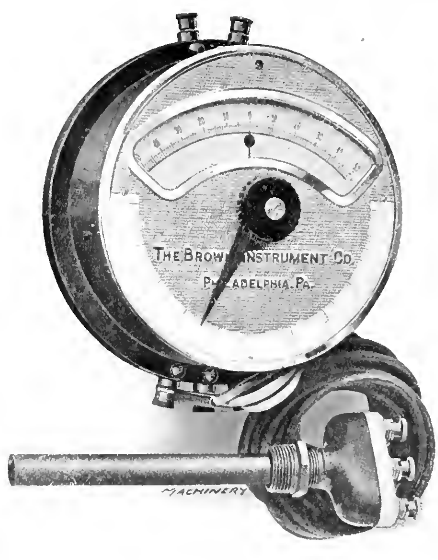
The advantages of the ground hob are not simply producing more nearly perfect gear teeth in the hobbed gears. The hob can be set up in the hobbing machine without reference to any particular tooth. When using unground hobs, it has been found necessary to center by some particular tooth in order to get the best results, but with the ground hob, the gears produced are equally good no matter what part of the hob is used for centering when setting up. Also, it is possible to use the end section of the hob and when this has become worn, the hob is moved along successively until all the teeth are dulled, when, of course, grinding the faces of the teeth to sharpen them is necessary.

To get the best results from ground hobs it is necessary that the gear cutting machine be in the best possible condition; in fact, it is more essential than ever that the machine be accurately adjusted and in perfect order. If end play in the spindle is present, or if the arbors are not true, the advantages of the ground hob will not be realized to the fullest possible extent. The superiority of ground hobs will not be so apparent on the general run of gear work as on the highest grade automobile gears and other constructions requiring smooth and noiseless action. The Union Twist Drill Co. furnishes the ground hobs at prices from 25 to 40 per cent higher than for the ordinary type of unground hob, the operation of grinding the sides of the teeth being a long and tedious one. At the present, the finest ground hobs that can be furnished are twelve diametral pitch.

BROWN RESISTANCE THERMOMETER

The Brown Instrument Co., Philadelphia, Pa., has recently brought out a new resistance thermometer for measuring temperatures from 200 degrees below zero to 1800 degrees Fahrenheit. This instrument is capable of great accuracy and is particularly adapted for measuring low temperatures which cannot be readily determined with the thermo-electric pyrometer. It is particularly suitable for determining the temperatures of driers and ovens, of the bearings of machines which may overheat, of the windings of motors and transformers, of refrigerating machines, and of furnaces used for the heat-treatment of steel where the temperature comes within the range of the instrument.

This thermometer consists of a bulb or coil of wire, the resistance of which changes with a change of temperature; and bulbs of this type can be located on various equipments in a plant, where information concerning the temperature of such equipments is desired. A three-wire cable connects these bulbs with the indicating instrument and switchboard which can be placed in any desired position. To determine the temperature, it is simply necessary to switch the proper bulb onto the indicating instrument. If a constant temperature is to be maintained, the pointer of the indicating instrument can be adjusted to the required temperature and



Brown Resistance Thermometer for Temperatures from — 200 to + 1800 Degrees F.

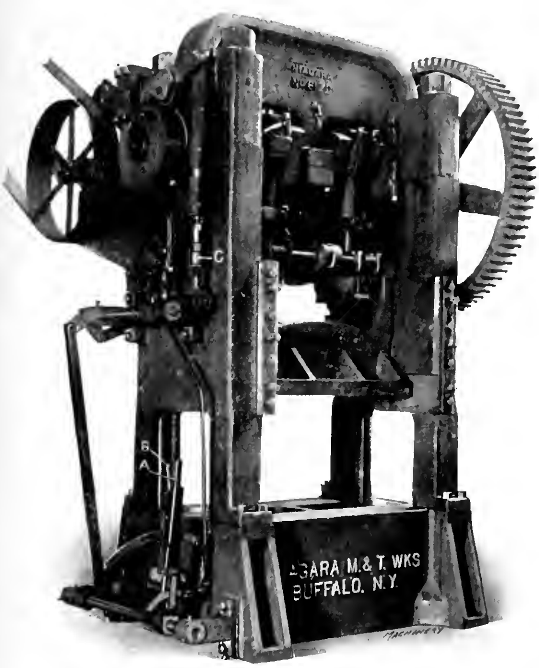
the deflection of the pointer on the upper scale of the instrument will show the increase or decrease in temperature from the required point. This new thermometer operates on either dry cells or storage batteries, or it may be connected with 110 or 220 direct current lighting circuits.

The chief advantages of the resistance thermometer are its suitability for use in determining moderate temperatures from one central location, eliminating the necessity of going about from one point to another to read the temperature as indicated by individual thermometers. As the bulbs used in connection with the new Brown thermometer are made entirely of metal, they are not likely to be broken. The indications of the instrument are guaranteed to be within 1 per cent of accurate.

NIAGARA DOUBLE CRANK PRESS

The accompanying illustration shows a large double crank press built by the Niagara Machine & Tool Works, Buffalo, N. Y. This machine is equipped with a device for controlling the clutch and the motion of the slide, which permits of engaging or disengaging the friction clutch at any time during the downward motion of the slide. The slide may also be automatically stopped at its highest position by this device, instead of by the treadle-actuated clutch that causes the crankshaft to make a complete revolution. The clutch is "non-repeating," as the controlling lever returns automatically to the starting point and is locked in position after the slide reaches its highest point.

In order to engage the clutch, the operator grasps the lever *A* and at the same time disengages locking lever *B*. The lever *A* is then pulled forward to the outer end of the segment and thus engages the clutch. The locking lever *B*

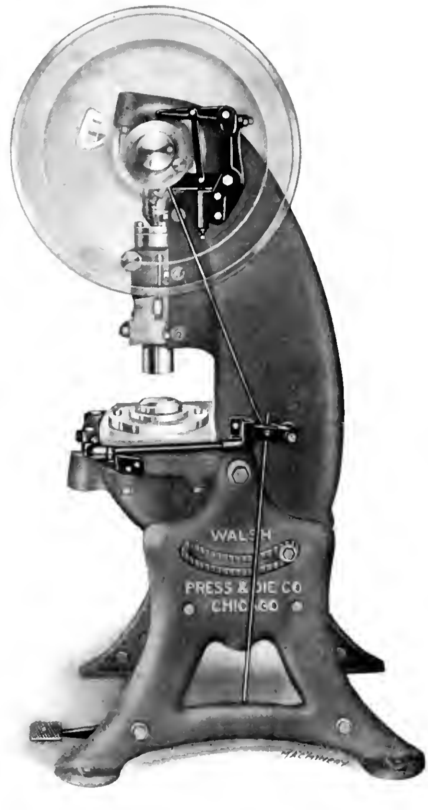


Niagara Double Crank Press equipped with Device for controlling Motion of the Slide

controls the action of a plunger engaging the connecting-rod *C*; *i. e.*, when the lever *B* is disengaged the connecting-rod *C* is also released, and the clutch lever *A* is free to be moved forward to engage the clutch. The return motion of the clutch lever is accomplished by means of a cam fastened to the outer end of the crankshaft. This improved feature can be applied to other presses equipped with a friction clutch. The present machine has the usual convenient features of adjustment that are found on all large Niagara presses. The driving mechanism is arranged overhead, thus making the machine accessible from all sides.

WALSH POWER PRESS SAFEGUARD

Among the various principles which have been applied in the design of safeguards to protect the operators of power presses from injury, one of the most successful is that in which the operator is required to use both of his hands in tripping the press. This principle has been applied to various forms of safeguards, one of the most recent of which is that manufactured by the Walsh Press & Die Co., 4709-4715 W. Kinzie St., Chicago, Ill. A Walsh inclinable press equipped with one of these guards is illustrated herewith. Referring to this illustration, it will be seen that there are two push buttons at the front of the die bed, and in order to trip the press, the attendant is required to push both of these buttons. The buttons are operated as easily as the keys of



Power Press Safeguard that requires the Operator to use both Hands to trip the Press

a typewriter, and they are placed at such a distance apart that it is impossible for both buttons to be pressed with one hand. In this way, it is impossible for a careless workman to have his hands on the die when the ram descends. The latch is automatically returned after each stroke of the press, so that it is impossible for the operator to only release the treadle enough to have it just draw the clutch bolt sufficiently to engage the edge of the latch—a practice which has been responsible for nine-tenths of the accidents where the claim has been made that the press "repeated." The entire mechanism can be locked back by means of a special key when the press is operated on ribbon stock. It is also possible to lock one of the two finger buttons, thus leaving one of the operator's hands free for feeding the press.

* * *

The effects of persistent advertising were never more forcibly felt than in the case of instructing workmen in the "safety first" movement. By the use of bulletins, lectures, printed warnings on pay envelopes and actual exhibitions, the need of caution on the part of the working-man is being emphasized. That it is having its effect is noticeable from the report of accident companies and industrial records.

NEW MACHINERY AND TOOLS NOTES

Draw-over Tool: J. Morrison Gilmour, 90 West St., New York City. A tool which takes the place of the hammer and chisel for drawing over holes which have run out at the starting point in drilling.

Portable Shear: The Canton Foundry & Machine Co., Canton, Ohio. A shear which is motor-driven and entirely self-contained; it is mounted on a truck so that it can be moved around the shop to any required position.

Gear Guards: Consolidated Expanded Metal Companies, New York City. Gear guards made of expanded mesh, which are known as the "steelcrete" mesh guards. They are made of cold-drawn mesh fabricated from basic open-hearth steel.

Surface Gage: W. P. Kirk, 336 W. 4th St., Cincinnati, Ohio. A surface gage of simple design which is particularly adapted for rapid manipulation. This gage is suitable for use on a wide range of work where accurate dimensions are required on interchangeable parts.

Hydraulic Press: E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y. A hydraulic press built for drawing steel barrels in the plant of the Hydraulic Pressed Steel Co., Cleveland, Ohio. This is said to be one of the largest equipments of this type which has ever been built.

Axle Turning Lathe: Niles-Bement-Pond Co., 111 Broadway, New York City. A lathe designed for use in railway shops for turning and truing axles. The machine may be used for turning axles before the wheels are pressed in place and also for truing the journals after they have become worn.

Portable Arbor Press: Brickell Mfg. Co., Boston, Mass. A portable arbor press designed for pushing pulleys off shafts and for similar operations. As the pressure is applied directly to the member to be removed—close to the point where it hugs the shaft—an unusually high efficiency is secured.

Planers: Cincinnati Planer Co., Cincinnati, Ohio. A line of light planers built in 24-, 26-, 28- and 30-inch sizes. The notable features of the design of these machines consist of an extremely simple belt-shifting mechanism and a bed constructed in such a way that all of the gears are completely enclosed.

Gap Lathe: Summitt Machine Works, Worcester, Mass. A 10-20 inch gap bed engine lathe. The machine is also built with a plain bed. The carriage is arranged for the use of a taper attachment which can be applied at any time. The swing is 7½ inches and the weight of the machine with a 4-foot bed is 550 pounds.

Self-lubricating Bushings: The Graphite Metallizing Corp., Yonkers, N. Y. Bushings made of a product known as "graphalloy." This consists of graphite impregnated with molten metal, and it is said that the material makes excellent bushings for use on light duty machines, these bushings being self lubricated.

Slotter: Newton Machine Tool Works, Inc., Philadelphia, Pa. A crank slotter in which the speed-gear change mechanism is located in the head. The cutter bar carries a relief tool apron with vertical and horizontal clamping faces. The face of the bar is serrated to relieve the adjusting screw from strain when the tool is under cut.

Shaper Feed Mechanism: John Steptoe Co., Cincinnati, Ohio. An improved feed mechanism applied to the line of shapers built by this company. The mechanism is so designed that it may be employed as either a vertical or a cross feed. Previous machines built by this company have been equipped with only power cross feed.

Universal Woodworking Machine: Crescent Machine Co., 56 Main St., Leetonia, Ohio. A machine consisting of five units which comprise a band saw, a saw table, a jointer, a shaper and a boring machine. All of these are so mounted that any f them can be used independently, and the machines which are not in use do not have to be driven.

Engraving Machine: Alfred H. Schütte, Cedar and West Sts., New York City. A precision engraving machine which operates on the pantograph principle. The pantograph has four arms, three of which are adjustable by means of scales furnished with the machine. By means of these adjustable arms, it is possible to obtain any reduction between the limits of 1 to 1 and 10 to 1.

Fuel Oil Burner: Bellevue Furnace Co., Detroit, Mich. A burner designed to operate on a low pressure of air which is the means of greatly reducing the tendency toward scaling. The oil control is effected by means of a regular needle valve. The air controller consists of a central tube which carries the oil through the jet nozzle where it is mixed with the air and thus atomized.

Milling Machine: Gooley & Edlund, 581 S. Clinton St., Syracuse, N. Y. A manufacturing milling machine which is styled a Type-B Briggs miller. The distance between the housings is 17 inches; the working surface of the table, 54 by 11 inches; the traverse, 34 inches; and the maximum distance from the table to the center of the arbor, 15 inches. The weight of the machine is 4500 pounds.

Circular Saw Guard: L. F. Grammes & Sons, Allentown, Pa. A guard consisting of a number of shields suspended from a horizontal bar which, in turn, is supported by a rod connected to the ceiling. The bar from which the shields are suspended is supported in such a way that it will not vibrate. As the work is advanced to the saw, the shields are raised to provide the necessary clearance.

Conversion Chart for Money Values: S. C. Carpenter Drafting & Engineering Co., Hartford, Conn. In the March, 1914, number of MACHINERY, the Nos. 1, 2, 3 and 4 conversion charts made by this company were described. Since that time a No. 10 chart has been brought out which affords an easy method of converting the value of various foreign moneys into the equivalent in United States money.

Roll Grinding Machine: A. Garrison Foundry Co., Pittsburg, Pa. This company has recently redesigned the machine of its manufacture used for grinding chilled rolls. The special feature of the new machine consists of a mechanism for grinding tapered rolls. The capacity is for rolls up to 32 inches in diameter with necks which are not more than 9 inches smaller than the body of the roll.

Air Compressors: Clayton Air Compressor Works, 115 Broadway, New York City. Three types of air compressors which are particularly adapted for use in industrial plants requiring small amounts of compressed air. One of these is a portable motor-driven unit. The other two units are also motor-driven, one being a two-stage compressor and the other an automatic outfit designed to operate either continuously or intermittently.

Horizontal Milling Machine: Newton Machine Tool Works, Inc., Philadelphia, Pa. A duplex horizontal milling machine which has a table 20 inches in width. The table has positive geared feed and reversing fast power traverse. The spindles are driven by solid bronze worm-wheels and hardened steel worms. The spindle saddles are counterweighted and provided with hand vertical adjustment. The minimum distance between the spindles is 3 inches and the maximum distance 28 inches.

SPRING MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The spring or semi-annual meeting of the American Society of Mechanical Engineers was held in St. Paul and Minneapolis, Minn., June 16-19. Several of the papers presented dealt with the great engineering developments of the Northwest, with moving pictures showing ore handling on the Great Lakes. Opportunity was afforded the members to visit the milling district of Minneapolis, with its daily output of 84,000 barrels of flour, and to see the water power developments of the Mississippi River. Three professional sessions were held at which the following papers were presented:

"Pulverized Coal Burning in the Cement Industry," by R. C. Carpenter.

"Pulverized Coal for Steam Making," by F. R. Low.

"Industrial Service Work in Engineering Schools," by J. W. Roe.

"Classification and Heating Values of American Coal," by William Kent.

"The Railroad Track Scale," by W. W. Boyd.

"Gear Testing Machine," by Wilfred Lewis.

"The Flow Metering Appliance," by A. M. Levin.

"Power Development of the High Dam between Minneapolis and St. Paul," by Adolph F. Meyer.

"The Handling of Coal at the Head of the Great Lakes," by G. H. Hutchinson.

"Minneapolis Flour Milling," by Charles A. Lang.

* * *

A Curtiss aeroplane driven by two 100-H.P. eight cylinder motors is being built at Hammondsport, N. Y., to cross the Atlantic. Lieut. John C. Porte proposes to make the trip starting from St. Johns, Newfoundland, and landing at the Azores to rest and replenish the supply of gasoline. Thence he will go to Vigo, Spain, and thence to Plymouth, England. The estimated distance from St. Johns to the Azores is 1199 miles; from the Azores to Vigo, 963 miles; and from Vigo to Plymouth, 523 miles, making a total of 2685 miles. The estimated speed is sixty miles an hour and the total elapsed time for the flight is to be fifty-five hours, which gives an allowance of ten hours at the stopping places for replenishing fuel and resting.

BAR STOCK GUARD FOR TURRET LATHES

BY S. H. EARL*

The accompanying illustrations show a bar stock guard for turret lathes which has recently been installed in the Gleason Works, Rochester, N. Y. Referring to these illustrations it will be seen that the portion of the bar extending out from the spindle of the machine is completely enclosed so that it is impossible for the operator or those working in the vicinity of the machine to be injured.

The pipe which surrounds the stock is about one inch larger in diameter than the hole through the spindle of the machine. This pipe is mounted on brackets which are permanently fitted to the stock support standards at a sufficient distance below the stock support crotches to allow the crotches to be adjusted for various sizes of stock without adjusting the pipe. It will thus be evident that the stock is supported by the standard crotches provided with the machine and not by the pipe, which is merely employed to cover the stock to provide for the safety of employes. The pipe is split and the two halves hinged together, so that the guard may be easily opened to provide access in handling short bars. Fig. 1 shows the guard with the pipe open and in Fig. 2 the guard is shown closed ready for operation. Fig. 3 shows one of the supporting brackets in detail, together with the way in which the stock support crotch may be adjusted independently of the guard.

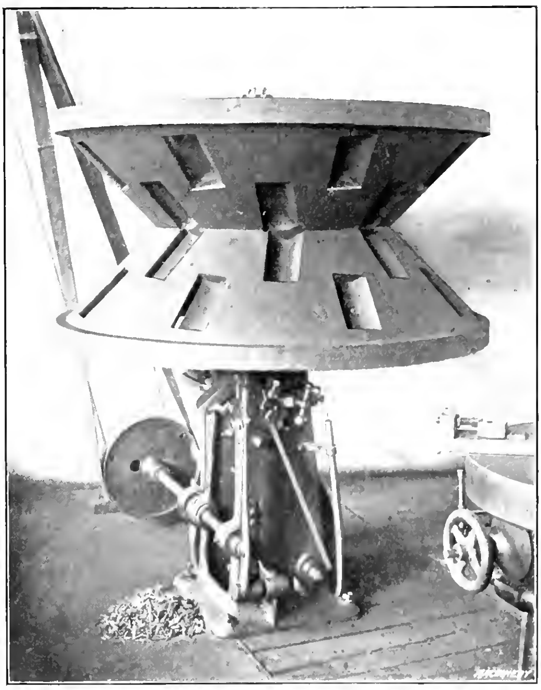
AN UNUSUAL KEYSEATING OPERATION

A No. 3A keyseating machine of 25-inch stroke, built by Mitts & Merrill, 843 Water St., Saginaw, Mich., is shown in the accompanying illustration, working on a decidedly unusual job. The work is a cylinder for an edging grinder which is used for grinding up refuse in saw mills. The capacity of this machine is 20 cords of wood per hour. The bore in the cylinder is 7 inches in diameter by 28 inches long, with a hub on each end which is 12 inches long. It is required to cut two keyways for tapered keys in this bore, the keyways being located 90 degrees apart; and they are $1\frac{1}{2}$ inch wide by 11/16 inch deep at the deep end. The deep end of one keyseat is at one end of the bore and the deep end of the other keyseat is located at the opposite end of the bore. This keyseating operation was performed without re-



Unusual Keyseating Operation on a Mitts & Merrill No. 3A Keyseater

quiring the cylinder to be reversed. As the combined length of the keyseats is longer than the stroke of the machine, the cutter and feed wedge had to be shifted. The keyways were cut in one hub at a time. Despite the conditions under which it was necessary to do the work it was found that the keyways were as accurately aligned as though they had been machined by a continuous cut.

GUARDS FOR GEARS AND DRIVING BELTS

In view of the stringent legislation enacted by various states in regard to the guarding of gears and belts in manufacturing shops, this subject has become of general interest.

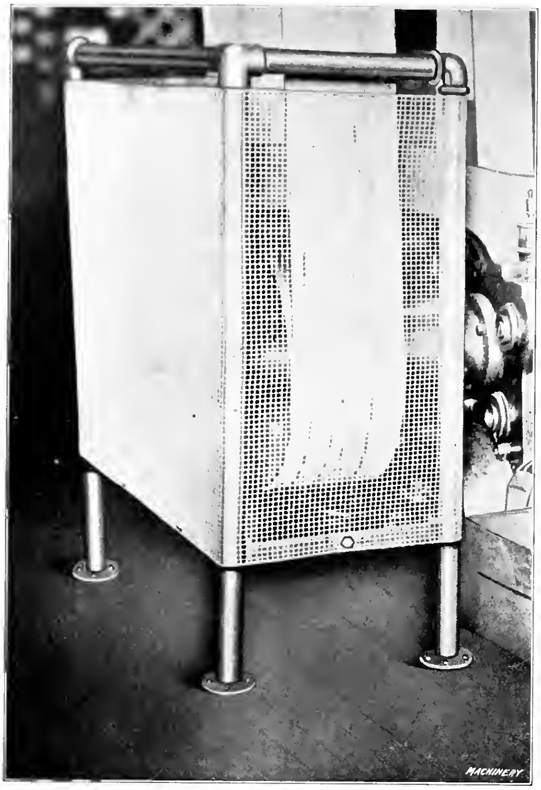

Fig. 1. Efficient Type of Guard for Gears or Driving Belts

An efficient belt guard is used in the shop of the Hays Mfg. Co., Erie. Pa. The illustration Fig. 1 gives a general idea of the way this guard is installed to protect a driving belt. The guard is composed of piping with the wire screening wrapped around. The most interesting feature, however, is the method by which the guard may be removed for shifting the belt, oiling or repairs. This is shown in the line illustration Fig. 2. The three uprights, composed of pipes, are not made fast to the floor, but are slipped over

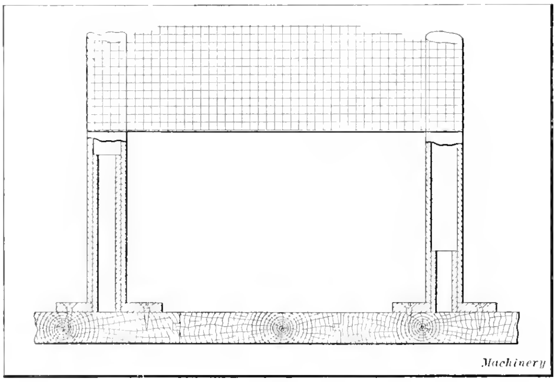

Fig. 2. Showing Removable Feature of Guard

short lengths of flanged pipes that are screwed into the floor in the correct locations. One of the flanged pipes is about six inches in height. The others are short sections of approximately three inches, as shown at the right of the illustration Fig. 2. To remove the guard for oiling, it is simply necessary, therefore, to lift it three inches to clear the short lengths of flanged pipe, and swing it around on the pivot of the longer section at the outer corner. If necessary the guard may be raised entirely from connection with the flanged part. Guards of this type are cheap and strong, yet at the same time they are effective. C. L. L.

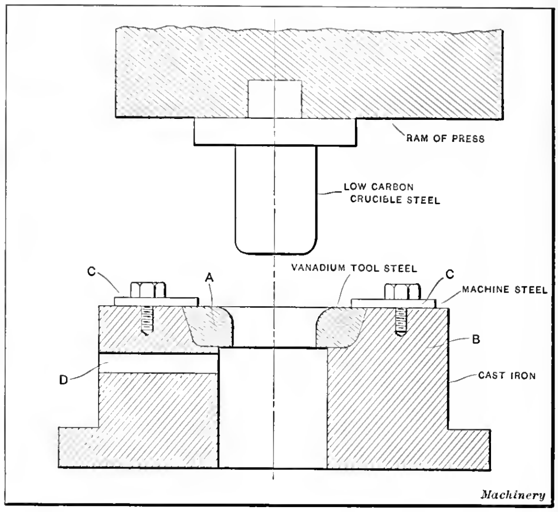
MOUNTING DRAWING DIE RINGS IN CAST-IRON SHOES

In the March number of *American Vanadium Facts*, the mounting of a die ring in a cast-iron shoe, a practice of the Acklin Stamping Co., Toledo, Ohio, was illustrated and described. The ring, which was made from a special brand of "Ceswic" vanadium tool steel, was turned to the form shown in the accompanying illustration and tapered 1½ degree on the sides. This die ring was used for blanking a cup from ¼-inch sheet steel, and produced 10,000 of these cups without any indication of wear. To draw up a cup of the following



Mounting Light Die Rings in a Cast-iron Shoe

dimensions—3½ inches in diameter by 1¼ inch deep—from ¼-inch stock requires that the die be rigidly supported.

Referring to the illustration it will be seen that the vanadium tool steel die ring *A* is held in a cast-iron shoe *B* by heavy steel plates *C*. In some cases these plates take the form of a continuous ring instead of individual plates. The three holes *D*, only one of which is shown, are utilized in operating dogs that remove the cup from the punch. The machine steel plates *C* also act as a gage for locating the blank when drawing. The taper on the edge of the die, which is shown greatly exaggerated in the illustration, is not over 1½ degree, and it has two advantages: First, it enables a close contact between the supporting cast-iron shoe and the light steel die ring to be secured. The outside of the die ring is ground so that it will be perfectly true with the hole, and to such dimensions that when it is dropped into place in the die shoe it will stand up about 1/64 inch above the top surface, resting only on the tapered sides. Pressure is then applied to force it down to the bottom, seating it in the die shoe; this puts a strain on the cast iron and insures the desired contact between the shoe and ring.

Another reason for the taper is that after the die ring has been in use for some time and it is necessary to redress it, it is much easier to chuck the ring up for machining than it would be to chuck up both the ring and shoe together, and the slight taper on the sides allows the ring to be easily driven out, whereas if the hole were straight and the die ring wedged in with the same pressure, considerable difficulty

would be experienced in removing it. For drawing heavy sheet metal 1/4 inch thick, very little, if any, float of the die is necessary, so this forms a very satisfactory means of holding the die ring. It also increases its life considerably, as the cast-iron shoe takes all the strain.

The heat-treatment given to drawing dies made from "Ceswic" special vanadium tool steel is as follows: The steel, which generally comes in flat disks 6½ inches in diameter by 1¼ inch thick, is annealed before it leaves the mill. After being machined the dies are heated to a temperature of about 1450 to 1500 degrees F. in a muffle furnace and are then quenched in cold water, a current of water being forced down to the center hole. The object in thus directing the water is to harden the surface of the hole, leaving the balance of the die ring comparatively soft and as tough as possible. The die blanks are then drawn to a light straw color, just enough to remove the hardening strain. The life of a die made from this brand of steel was found to be over twice as long as that of one made from any other steel that the Acklin Stamping Co. tested for this job.

* * *

A NEW ARC WELDING MACHINE

A wide field has been opened up to electric arc welding within the last few years. For boiler repairs in particular, this form of welding has been extensively adopted. There are three different systems of arc welding, the oldest of which is the Bernardos. In this system a carbon electrode is connected to one pole of a source of supply, the article to be welded being connected to the other. In this manner an arc can be formed between the carbon and the work which corresponds to the flame in autogenous welding. The workman manipulates the carbon rod similarly to an autogenous welding burner; he has the advantage of only having to use one hand, however. As soon as he touches the work with the carbon electrode, current passes; when he removes the electrode a few millimeters a welding arc is formed which causes the surface of the work to melt on account of its heat. If fresh metal has to be added, a bar of metal is held in the arc, where it reaches a molten condition and drops onto the part to be welded. In place of the Bernardos process that of Slavianoff is frequently employed. In this latter process, in place of the carbon electrode, a metal rod similar in composition to the article to be welded is employed. This rod melts gradually.

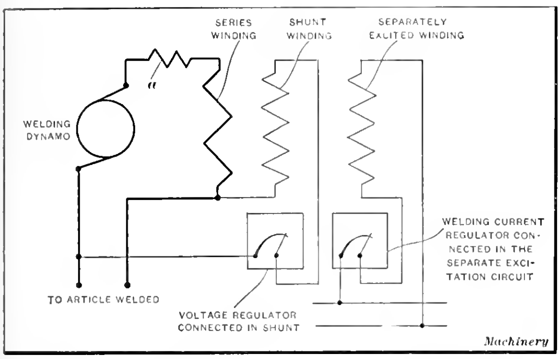


Fig. 1. Wiring Diagram of Kramer Electric Welding Machine

The third welding process is Zerener's. By this method, two carbon electrodes are fixed in a suspended armature at an angle to each other. The arc formed between them is blown against the article to be welded by an electro-magnet. Both carbon rods are connected through the armature and brought over the work together, thus forming a substitute for an electric welding burner. Direct current is used in all three processes. The arc requires pressures from 45 to 65 volts. The special properties of the arc welding process make it necessary to employ special dynamos for generating the welding current. It is impossible to avoid the constant lengthening of the arc, and therefore the alteration of its resistance while welding. When the electrodes touch, for example, a short circuit is set up, and on moving them backward and forward the length of the arc can be varied within wide limits. In consequence of the considerable changes of resistance thus brought about the current can only be taken from a direct-current network or shunt generator after special series resistances have been connected in circuit, which occasions a great loss of energy.

The Allgemeine Elektricitäts-Gesellschaft, Berlin, Germany, developed methods some time ago for utilizing the welding energy without losses. Further progress has now been made in this direction by the use of a welding dynamo connected in accordance with the Krämer patent. This machine generates energy at the required voltage directly, and always supplies current of the same strength, notwithstanding considerable resistance fluctuations in the welding circuit. At the same time a perfectly steady arc is obtained. The heat flowing to the article welded is therefore quite constant, a matter of cardinal importance for satisfactory welding. The peculiar property of the new Krämer welding dynamo of giving a

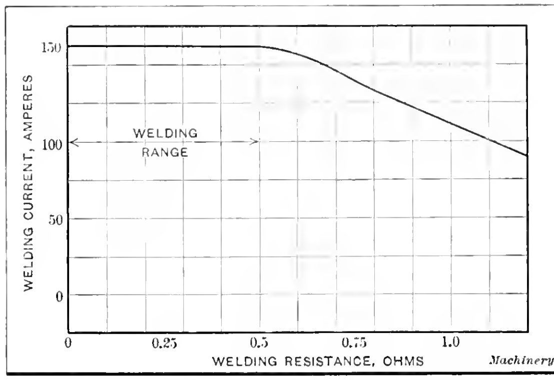

Fig. 2. Diagram of Current in Relation to Resistance

constant current with a variable resistance is obtained by means of a three-fold field excitation, as may be seen from the diagram of connections in Fig. 1, reproduced from *The Mechanical Engineer*. One field winding is a differentially connected series winding, the second is a shunt, and the third a separately excited winding which receives current from a special network with a constant voltage. Any given welding current most suitable for the work can be obtained by adjusting the regulator for the separate excitation. The voltage of the machine may be altered by the regulator for the shunt excitation. Thus a finely graduated adjustment of the current and voltage may be obtained by suitably arranging the two regulating resistances, so that the machine can be adapted within wide limits to the requirements for the welding work in hand. Fig. 2 illustrates the value of the current for a Krämer machine adjusted for a welding current of 150 amperes. It clearly shows that the welding current remains constant even when the arc resistance varies from zero (*i. e.*, short circuit) to 0.5 ohm. Only after attaining a still higher resistance does the current begin to fall gradually.

PERSONALS

Augustus Teuchter, of the Cincinnati Bickford Tool Co., Cincinnati, Ohio, sailed June 16 for a European trip.

James O. Smith, formerly domestic sales manager of the American Emery Wheel Works, Providence, R. I., has been elected vice-president.

Erik Oberg, associate editor of MACHINERY, sailed with his wife and son, May 13, for a two months' trip to England, France, Germany, Denmark, Sweden and Belgium.

Henry Dreses of the Dreses Machine Tool Co., Cincinnati, Ohio, builder of drilling machines, sailed June 16 on the *Kronprinzessin Cecilie* for a three months' business trip in Europe.

H. P. Fairfield, instructor in shop engineering with the Worcester Polytechnic Institute, Worcester, Mass., has been promoted to an assistant professorship of machine construction.

R. S. Alter, secretary of the American Tool Works Co., Cincinnati, Ohio, left on Saturday, June 13, for a combined business and pleasure trip through Great Britain and the Continent.

Read Page 71

Elmer E. Metzger recently resigned the position of works manager with the Esterline Co., Indianapolis, Ind., and has been appointed works manager by the Geometric Tool Co., New Haven, Conn.

M. J. O'Neill, general manager of the Industrial Press, sailed with his family, June 25, for a two months' trip in Europe, visiting England, Holland, Belgium, Germany, Switzerland and France.

Dr. Robert Grimshaw of Dresden, Germany, a well-known contributor to technical journals and a former resident of the United States, was married to Miss Marta Scharfstein at the home of the bride, Schleswig-Holstein, May 15.

R. Poliakoff, assistant professor and lecturer in mechanical technology in the Imperial Technical Institute of Moscow, Russia, is visiting manufacturing plants in the United States to study their methods of manufacturing, management, etc. Prof. Poliakoff expects to be in the United States about ten weeks.

J. L. Bender, recently sales manager of the Grant-Lees Gear Co., Cleveland, Ohio, has taken charge of the sales department of the Yuster Axle Co. of Cleveland. Mr. Bender has been in the automobile field for years and has the benefit of long training in the organizations of two companies in the automobile axle field, the American Ball Bearing Co. and the Timken Roller Bearing Co.

William A. Bole has been elected by the directors of the Westinghouse Machine Co. vice-president in charge of production and erection for the plants at East Pittsburg and Trafford. Mr. Bole has been in the continuous employ of the company since August, 1882, having successively filled the positions as general shop foreman, superintendent, manager of works and consulting engineer. He has therefore taken part in the growth and development of the company since the time when it employed less than one hundred men until the present, when the total forces run up into the thousands.

Richard Ward Baker, for fifty years an employe of the Watson-Stillman Co. of Aldene, N. J., and New York City, was presented with a substantial check and a month's vacation in recognition of his long term of service. Mr. Baker began his apprenticeship in a small factory in Grand St. June 2, 1864, and has been continuously identified with the Watson-Stillman Co. and its predecessor ever since. The board of directors of the company passed a special resolution expressing its high esteem of Mr. Baker's long and loyal service, which was presented to him in the presence of the employes, officers and directors at its Aldene plant.

OBITUARY

Paul L. Heroult, who developed the electric furnace process of manufacturing aluminum in 1887-8, simultaneously with C. M. Hall in America, converting it from a laboratory curiosity into a common household article, died in Paris May 9, aged fifty-one years.

COMING EVENTS

July 15-22.—Second International Congress of Consulting Engineers, to be held in Berne, Switzerland.

September 5-11.—Foundry and machine exhibition, showing machinery, tools, equipment and supplies for the foundry and machine shop, Chicago, Ill. C. E. Hoyt, secretary, Foundry & Machine Exhibition Co., 1949 W. Madison St., Chicago, Ill.

September 15-18.—Twenty-second annual convention of the Traveling Engineers' Association at the Hotel Sherman, Chicago, Ill. W. O. Thompson, secretary, c/o New York Central Car Shops, East Buffalo, N. Y.

September 17-22.—Autumn meeting of the Iron and Steel Institute in Paris, France. Offices of secretary, 28 Victoria St., London, S. W., England.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal. In connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

SOCIETIES, SCHOOLS AND COLLEGES

University of the State of New York, Albany, N. Y. Bulletin 569 containing list of helpful publications concerning vocational instruction, prepared by Lewis A. Wilson, specialist in industrial schools. 41 pages, 6 by 9 inches. Published by the University of the State of New York, Albany, N. Y.

Williamson Free School of Mechanical Trades, Williamson School P. O., Delaware County, Pa. Bulletin 15 containing record of graduates. This bulletin gives a summary of replies sent in answer to a letter of inquiry addressed to 863 former students. The annual income of 664 graduates is a little over $1,000,000, or an average of $1512 yearly each.

NEW BOOKS AND PAMPHLETS

Mine Signboards. By Edwin Higgins and Edward Steidle. 13 pages, 6 by 9 inches. Illustrated. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 67.

Abstracts of Current Decisions on Mines and Mining. By J. W. Thompson. 140 pages, 6 by 9 inches. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 79, Law Serial 2.

Problems of the Petroleum Industry. By Irving C. Allen. 20 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 72, Petroleum Technology 17.

Safety and Efficiency in Mine Tunneling. By David W. Brunton and John A. Davis. 271 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Mines, Department of the Interior, Washington, D. C., as Bulletin 57.

Physical and Chemical Properties of the Petroleums of California. By Irving C. Allen, Walter A. Jacobs, A. S. Crossfield and R. R. Matthews. 38 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 74, Petroleum Technology 18.

Hydraulics. By Ernest H. Sprague, 184 pages, 4½ by 7¼ inches. 89 illustrations. Published by Scott, Greenwood & Son, London, England, and sold in the United States by D. Van Nostrand Co., 25 Park Place, New York City. Price $1.25 instead of $1, as quoted in the review notice which appeared in the May number.

Tests of Bond between Concrete and Steel. By Duff A. Abrams. 238 pages, 6 by 9 inches. 86 illustrations. Published by the Engineering Experiment Station, University of Illinois, Urbana, Ill., as Bulletin 71.

This bulletin furnishes one of the most exhaustive studies of the amount and distribution of the bond stress between concrete and steel that has been published. It records the results of tests of about 1500 pull-out specimens and 110 large reinforced concrete beams. The tests covered a wide range of ages, mixes, size of bar, length of embedment, condition of storage, method of supplying the load, etc. Both plain and deformed steel bars were used.

Official Report of the National Machine Tool Builders' Association. 161 pages, 6 by 9 inches. Illustrated. Published by the National Machine Tool Builders' Association, Charles E. Hildreth, general manager, Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass.

This report contains the proceedings of the semi-annual convention of the National Machine Tool Builders' Association, held at the Hotel Bancroft, Worcester, Mass., April 23-24. The papers presented were: "What Features of Electric Motors can be Standardized for Machine Tools," by Charles Fair of the General Electric Co., Schenectady, N. Y.; "How May We and Our Men Earn More Money," by J. C. Spence, superintendent, Norton Grinding Co., Worcester, Mass.; and "Safety as applied to Grinding Wheels," by R. G. Williams, safety engineer of the Norton Co., Worcester, Mass.

Modern Methods of Waterproofing. By Myron H. Lewis. 40 pages, 6 by 9 inches. Illustrated. Published by Norman W. Henley & Son, New York City. Price, 50 cents.

The efficiency and durability of ordinary concrete work are detrimentally affected in many instances by the fact that it is not waterproof. Permeable concrete is likely to be seriously damaged in winter by freezing and in many instances it is absolutely necessary that the seepage of water be prevented, especially in cellars and other places where goods are stored. The pamphlet which forms a chapter of the author's new book, "Popular Handbook for Cement and Concrete Users," treats of the necessity for waterproofing; method of conducting the work; methods of waterproofing, which are designated as three, these being the membrane, integral and surface coating method. The composition of some of the waterproofing compounds in use is given and an outline of the methods available for various structures. The approximate cost of waterproofing is included, a feature that will be generally appreciated by builders.

Fan Engineers' Handbook. Edited by Willis H. Carrier, chief engineer. 581 pages, 4¼ by 6¾ inches. Illustrated. Bound in leather with rounded corners and gilt edges. Published by Buffalo Forge Co., Buffalo, N. Y. Price $3.

This work, containing tables, charts and data on the application of centrifugal fans and fan system apparatus, including engines and motors, air washers, hot blast heaters and systems of air distribution, is essentially a handbook for the heating and ventilating engineer. It is divided into five parts, the contents of which are as follows: Part 1, Properties of Air; Part 2, Applications—Heating, Ventilation, Air Washing, Cooling, Humidifying, Drying, Mechanical Draft, Exhaust Systems and Miscellaneous Applications; Part 3, Air Ducts; Part 4, Apparatus, Fans, Fan Testing, Fan Capacities, Fan Dimensions, Heaters, Air-conditioning Apparatus, Steam Engines, Practical Applications and the Selection of Apparatus for Heating and Ventilating; Part 5, Specifications, Miscellaneous Engineering Data. This valuable compilation of data edited by Mr. Carrier should be welcomed by engineers generally concerned with any of the problems incident to the movement of air.

Standard Gear Odontographs. By Warren E. Thompson. 37 pages, 8½ by 11 inches. Illustrated. Published by Warren E. Thompson, 42 Sayles St., Southbridge, Mass. Price $2.

The book is issued in a small edition, the illustrations and tables being blueprinted and the text "multigraphed." It describes the method of laying out 14½-degree and 20-degree pressure angle gears, giving odontograph tables for both which agree closely with the tables used by the principal manufacturers of so-called "involute" gear cutters. Contrary to the general impression, commercial form cutters do not produce true involute teeth; the curves are modified to eliminate the interferences that are developed in a set of interchangeable gears ranging from a 12-tooth pinion to the rack. The diagrams show exactly how to lay out the empirical curves, giving all the required data. A feature of the book that will be of great interest to all toolmakers is the description of making the forming tool. Probably the making of tools for forming gear cutters is the most highly developed toolmaking practice. The block templet system is described which enables the toolmaker to produce forming tools of any required circular or diametral pitch for a given number of teeth from one pattern.

NEW CATALOGUES AND CIRCULARS

Kales-Haskel Co., Detroit, Mich. Folder giving dimensions of card-holders and pipe and wire clips.

Link-Belt Co., Chicago, Ill. Book 195, 40 pages, 6 by 9 inches, treating of Link-Belt newspaper conveyors.

W. W. & C. F. Tucker, Hartford, Conn. Circulars of self-closing oil hole covers, styles D, E, F and G.

M. H. Fischer & Sons Co., Inc. 41 Park Row, New York City. Circular of Fischer's automatic press guard.

C. G. Garrigus Machine Co., Bristol, Conn. Circular of 12-inch rotary precision surface grinder with magnetic chuck.

Buckeye Engine Co., Salem, Ohio. Bulletin 111-B descriptive of the "Buckeye-mobile" engine for which a very low fuel consumption is claimed.

Chambersburg Engineering Co., Chambersburg, Pa. Calendar for June, 1914, to June, 1915, illustrating a Chambersburg 10-ton steam drop-hammer.

Sterling Grinding Wheel Co., Tiffin, Ohio. Circulars and price lists of "Seneca" hacksaw blades and "Sterling" and "Advanced Safety" grinding wheels.

Manufacturing Equipment & Engineering Co., Boston, Mass. Leaflets of sanitary bubbling fountain, sanitary washbowls and metal and fire-proof equipment for shop and office use.

Volcano Torch & Mfg. Co., Erie, Pa. Circular supplementing catalogue 17, describing "Volcano" torch No. 3-C. This torch generates its own pressure and no air pump is required.

Walworth Mfg. Co., maker of brass and iron valves and fittings, Boston, Mass., is issuing a monthly publication entitled "The Walworth Log" devoted to the interests of the company.

H. G. Smith & Co., Plantsville, Conn. Leaflet illustrating the "Gittatit" off-set combination slip joint plier, illustrating its use as a cotter-pin extractor, wire cutter and off-set handle wrench.

Pawling & Harnischfeger Co., Milwaukee, Wis. Bulletin 3018 on the applications of electric hoists, showing one- and two-ton hoist installations handling paper, bar iron, pipe, plates, boxes, machinery, etc.

Bury Compressor Co., Erie, Pa. Catalogue 44, 40 pages, 6 by 9 inches, on air and gas compressors and vacuum pumps. A number of installations of Bury air compressors in various plants are shown.

W. L. Brubaker & Bros., 50 Church St., New York City. Illustration and list of hexagon bolt

COLD CHIPS

450 FEET CUTTING SPEED

Feed, 30½"; depth, ⅛"; width, 5"; length, 18"; material, machinery steel; 55,000 pounds tensile strength.

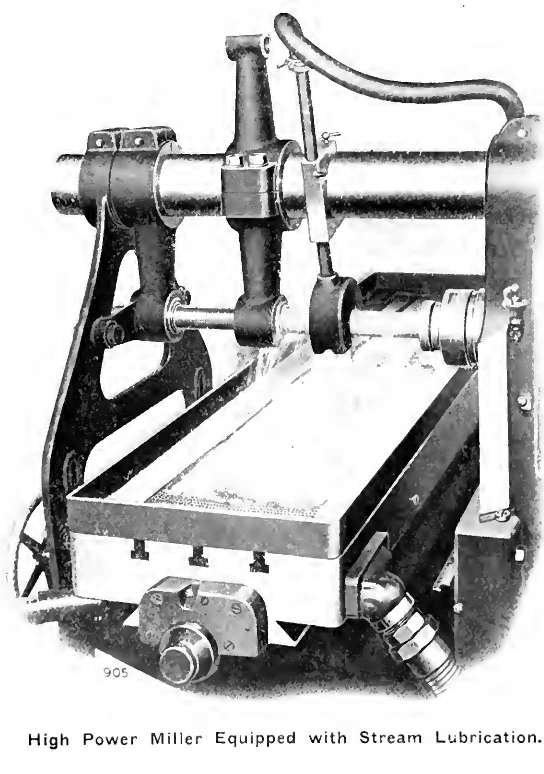
At this speed these chips came off as cold as the block from which they were milled. The cutter ran all day with no appreciable signs of distress.

The Cincinnati Stream Lubrication or Cutter Cooling System (patented) enables us to mill in actual practice THREE to FIVE times faster than has been possible in the best practice with high-speed steel cutters.

The fundamental principle of the system is the container—or CUTTER HOOD that retains the lubricant around the cutter, forcing it to run in an inverted bath, completely cooling it. This device is patented. The system has other essential features, described fully in our pamphlet.

Why don't you profit by this new discovery? Write us for details how to apply its advantages to your milling work.

A copy of "Cold Chips" is yours for the asking.



High Power Miller Equipped with Stream Lubrication.

The Cincinnati Milling Machine Company

CINCINNATI OHIO, U. S. A.

dies. This form of die is very convenient for use in close quarters in straightening bruised threads on studs and bolts.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin 31-C describing and giving specifications for Chicago Classes "H-SO" and "N-SO" pneumatic gasoline and fuel oil engine driven compressors.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Pamphlet on Hess-Bright ball bearings for axle lighting generators, comprising a brief discussion of ball bearings and their application to axle generators.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Catalogue 3002-A, Section 3049-A on electric arc welding processes, illustrated with examples of work done and describing Westinghouse electric arc welding outfits.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Sheets 99, Class IV and 100 Class V, dealing with ball bearing mountings for semi-floating rear hub and ball bearing mountings for jib crane columns, respectively.

Canedy-Otto Mfg. Co., Chicago Heights, Ill. Circular of wall or post radial drill No. 50, especially adapted for work in shops where a radial drill is necessary but too costly. It drills to center of circle 64 inches diameter, outside of column.

Standard Tool Co., Cleveland, Ohio. Folder descriptive of the "Standard" patent emery wheel dresser. The cutter is of hardened tool steel and of such construction that the cutting edges always retain the same sharp angle until worn to the hub.

Greenfield Machine Co., Greenfield, Mass. Circular of the Greenfield No. 4 plain grinding machine with hydraulic table feed. The advantages claimed for this feed are very smooth and even movement and unlimited number of speed changes from zero to the maximum.

Walsh Press & Die Co., 4709-4711 W. Kinzie St., Chicago, Ill. Circular of the Walsh safety device for power presses which makes it necessary for both of the operator's hands to be placed on finger buttons before the treadle can be tripped and the clutch of the machine released.

Gisholt Machine Co., Madison, Wis. Folder B. M. F.-1, descriptive of the Gisholt 42-inch boring mill, especially adapted for machining locomotive driving boxes. A special type of chuck is employed which allows this work to be done much more rapidly than by former methods.

Hannifin Mfg. Co., Chicago, Ill. Catalogue on "Aero" chucks, 38 pages, 4¾ by 7 inches, showing air-operated chucks of the universal, collet, alligator, releasing, and milling machine types. Air-operated countershafts, clamping fixtures, vises and special tools are also illustrated.

Dazie Mfg. & Supply Co., Inc., Lawrence & Clearfield Sts., Philadelphia, Pa. Circular of "Drive-Em-All" drill sockets, consisting of a rifled ferrule forced onto the shank of the drill which interlocks with the end of the regular Morse collet or socket, the same having been milled to fit.

Westmacott Gas Furnace Co., Providence, R. I. Sectional catalogue of Westmacott gas blast furnaces, showing bench furnaces, oven furnaces, muffle furnaces, melting furnaces, tinning and galvanizing furnaces, blast soldering iron heaters, brazing blow-pipes and positive pressure blowers.

Automatic Drill Chuck Corporation, Majestic Bldg., Detroit, Mich. Catalogue of "Quictite" automatic drill chuck operated by hand without keys or wrenches while spindle is running. The chuck grips straight shank drills, reamers or counterbores and holds more tightly as the load increases.

Lutz-Webster Engineering Co., Inc., Philadelphia, Pa. Circular of the Lutz compressed pipe and stud wrenches, lathe dogs and drill ratchets. The compression wrenches grip the smooth surfaces of pipe or studs without marring and drive positively, releasing on the back stroke and gripping again on the reverse.

Fort Wayne Electric Works of the General Electric Co., 1616 Broadway, Fort Wayne, Ind. Bulletin 46203 for March, 1914, illustrating and describing type K5 single-phase watthour meters. The advantages claimed for this meter are simplicity in mechanical construction, compactness, and a high degree of accuracy.

Ingersoll-Rand Co., 11 Broadway, New York City, is issuing a limited number of books containing a reprint of an article from "Scribner's" magazine on the Panama Canal. The book is handsomely illustrated with plates showing the dams and locks in natural color. The last two pages show Ingersoll-Rand drills used in excavating the canal.

Link-Belt Co., Chicago, Ill. New book No. 190, 31 pages, 6 by 9 inches, illustrating and describing the Link-Belt portable wagon and truck loader. This machine will load coal, coke, gravel, stone, sand and similar loose materials from ground storage at the rate of sixty tons an hour. It will load a five-ton auto truck in less than five minutes.

Sanitation Corporation, 50 Church St., New York City. Bulletin, Series G, No. 2 containing an article by Dr. Endris on the mechanical treatment of sewage in Germany and the application of the Reinsch-Wurl screen thereto. Managers of isolated manufacturing plants having to render their sewage innoxious will find this bulletin of interest.

Bonney Vise & Tool Works, Inc., Allentown, Pa. Catalogue 18, comprising 68 pages, 6 by 9 inches. This book was compiled with the idea of presenting not only a catalogue of Bonney products but a reference book on vises and wrenches as well. All the types of wrenches and vises (with the exception of pipe vises) in common use are illustrated.

Cincinnati Bickford Tool Co., Oakley, Cincinnati, Ohio. Circular R-3-A, descriptive of 4-, 5- and 6-foot regular plain radial drills equipped with variable speed motor drive and motor and speed box drive. The machines may, at extra cost, be fitted with a special base, cooling equipment, tapping hood, tapping lead mechanism and other special attachments.

Prince-Groff Co., 50 Church St., New York City. Circular of the "Kwik-grip" positive lock vanadium steel pipe wrench. This wrench of the "alligator" type is made with the serrated jaw in line with the axis of the handle. This construction is claimed to effect an improvement in the gripping power and efficiency of the wrench as compared with the ordinary alligator type.

Jaeger Rotary Valve Motor Co., Inc., Mount Vernon, N. Y. Catalogue of the Jaeger rotary valve, six-cylinder 60-horsepower motor. The design of the motor eliminates poppet valves and camshafts, one valve serving for all cylinders, being located longitudinally in the tops of the cylinders. This valve is cooled internally and externally and it is driven by gearing from the crankshaft.

Hess-Bright Mfg. Co., Front St. and Erie Ave., Philadelphia, Pa. Catalogue on the application of Hess-Bright ball bearings in flour and feed milling machinery. It is claimed that these bearings when properly mounted and not overloaded, have practically no wear and should last as long as the machine. They require no refitting or other attention of any sort, save to supply lubricant once in two or three months.

Newton Machine Tool Works, Inc., Philadelphia, Pa. Catalogue 48 of horizontal milling machines of the planer type. Examples of the company's slotting machines; special grinding machines, including locomotive link grinding machines; cylinder and valve chamber boring machines; vertical milling machines; crank planing machines; locomotive rod boring machines; cold metal sawing machines are also shown.

Lufkin Rule Co., Saginaw, Mich. Catalogue 9, containing 110 pages, 6 by 9 inches. This catalogue is devoted exclusively to measuring tapes and rules. Attention is called to the fact that in addition to this line which the company has manufactured for the last twenty-five years, it now has ready for the market a complete line of folding boxwood, and flexible spring joint wood rules. Requests for copies of this catalogue will receive prompt attention.

Electric Controller & Mfg. Co., Cleveland, Ohio, is distributing a booklet which is a reprint of an article entitled "Lifting the One Hundred and Thirty Million Pound Quebec Bridge," by H. F. Stratton, that appeared in the December, 1913, issue of the "Engineering Magazine." With the exception of the motors, all the electrical apparatus used in erecting the Quebec Bridge is being designed and supplied by the Electric Controller & Mfg. Co.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue P, 35 pages, 6 by 9 inches, treating of "Brownhoist" overhead hand-traveling cranes. These cranes consist of a single I-beam supported at each end on a patented truck-frame of cast steel. The construction is such as to permit them to be used where there is very limited head-room. The tables of dimensions, prices, etc., will be found useful by those desiring to purchase this equipment.

Peter A. Frasse & Co., Inc., 417 Canal St., New York City. New catalogue on steel. 40 pages, 4¼ by 6½ inches. This book contains a complete description of high-speed tool steels, alloy tool steels, carbon tool steels, die-sinking steels, special tool steels, construction steels, spring steels, etc., made by this company. Some valuable tables on machining allowances, hardening colors and temperature equivalents, weights of bar steel per foot, etc., are included.

American Roller Bearing Co., Pittsburg, Pa. Catalogue entitled "Roller Bearings for All Purposes," 16 pages, 6 by 9¼ inches, dealing with the advantages, construction and application of the "American" roller bearing. These bearings are especially designed for conditions where the load is unusually severe. They are adapted for motor car construction, lineshaft hangers, loose pulleys, railroad service, trolley wheel equipment, and many other classes of service.

National Tube Co., Frick Bldg., Pittsburg, Pa. Proceedings at the annual meeting of the stock holders of the United States Steel Corporation, April 20, 1914, and statement as to wages, hours and other conditions of labor among employes of the United States Steel Corporation and subsidiary companies. Those interested in profit sharing plans and the relation of employes to one of the largest corporations in the world will find these reports of extraordinary interest.

Mesta Machine Co., Pittsburg, Pa. Bulletin on air compressors and vacuum pumps. The air compressors manufactured by this company have been equipped with an automatic plate valve (Iversen patent) which makes possible the economic use of much higher piston or rotative speed. The higher speed permissible means a smaller cost of installation, inasmuch as the compressor equipped with plate valves takes only about two-thirds of the floor space required by other compressors.

Pratt & Whitney Co., Hartford, Conn. Catalogue on the Pratt & Whitney side head boring mill, 34 pages, 9 by 12 inches. This catalogue is handsomely illustrated with a number of halftones showing the machine in its various working positions. The side head of the machine is operative on work up to 38 inches in diameter and the vertical head is operative on work 44 inches in diameter. The independent side head which may be lowered below the work table permits of increased swing.

Lumen Bearing Co., Buffalo, N. Y. Booklet on "Lesoyl," a semi-fluid concentrate containing graphite in suspension. "Lesoyl" is mixed with lubricating oil and grease to improve its lubricating quality; its virtue does not lie in the graphite alone, but in a large measure is due to the ingredients composing the menstruum in which the graphite was ground. While "Lesoyl" is used to improve lubrication on all bearing surfaces, it is especially valuable where the pressure on the bearings is severe and intermittent.

R. D. Nuttall Co., Pittsburg, Pa. "Heat-treatment of Gears and Pinions," a treatise prepared by W. L. Allen, commercial engineer, which is intended to give builders and users of machinery a better idea of the great improvement in the physical characteristics of steel to be obtained by heat treatment. The company makes a specialty of heat treating gears and pinions and the booklet is written with the view of informing the average man on some of the technical features of modern heat-treatment methods.

Vulcan Process Co., Inc., 25th and University Aves., S. E., Minneapolis, Minn. New book entitled "Vulcan Process Instructions on Oxyacetylene Welding and Cutting," 86 pages, 6¼ by 8¾ inches. Although pertaining especially to Vulcan apparatus, this book contains much general information on welding. It takes up the formation and composition of the oxyacetylene flame, its use and application, as well as the various equipment with which it is used. A number of interesting repairs made by the oxyacetylene process are shown.

Schuchardt & Schutte, Cedar and West Sts., New York City. Circular of gage standards adaptable in combinations of 0.00001 inch, the individual block units being of such precision that a combination of four or five of them will have a total error of not more than 0.00004 inch. These gage standards are made of high-carbon steel rectangular prism shapes with highly polished parallel surfaces, each block being stamped with its dimension. The standard gages are sold in various combinations and numbers. The circular also illustrates and describes a precision measuring and screw testing microscope which gives means of measuring the pitch, depth of thread and angle of screw threads.

Builders Iron Foundry, 9 Codding St., Providence, R. I. Bulletins Nos. 1 to 7 inclusive in "Builders Construction Series," entitled "The Better Grinder," illustrating methods of construction employed in manufacturing "Builders" grinding machines, as follows: 1, Machine-molding "Builders" Heads; 2, Grinding Grinders; 3, Grinding Spindles; 4, Milling Heads; 5, Inspecting Spindles; 6, Shrinking on Pulleys; 7, Assembling Smaller Sizes of Heads. These bulletins, 9 by 12 inches, are issued each month and each is illustrated. Mechanical men generally will find the series of interest and value as they illustrate and describe the methods followed in the manufacture of a well-known floor grinder.

National Machinery Co., Tiffin, Ohio. "National Forging Machine Talk No. 3" discusses the value of large "gather" in the forging machine. By "gather" is meant the distance of travel of the heading ram after the gripping dies close. Realizing the importance of this point in design, the National Machinery Co. makes its heavy-pattern forging machines with three different "gathers" as follows: 246 heavy-pattern forging machine, 2 inches rated capacity, 4 inches die opening, 6 inches gather; 357 heavy-pattern forging machine, 3 inches rated capacity, 5 inches die opening, 7 inches gather; 469 heavy-pattern forging machine, 4 inches rated capacity, 6 inches die opening, 9 inches gather.

Bristol Co., Waterbury, Conn. Bulletins 188 and 189 on two types of Bristol recording differential pressure gages. Bulletin 188 describes the patented spring type of Bristol recording differential pressure gage equipped with diaphragm or helical type pressure tubes and a patent frictionless sleeve. Bulletin 189 treats of the patent float type of Bristol recording differential pressure gage in which no springs are employed. This type is especially recommended, although there are certain applications for which the spring type is adapted. These gages are particularly valuable for use in connection with pitot tubes and venturi tubes for measuring and recording the rate of flow of air, gas, steam, water and other liquids.

General Electric Co., Schenectady, N. Y. Bulletin 41302 covers the complete line of G-E standard polyphase induction motors. The repair parts for this line are also illustrated. Bulletins 43400, 43401 and 43402 deal with the subject of modern lighting in woodworking plants, the clothing industry and machine shops and metal working plants, respectively. The various lamps adapted for this service are described and suggestions are given as to the size and style of the units best suited to secure the greatest efficiency. Bulletin 46201 takes up the construction of the single-phase watthour meter, type I-14. Bulletin 48010 is devoted to the use of electricity in the shoe and leather industry. Illustrations show numerous installations in various factories of prominence in the East.

Ingersoll-Rand Co., 11 Broadway, New York City. Bulletin Form 8011 describing the construction and operation of "Little David" riveting hammers. Illustrations show the application of these tools. All "Little David" riveting hammers can be furnished with a rivet set retainer as illustrated in Form 8011-I. This retainer is simple in design and meets the requirements of the safety laws being drafted by the various states. All those interested in "Safety First" as applied to the operation of pneumatic riveting hammers should have this booklet. Copies sent free on request. Form 4020 treats of Leynor-Ingersoll water drills. Among the unique features of construction may be mentioned the hand hammer blow, the water feature, the oiling system, the butterfly valve, etc. A descriptive table giving sizes and capacities of these drills is included.

MANUFACTURE OF SAVAGE 0.22 CALIBER HIGH-POWER RIFLE—2

INTERESTING MACHINING OPERATIONS ON VARIOUS RIFLE PARTS—SPECIAL MACHINES AND FIXTURES USED AT FACTORY OF SAVAGE ARMS CO.

BY FRANKLIN D. JONES*

IN the manufacture of a Savage rifle such as the 0.22 caliber high-power type, 815 operations are necessary. To handle this amount of work and at the same time produce a high-grade rifle which can be sold at current prices is a striking illustration of what can be accomplished with modern tools backed by efficient and systematic manufacturing methods. In the preceding installment of this article (published in the July number) the action for the 0.22 caliber high-power rifle was described, and the manufacturing and inspection systems employed at the factory of the Savage Arms Co. were referred to in a general way. In the present article reference will be made to some of the more important operations on various rifle parts.

Machining a Rifle Barrel

The barrel for a Savage high-power rifle is made of alloy steel of special composition to withstand the enormous pressure to which it is subjected. This pressure, in the case of the 0.22 caliber high-power rifle, is approximately 48,000 pounds per square inch at the instant of discharge. The barrel, after being centered, is rough-turned tapering in an ordinary lathe equipped with a follow-rest. This roughing operation is for removing most of the outer stock, thus relieving the barrel of any strains which might exist in or near the outer surfaces. The barrel is then drilled in a Pratt & Whitney drilling machine, as will be described later. There are two additional turning operations on the barrel after the hole is drilled, one being a second roughing cut and the other a finishing cut.

One of the special lathes used for these turning operations is shown in Fig. 2. The barrel is supported by a three-roller back-rest *A* carried by the large bracket *B* extending along the bed at the rear. This roller-rest remains in a central position with relation to the barrel being turned, and the tool is guided by an attachment which operates on the principle of an ordinary taper attachment; that is, the cross-slide carries a bar and roller which bears against a former at the rear, curved to correspond with the shape required for the barrel. (The octagonal barrels used on the smaller rifles are gang milled, several being held at a time in multiple index centers set to give the required taper.) When taking the finishing cut over the barrel, the mark which is sometimes left by a roller-rest is prevented in the following manner: The central bearing for the roller-rest is turned down a few thousandths larger than the required size, and the tool, when taking the finishing cut is automatically stopped when it reaches this roller-rest spot. The cut is then started on the opposite side and the turning continued. The spot is finally removed in the polishing department on a leather-faced polishing wheel.

Drilling a Rifle Barrel

One of the most delicate operations in rifle manufacture is that of machining the hole through the barrel. To drill a straight hole 0.22 inch in diameter through twenty inches of tough alloy steel is a job that requires the right tool and the right machine. The drilling machines used are of a duplex type, two barrels being operated on at the same time. A detail view of one of the barrel drilling machines used at the Savage factory is shown in Fig. 3. The barrels *A* revolve and the drills *B* remain stationary, except for the feeding movement. This is in accordance with the well-known principle of deep-hole drilling. When the drill revolves, a slight deviation from the true course tends to increase, but when a rotary motion is given to the work instead of to the drill, if the drill point varies from its central position, it will be carried around in a small circle and, consequently, the drill shank will be bent in various directions. The result of this bending action tends to force the drill point back to the course of least resistance, which is along the axis about which the work revolves; therefore, because of this tendency, the drill follows a true course if all conditions are favorable.

First, the drill must be properly ground; moreover it must be guided by a close-fitting bushing when starting the hole and the hole must be kept clear of chips. The drills are supported in brackets *C* attached to the base of the machine, and they are started true by passing them through bushings which fit over the turned ends of the barrels. The drill used

Fig. 1. An Example of Artistic Carving and Engraving on a Savage Rifle

* Associate Editor of MACHINERY.

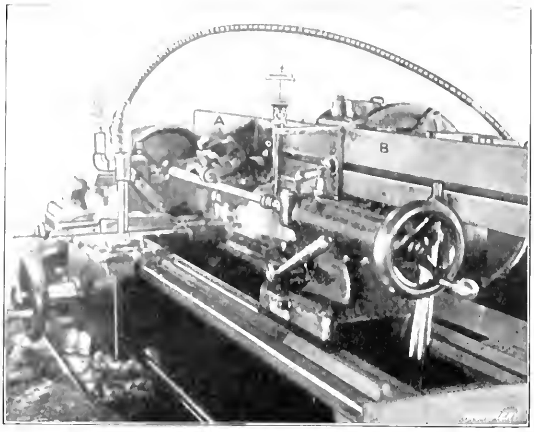

Fig. 2. Special Lathe used for turning Rifle Barrels

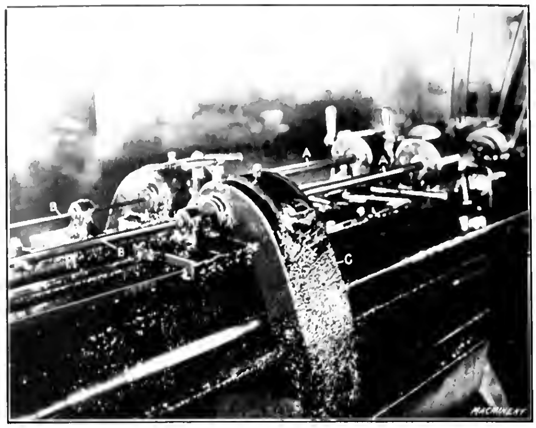

Fig. 3. Detailed View of Pratt & Whitney Rifle Barrel Drilling Machine

for this work has one straight flute and one cutting edge. Back of the cutting edge there is a section that is practically straight, which supports the cutting end so that the hole itself form a bushing as the drill feeds through the barrel. The drill tip is from four to eight inches long and is held at the end of a tube or shank. The lubricant is forced through this shank and also through a duct passing through to the drill point. As the pressure of the lubricant is about 200 pounds per square inch, the chips are forced back along the straight flute with the lubricant.

The feed of the drill per revolution of the barrel, for drilling a 0.22 caliber rifle, is about 0.0025 inch per revolution of the work. The speed at which the barrel rotates depends upon the material and the size of the bore, varying from 1500 to 2400 revolutions per minute. When the hole is drilled, a trip automatically shifts the driving belt and stops the machine. The hole is drilled to within 0.005 inch of the finished diameter.

Reaming the Barrel Hole

The next operation on the bore is that of reaming, in order to finish the hole to the exact diameter required. The reaming is done in a machine which is duplex but differs from the drilling machine in that the reamers are revolved slowly by the machine spindles while the barrels feed over them and remain stationary except for the feeding movement. Two kinds of reamers are used: The first is a cutting reamer and its cross-sectional shape is shown by the enlarged view at *A*, Fig. 5. This type of reamer removes about 0.003 inch; the remaining 0.002 inch is then removed by a scraping reamer, the shape of which is shown at *B*. The tops of the teeth of this scraping reamer are ground and stoned to form sharp ridges which take very light scraping cuts and leave a "mirror finish" in the bore of the rifle.

The number of times these cutting and scraping reamers have to be passed through the bore depends upon the caliber. After the first reaming operation, the accuracy of the bore is tested by dropping through it a close-fitting plug eight inches long. If this passes through without being forced, it shows that the barrel is straight within very close limits. The accuracy of the bore is also tested by holding the barrel in line with a narrow strip placed across a ground glass in one of the windows. By sighting through the bore on this strip and then turning the barrel, any inaccuracy will be shown by the movement of the shadows of the strip reflected along the sides of the bore. (This method was described and illustrated in an article entitled "The Ross Rifle and its Manufacture," published in the November, 1911, number of MACHINERY.)

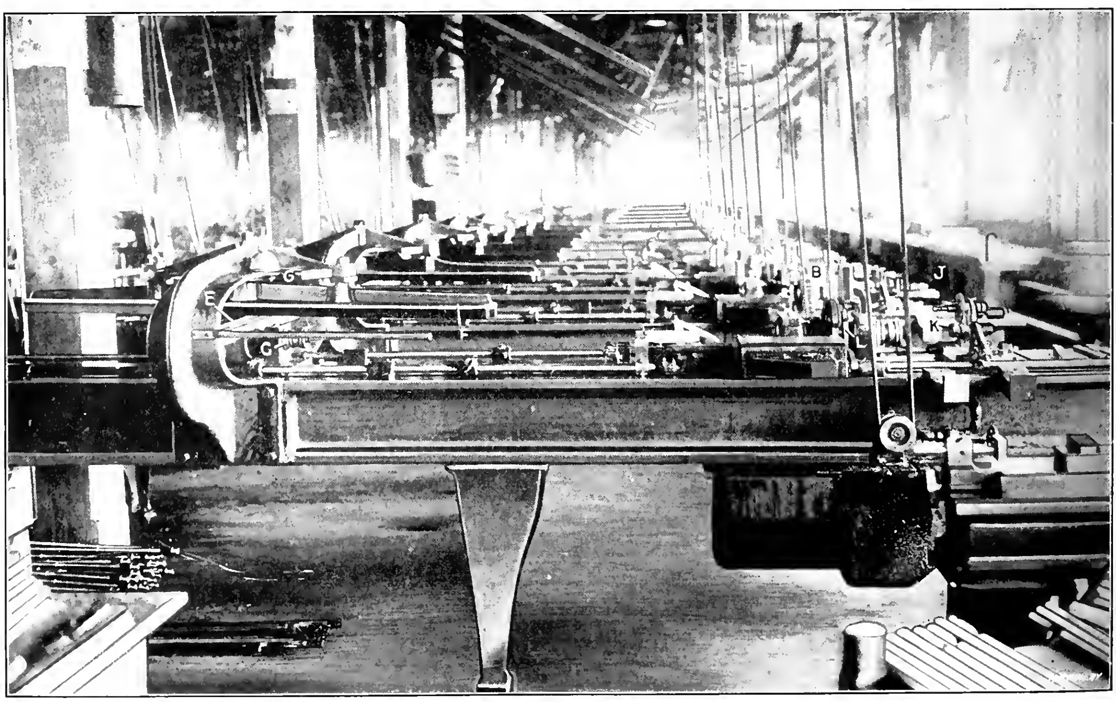

Fig. 4. Group of Pratt & Whitney Rifling Machines at Factory of Savage Arms Co.

Rifling the Barrel

Helical or spiral grooves are cut in the barrels of all modern firearms to impart a rotary motion to the bullet, as is generally known. This rotary motion causes the axis of an accurately made bullet to keep in a line with its flight or trajectory, which increases the range, accuracy, and penetration. Experiments have demonstrated that the mean deviation of the shots fired from a rifled gun at medium ranges is only one-third that from a smooth bore, when all known and controllable causes of deviation have been eliminated.

In the Savage 0.22 caliber high-power rifle, there are six of these rifling grooves which have a pitch or lead of twelve inches, this being the distance that the grooves advance in one turn. The cutting of these grooves, which are only 0.003 inch deep and 0.065 inch wide, is a very interesting operation. Pratt & Whitney rifling machines are used. A group of these machines is shown in Fig. 4. The operation, briefly described, is as follows: The rifle barrel is held in an indexing head *B* and remains stationary except when indexing from one groove to the next. The grooves are cut by a small tool, the cutting edge of which corresponds to the shape of the groove required. This tool is carried in a tool-head screwed to a long shank which is gripped by chuck *C*. This chuck, in turn, is carried by the draw-head of the machine which is moved back and forth by a horizontal screw that is rotated in first one direction and then the other, by open and cross belts. The rifling cut is taken on the draw stroke and after the tool has passed through one groove and has returned to the starting point at the breech end of the barrel, the latter is indexed so that the tool on the next stroke passes through another groove. When a cut has been taken through the six grooves, the tool is automatically fed outward a slight amount and another series of cuts is taken through the groove, and so on until all the grooves are machined to the required depth.

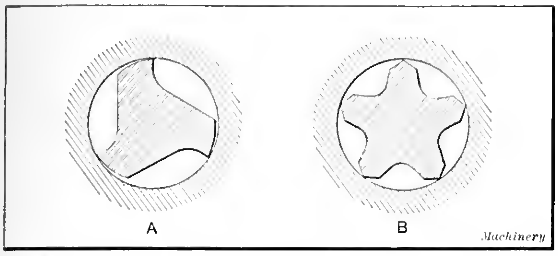

Fig. 5. Sectional Views showing Shape of Reamers used for finishing the Bores of Rifle Barrels

The tool is turned as it passes through the barrel, to produce helical or spiral grooves, by the arrangement seen at the left-hand end of the machine. On the spindle which carries the chuck *C*, there is a gear which meshes with a rack on cross-slide *E*. This cross-slide has a roller on the top which engages with a groove or channel extending along the under side of arm *F*. When the draw-head is traversed along the machine bed by the screw, the cross-slide *E* is caused to move laterally (provided arm *F* is set at an angle with the travel of the draw-head), and this lateral movement turns chuck *C* and the cutter. The amount of this cross movement depends, of course, upon the angular position of arm *F*; graduations on the quadrant *G* show what the position of the arm should be for generating grooves of different leads.

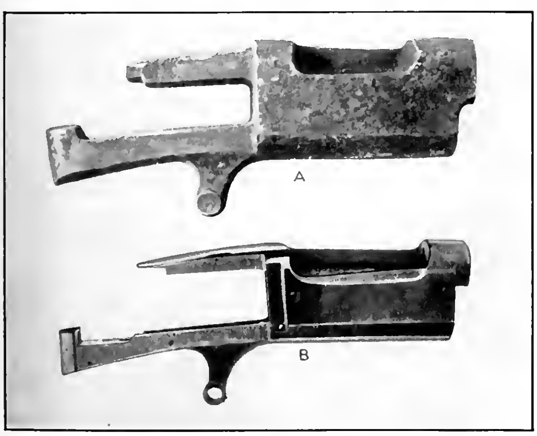

Fig. 6. (A) Drop-forging for Receiver; (B) Finished Receiver

The cutter, which is small and delicate, is relieved on the return stroke to prevent dulling the edge. This is done by a small finger which pushes the cutter back into the head at the end of each stroke. At the opposite end of the stroke a pin in the end of the cutter-head strikes a stop on the feeding head *J* and forces the cutter out (by means of a wedge in the head) to the cutting position. The feeding of the cutter outward at the completion of each revolution of the barrel is effected by a feed-screw at the end of the cutter-head. This screw has a square head, which at the extreme end of each stroke enters a square hole in stop *K*. When the barrel has made one turn, a lug on the indexing disk *L* comes around and through suitable mechanism turns stop *K* slightly. The result is that on the next stroke the feed-screw of the cutter-head, as it enters the square hole, is turned a corresponding amount, the end of the square hole being rounded so that the feed-screw can enter readily. (A sectional view of the cutter-head and a more detailed description of the feeding mechanism was given in the November, 1911, number of MACHINERY.) Lubricant for the cutter is forced through the hollow shank of the tool, connection being made with the draw-head by telescoping pipes which permit the necessary reciprocating movement.

The cartridge chamber in the barrel is reamed to conform to the shape of the "bottle-necked" cartridge used in the 0.22 caliber high-power rifle, and the end of the barrel is finished in the turret lathe by using a combined reamer and face mill. The chamber is then finished by hand reaming to obtain as smooth a surface as possible, because if this chamber were at all rough, the shell when exploded would be forced out into the minute depressions and could not be extracted easily.

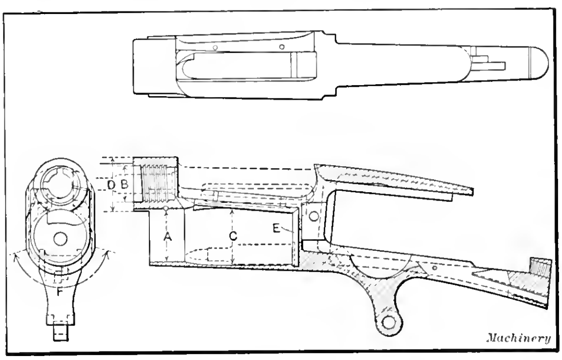

Fig. 7. Plan View and Section of Receiver

Machining the Receiver

The receiver of a rifle is that part between the barrel and breech which contains the "action" or loading and firing mechanism. The receiver of a Savage rifle of the '99 model, which is the style used on the 0.22 caliber high-power type, is illustrated in Fig. 6. The rough drop-forging *A*, from which the receiver is made, weighs 6½ pounds, which is one-quarter pound heavier than the entire weight of the finished rifle, whereas, the finished receiver *B* weighs only one pound thirteen ounces. The total number of operations required on this receiver is 128. A few of the more interesting operations will be referred to in detail.

In order to machine the various interior and exterior surfaces and have them properly located with reference to each other, it is important first to provide surfaces which can be used for locating the receiver in the various jigs and fixtures. The top and left side are machined first on an ordinary Lincoln type milling machine, and practically all subsequent operations are located with reference to these surfaces.

Fig. 8 shows a detail view of a very interesting special machine used for roughing out the magazine chambers A and C (Fig. 7) and the hole B for the barrel, as well as the end surfaces. The magazine chamber is cylindrical at the forward end A, but part C is enlarged and shaped to conform somewhat to the tapering cartridges. This enlarged part is milled out in an ingenious way by the semi-automatic machine shown in Fig. 8. This machine has a spindle for each separate operation to be performed, and the receivers are held in a circular fixture which forms the machine table. The spindles are all fed downward simultaneously by a large cam drum in the center, to which suitable cams are attached. After all the spindles have been fed to depth, the machine is automatically tripped; the spindles are then raised and the work-table is indexed by hand, so that each receiver moves around to the next spindle where the succeeding operation is performed. As all the spindles perform their operations simultaneously, a finished part comes around to the front each time the table is indexed and the operator removes it and inserts a rough forging.

The order of the operations is as follows: First the cartridge chamber hole is drilled with an ordinary twist drill. The bottom of the hole is then squared out by another drill held in the next spindle. The milling of the enlarged part C (Fig. 7) of the chamber then follows. First, a milling cutter enters the hole and for a time simply revolves in a central position while the other tools are at work. When it has reached the proper depth, a gear which is cam-operated and independent of the driving gear turns part of a revolution,

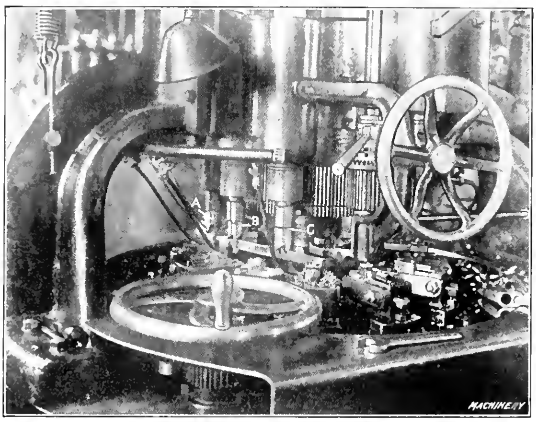

Fig. 8. Special Multiple-spindle Machine for drilling, reaming and milling Rifle Receivers

which locates the spindle and milling cutter in an eccentric position. Then the cutter not only revolves about its own axis but, at the same time, has a circular or planetary motion around the hole, thus enlarging it. When the cutter has finished one revolution, the cam-operated gear again turns slightly in the same direction, thus placing the cutter more off center for taking another cut. At the end of the second cut the gear is automatically returned to the starting point, thus bringing the cutter spindle back to its central position before it is raised for indexing the work-table.

After the chamber is milled as described, the work is indexed to a second milling cutter which operates in the same way and takes a lighter cut around the cartridge chamber. The receiver is now indexed to another drilling spindle where the barrel hole is drilled. This hole is then reamed out by the spindles A and B, Fig. 8, and the top surfaces faced. Finally the outside diameter D (Fig. 7) is machined by the hollow mill C. There are two of these machines, both of which were built by the Adriance Machine Works of Brooklyn.

The surfaces roughed out on the Adriance machine are finished by separate operations on other machines. The cylindrical part A (Fig. 7) and the bottom of the cartridge chamber, as well as hole B and the outside of the circular boss D, are finished in a four-spindle drilling machine equipped with reamers and a hollow mill.

Fig. 9 shows a special fixture used for finishing the enlarged part C (Fig. 7) of a cartridge chamber and for milling a narrow annular recess E at the bottom for receiving the projecting rims of the cartridges. This fixture A is revolved by worm gearing B and the receiver R feeds around the rotating cutter, which removes just enough stock to finish the cartridge chamber.

Another revolving fixture used for milling the outside surface F (Fig. 7) on the bottom of the receiver is shown in Fig. 10. The fixture in which the work is held is also revolved by

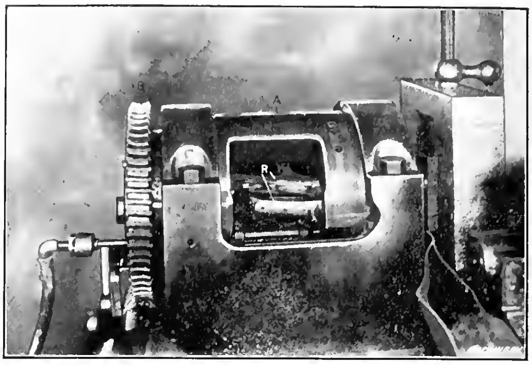

Fig. 9. Special Attachment on Lincoln Milling Machines used for finishing Cartridge Chamber of Receiver

worm gearing. The receiver R is located by the top and side locating surfaces and it is held by a clamp across the tang and plugs which enter the barrel and chamber holes. The milling cutter C, which is supported at the outer end by a bracket A, simply revolves in a fixed position and the work feeds around it. When the cut is completed, the rotation of the fixture is stopped automatically by the disengagement of the driving worm.

Fig. 11 illustrates how the thread for the rifle barrel is cut in the receiver. This thread is milled by cutter A and the receiver R is held on a rotating fixture B. The spindle of this fixture passes through a bronze nut in the main bearing of the machine, and when milling the thread the revolving spindle and fixture feed forward at a rate proportional to the pitch of the thread. The spindle is rotated through worm and spur gearing. When the thread is completed, the forward feeding movement of the fixture is automatically stopped by a trip which releases a catch and allows the feed-worm to be quickly drawn out of mesh by a spring. The continuous thread which is milled with this machine is partly cut away at the top and bottom of the threaded hole so that the barrel, the thread of which is also milled and then cut away to match the receiver, can be removed by simply turning it one-fourth of a revolution. When the barrel has been

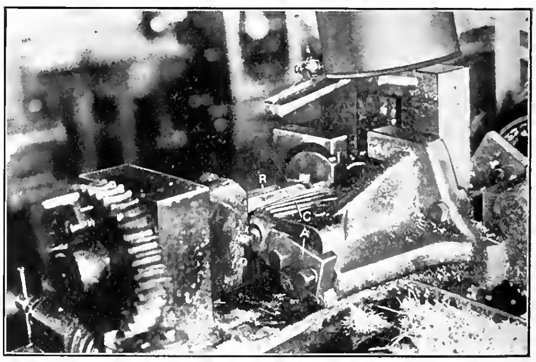

Fig. 10. Rotating Fixture used for milling Round Bottoms of Receivers

turned this amount, the threads on it are aligned with the unthreaded part of the receiver. The threads in the latter are cut away in a profiling machine.

Stock Turning Machine—Wood Profiler

A detail view of one of the lathes used for turning the rifle stocks is illustrated in Fig. 12. This lathe is similar to

the type used for turning shoe lasts and other irregular shapes. There is a former A which corresponds to the shape of the finished stock. This former is mounted on one side of an oscillating frame B which carries on the opposite side the walnut stock C that is to be turned. The former and stock are rotated simultaneously by gears connecting shafts D and E. The cutter-head H, which is equipped with six U-shaped cutters, is mounted on a carriage F and traverses along the bed as the stock is turned. The wheel G, which bears against the former, also moves along with the carriage.

Fig. 11. Detailed View of Special Machine used for milling Barrel Thread in End of Receiver

The contact of the former with this wheel causes frame B and its shafts D and E to oscillate in such a way that the stock is turned to the same shape as the former. The cutter-head rotates very rapidly and when the cut is completed the carriage feed stops automatically.

The walnut which is used for rifle stocks must be carefully seasoned and dried before it is suitable for use. There are four classes of stocks, *viz.*, the plain walnut, the semi-fancy, the fancy, and the circassian. The "fancy" stocks are so classified because of the beauty of the grain and are used for the more expensive rifles.

The forward ends of the stocks are cut out to fit the upper and lower receiver tangs in a machine similar to that shown in Fig. 13, which operates on the same principle as a metal profiling machine. The cutters revolve very rapidly and are guided by a former plate as at A, which is engaged by a guide-pin, thus controlling the movement of the cutter. This machine has four spindles into which cutters of different shapes and sizes can be inserted. In this case only three of the four spindles are being used. The vertical position of each cutter is regulated by the adjustable stop-screws seen at the right of each spindle slide. Such accurate work is done by this machine that practically all hand fitting is eliminated. The stocks are next finished smooth by the use of garnet

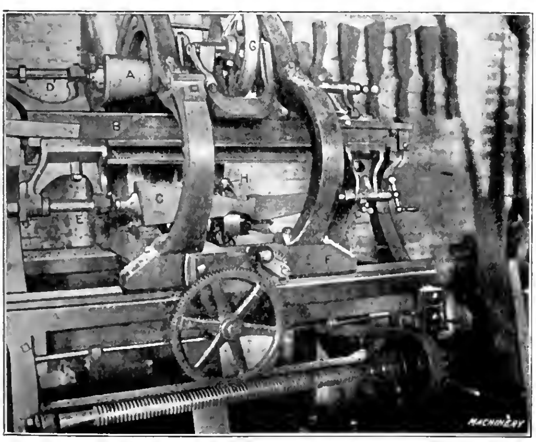

Fig. 12. Machine used for turning Walnut Rifle Stocks

paper and then they are ready for finishing. The grain of the wood is filled to secure a smooth surface and after the application of shellac and varnish, the stocks are given a polish by rubbing with a mixture of pumice stone and paraffine.

Checking and Ornamental Engraving

The checking on the stocks as well as the carving on the fancy stocks is done entirely by hand and, obviously, requires a great deal of skill and artistic ability. The engraving on the sides of the receiver, etc., is also done by hand. In many cases special designs have to be engraved to order. A drawing of the design is first made on paper. When this has been approved, another drawing is made directly on the polished steel surfaces to be engraved. A very light coating of grease is first applied to the polished surface, and part of the design, in case there is considerable detail and the design is large, is then drawn with a sharp-pointed lead pencil; these lines are then traced with a sharp steel pencil. The engraver now has a light outline to serve as a guide and the design is then cut out by small hand tools. This work must be done by the aid of a magnifying glass, and great care is required to prevent the tool from slipping and cutting farther than was intended or in the wrong direction. An example of artistic carving and engraving is shown in Fig. 1. To engrave a fancy design such as this one requires considerable time and a degree of skill which few men possess.

In a succeeding article some interesting profiling operations on rifle and automatic pistol parts will be described.

* * *

Some years ago, it was shown by a series of experiments conducted by A. E. Outerbridge (*Journal of the Franklin Institute*, February and April, 1904) that cast iron subjected to alternate heating and cooling increased in dimensions with-

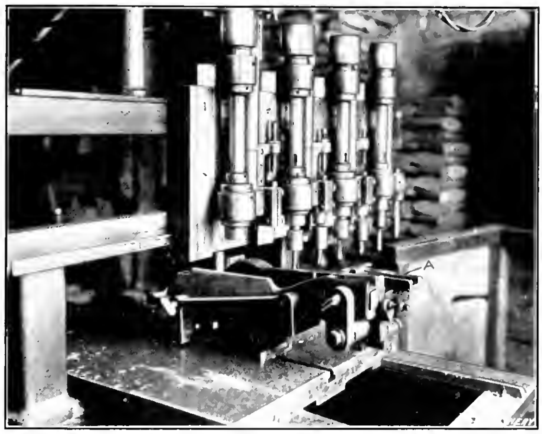

Fig. 13. Profiling Machine for cutting out Forward End of Stock to fit Receiver Tangs

out increasing in weight, whereas wrought iron under the same treatment contracted slightly in all dimensions. The cast-iron test bars used in these experiments increased in dimensions from 14 13/16 by 1 inch by 1 inch to 16 1/2 inches by 1 1/8 inch by 1 1/8 inch. The wrought iron bars decreased 1/8 inch per foot in dimensions and the cast-iron bars increased in volume about 40 per cent. The opinion was expressed in connection with these experiments that the strength of cast iron decreases in proportion to the increase in volume. These facts indicate that cast iron is not the best material to use where castings have to be subjected to comparatively high temperatures. Wrought iron castings now available have been demonstrated by comparative tests and observations to be far superior, outlasting ordinary cast iron from four to six times.

* * *

A German chemical publication states that coatings composed of rubber mixtures, raw or semi-vulcanized, prepared from low-grade rubbers rich in resin, and preferably containing large proportions of factis (a rubber substitute) and inorganic fillers, when pierced by a projectile, will close over the hole and so prevent the inrush of water. The coating may be made more resistant to water by adding tar. It is laid on or cemented to the hull of a ship and painted to protect it from attack by marine life.

METHODS OF HOLDING AND MACHINING THIN WORK*

SHOWING WAYS OF SUPPORTING SLENDER PARTS AND EQUALIZING THRUST OF CUTS TO AVOID DISTORTION

BY ALBERT A. DOWL†

IN nearly every kind of manufacturing it becomes necessary to machine certain pieces of work which are of a fragile nature, and which can neither be held nor machined by ordinary methods without considerable distortion. Sometimes the work is a casting of very thin section, while in other instances a forging is to be cut down until the walls are not over 1/8 inch in thickness. The work may be of comparatively small diameter or it may of large size, and it may also be either long or short. It may be cylindrical in form or of irregular shape, and may occasionally require the addition of holding lugs in order to hold it properly. In the machining of this class of work we shall consider two types of machines only—the horizontal and the vertical turret lathes. The horizontal type of machine would naturally be used for the smaller work, while the larger pieces can be more profitably handled on the vertical machine. While work of this character must be very carefully held in order to avoid distortion, the problem of machining is also of great importance. It is quite possible to hold a piece of work so that it will not spring out of shape, and yet the machining operations may be very unsatisfactory due to vibration in the work itself. This causes chatter which nearly always ruins both the work and the tools used in machining. Vibration is more apt to be troublesome on long work than on the shorter pieces, because the torsion or twisting action induced by the pressure of the tools in removing stock is more apparent when this action takes place at a considerable distance from the points at which the work is supported and held. On short work the support is nearer the point at which the work is being done, and there is consequently less chance for the metal to twist under the pressure of the cut.

In connection with the machining it is well to note that the speed and feed have a great influence on the vibration, but it is difficult to give a definite rule which will apply to all conditions. Methods of holding have a great influence on this matter, for it is obvious that the more securely the work is held, the greater may be the feed and speed, other things being equal. Speaking generally, less vibration results when slow speeds are used with fairly coarse feeds, but this is not always the case. Sometimes it is possible to run the work at a fairly good speed using a fine feed, while at other times a procedure of this kind will cause chatter which can be heard all over the factory. An increase of one step in the feed or a decrease of one step in the speed will frequently stop the trouble, but there are occasional instances which require considerable experimenting before the desired result is obtained. When outside and inside cutting are going on at the same time, it is a good plan to arrange the boring and turning tools so that they are working opposite each other; that is, the tools should be working one against the other with nothing but the wall of the casting between them. If used in this way there is less chance of springing the work, and also less chance of vibration. In handling thin work, special care must be taken to see that all bearings, gibs, etc., are set up snugly, so that no chatter will be caused in the machine itself. The tool-holders and the tools themselves must also be as solid as possible. A few points in connection with the handling of work of this character may be of interest and are given herewith.

Important Points relating to the Handling of Thin Work

1. The method of holding should be very carefully thought out with a view to rigidity and freedom from distortion of the work itself. It may be advisable in some cases to have supplementary lugs or pads added to the pattern in order to facilitate chucking. When this is necessary it is well to consult with the pattern-maker, so that unnecessary expense in the pattern will be avoided.

* For articles on work holding devices and kindred subjects, see "External Holding Devices for Second-operation Work," in MACHINERY, June, 1914.

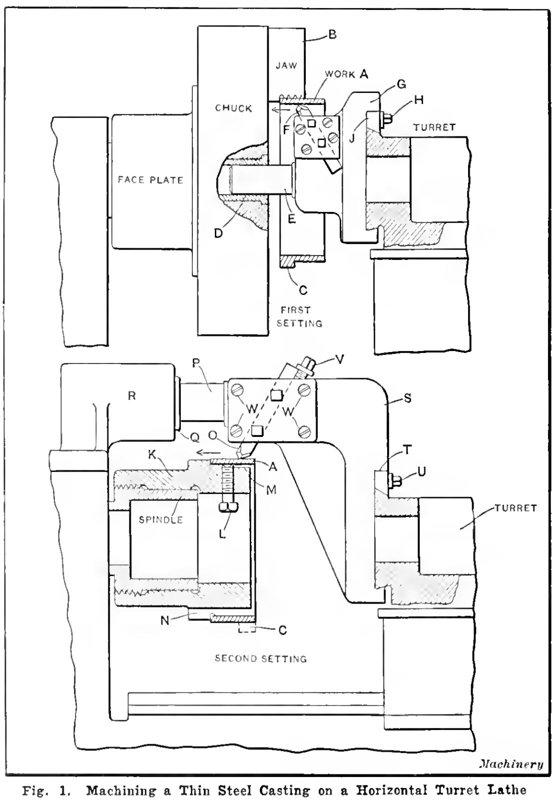

Fig. 1. Machining a Thin Steel Casting on a Horizontal Turret Lathe

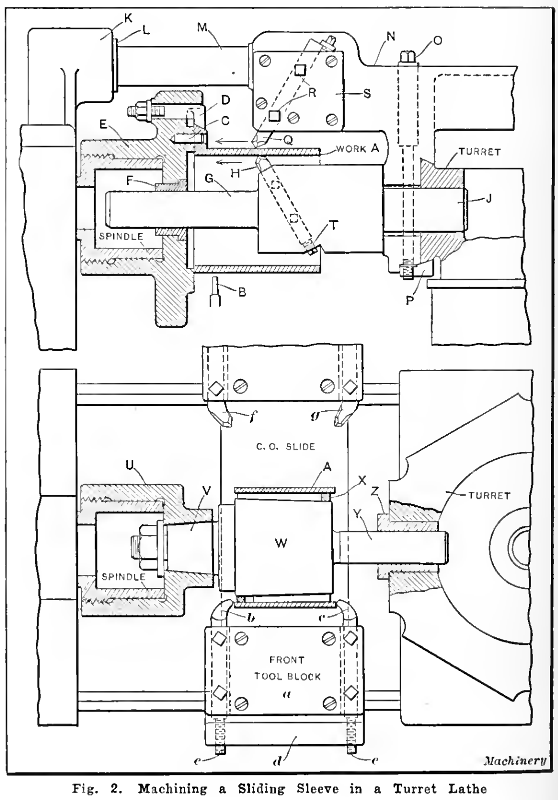

Fig. 2. Machining a Sliding Sleeve in a Turret Lathe

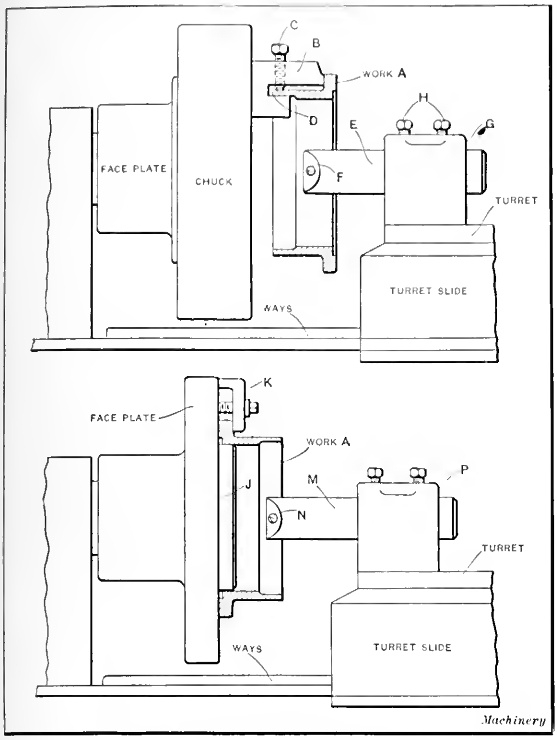

Fig. 3. Thin Flanged Collar machined on a Pratt & Whitney Turntable Lathe

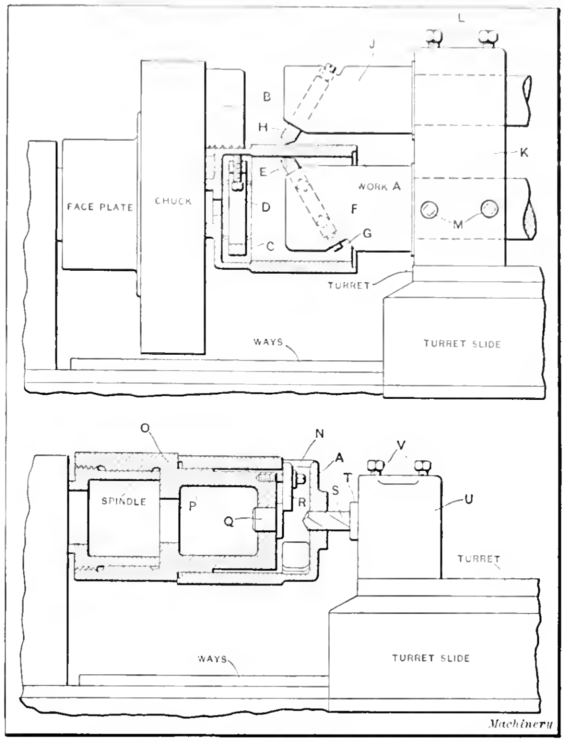

Fig. 4. Steel Casting of Fragile Construction machined on Turntable Lathe

2. The overhang from the spindle should be as short as possible, so that vibration will not be caused by an excessive weight revolving without support at its outer end.

3. The rapidity of operation is an important point if a great many pieces are to be machined. Clamps should be easily accessible and conveniently operated. It is advisable to make all nuts of the same size so that one wrench can be used for all. It is also desirable to make them of such a size that a standard machine wrench can be used.

4. The locating surfaces, if the work is irregular, should be carefully selected, so that inequalities of the casting will be equalized as far as possible. Care should be taken so that no locating points come where the casting is gated or where letters or numbers appear. Neither should they come where the pattern is parted.

5. The tooling should be very carefully studied both from the viewpoint of upkeep and of rigidity, so that every possible precaution may be taken to prevent chatter.

6. The cost of equipment should be considered on the basis of the number of pieces to be machined. Obviously, it does not pay to design very elaborate equipment for work which will not be machined in large quantities.

7. The selection of a machine best adapted to the work is an important point, and should be decided upon before anything is done in the line of equipment.

Machining a Thin Steel Casting on a Horizontal Turret Lathe

The work shown at *A* in Fig. 1 is a steel collar which is to be finished all over on a horizontal turret lathe. When in the rough, the thickness of the wall of the casting is 5/16 inch, and it is to be finished to 3/16 inch. As the work is so thin that the action of the chuck jaws would tend to crush it out of shape, if they were used in the ordinary manner, the driving lug *C* was added to the casting. In this way much less pressure is required on the jaws than would be the case if friction only were used for driving. It will be noted that the jaws *B* have a narrow shoulder against which the work rests. The body *G* of the boring tool is of cast iron and is fastened to the turret by the angular gib *J* and the screws *H*. A pilot *E* of tool steel is hardened and ground to fit the bushing *D*, which is forced into the chuck body. The tool *F* is set in a vertical plane in the holder in order to minimize errors in indexing the turret. Two holders of this kind are used for the work, and the cut-off slide tools face the end of the collar. While the piece is being rough-bored, the jaws are set up firmly on the work, but care is used so that too much pressure is not applied. Before the finish-boring takes place the jaws are loosened up to take care of the spring of the casting.

In the second setting (shown in the lower part of the illustration), the work *A* is pushed onto the arbor *K* which is screwed onto the end of the spindle; the cup-pointed driving screw *L* is set up against the finished inside surface. A shallow groove *M* is provided so that the burr thrown up by this screw will not cause trouble when removing the work. A moment's work with a scraper takes out the slight roughness after the work has been removed from the arbor. The grooves *N* on the periphery of the arbor facilitate the removal when the casting has been machined. The body of the turning tool *S* is fastened to the turret by gib *T* and screws *U*, and it has a pilot of steel at its forward end *P*. This pilot enters a bushing *Q* in the spindle cap bracket *R*, thus greatly assisting in the prevention of chatter. A steel plate is fastened to the body by four screws *W*, and supports cutting tool *O*. A refinement will be noted in the backing-up screw *V* which permits fine adjustments to be made. It was found advisable to cut off the lug *C* with a hacksaw previous to this setting, as the interrupted cut produced when attempting to machine it off with the turning tool tended to twist the work on the arbor.

Machining a Sliding Sleeve

The sliding sleeve shown at *A* in Fig. 2 is of cast iron, 1/4 inch thick when finished. Its outside diameter is important and its overall length also. It is likewise essential that the two ends should be parallel, and square with the outside. The casting is made up in the form of a pot with three beveled lugs spaced 120 degrees apart. The end of the pot is rough-ground on a surface grinder, and three holes *C* are jig-drilled to act as drivers and locaters. This work was done previous to the machining of the piece on the turret lathe. The fixture body *E* is then screwed to the spindle of the machine and is furnished with driving and locating pins which enter the drilled holes. The hook-bolts *D* are beveled

to the same angle as the lugs and extend back through the body so that they may be tightened from the rear, thus leaving the front of the fixture free from projections and permitting the turning tool to work without interference. Attention is called to the manner in which the hook-bolts are backed up by the boss, which is cut away at one side so that the bolt can be turned out of the way when assembling or disassembling the work. The body of the fixture is provided with a bushing *F* which acts as a guide for the pilot of the boring-bar *G*. This bar is firmly secured in the turret at *J*, the regular turret binder being used to hold it. The tool *H* is adjustable for diameters through the backing-up screw *T*. The outside turning is accomplished by means of double-end turning tool *N* which is fastened to the turret faces by the gibs *P* on the lower dovetailed faces, these being secured by the long special screws *O* which pass down through the body of the tool. A steel pilot *M* enters the bushing *L* in the spindle cap bracket *K*. A steel plate *S* is mounted on the body, and tool *Q* is secured in place by two screws *R* which pass through the plate. A collar-head screw is provided by means of which fine adjustments can be readily made. Attention is called to the manner in which the turning and boring tools are arranged so that they are working opposite each other, thus tending to keep the work nearer to size than would be the case if they were set to cut on different portions of the casting. After the work has been finished, the parting tool *B* cuts off the end of the sleeve slightly longer than required, so that a finish allowance is made for the second setting.

The second setting is shown in the lower part of the illustration and consists of roughing and finish-facing both ends of the sleeve to the prescribed size. For this setting the work *A* is held on the arbor *W*, the expanding sleeve *X* being forced up on the taper in the usual manner. A nose-piece *U* is screwed to the spindle and receives the tapered end of arbor *V*, while the other end *Y* is hardened and ground to a nice running fit in bushing *Z*, located in the turret. A special tool-block *a* is mounted on the front of the cut-off slide and holds the two rough-facing tools *b* and *c*. The tools enter slots in the block and are held in place by the set-screws shown. A ledge is cast at *d* on the rear of the block to allow the use of adjusting screws *e*. The finishing tools *f* and *g* are mounted in a special block on the rear of the cut-off slide in the same manner as those in front.

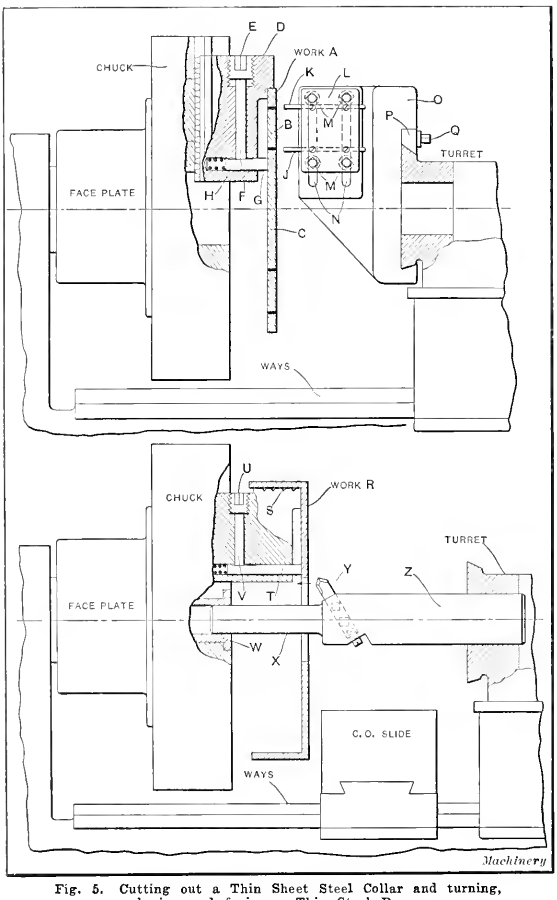

Fig. 5. Cutting out a Thin Sheet Steel Collar and turning, boring and facing a Thin Steel Drum

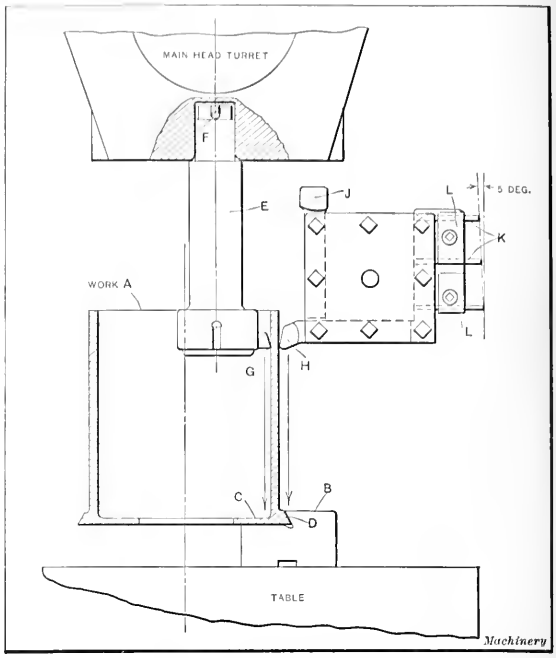

Fig. 6. Machining a Thin Casting to be cut up into Rings on the Vertical Turret Lathe

Machining a Thin Flanged Collar on the Turntable Lathe

A turntable lathe made by the Pratt & Whitney Co. is used to machine the collar shown in Fig. 3, the cross-sliding turret of this machine being used to perform the facing operation on the flange and the cutting of the recess. The work *A* is held in the special jaws *B* of the three-jawed chuck, that portion of the jaw marked *D* being brought up lightly against the inside of the thin end of the work and the set-screw *C* tightened. The forward end of the jaw is used as a support for the flange and also serves to locate the work longitudinally. The boring-bar *E* holds the tool *F* which does the boring, the turret being set off center a sufficient amount to bore the required diameter. The tool-holder *G* is one of the regular type commonly purchased with the machine. The two set-screws *H* are used to force down a beveled shoe which, in turn, serves to contract a split bushing which grips the bar. In connection with this equipment attention is called to the fact that the jaws are used principally for centering the work, being brought up very lightly on the inside of the work so that they have no tendency to distort the casting. The set-screws are then set up tightly on the outside, and as the piece is backed up by the jaws on the inside, there is no danger of springing. A metal-to-metal contact is obtained in this way and any tendency toward vibration is avoided.

The second setting of the work is shown in the lower part of the illustration. For this setting a faceplate is used with a locating plug *J* which fits the previously bored interior, the flange face being brought up against the finished face of the plate. Three clamps *K* secure the work. The boring-bar *M* holds tool *N* for boring the thin portion of the work, the turret being set off center for this purpose as in the first setting. The bar is held in the same type of holder *P* as that shown above.

Machining a Steel Motor Casting

The work shown at *A* in Fig. 4 is a steel motor casting of somewhat fragile construction at its inner end. This is

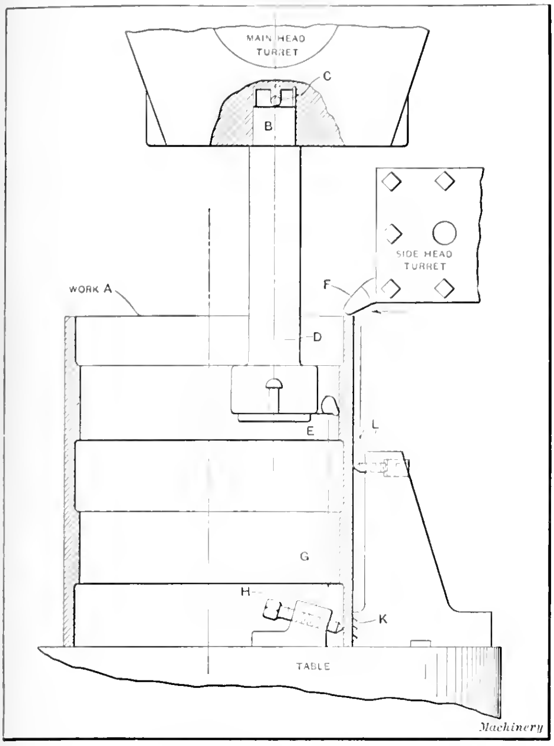

Fig. 7. Boring, facing and turning a Thin Casting in a Vertical Turret Lathe

another instance in which the turntable lathe is used. It will be noted that the casting is cored out at its inner end, so that there are three elongated openings at this point. In order to clamp the work without distortion, a steel ring *C* is provided with three set-screws *D*. This ring is placed in position in the casting before it is gripped by the jaws, the set-screws being set up with a moderate pressure against the inside of the walls. The casting is then placed in the chuck in such a way that these set-screws come opposite to the jaws. The jaws *B* may now be set up firmly without danger of crushing the work, the pressure being taken by the screws. The double tool-holder *K* is fastened to the turret face, and the set-screws *L* and *M* clamp the bars in position. These bars extend across the turret and the other ends are used for the finishing tools. The turning bar *J* is provided with a tool *H* which goes through the bar at an angle so that the tool is slightly in advance of the bar, thus permitting work to be done close up to a shoulder. A backing-up screw is provided for fine adjustments. The boring-bar *F* is arranged in the same manner, tool *E* being backed up by screw *G*.

The second setting is shown in the lower part of the same figure, the work *A* being held on a special arbor *O* which is screwed onto the end of the spindle. The finished end of the work is brought up against the shoulder on the arbor, the work being held on the portion *P* which fits the inside of the casting. The clamps *R* enter the cored holes in the casting *N*, and the steel stud *Q* forms a support for their inner ends. The tool-holder *U* is of the same type as previously described, the bushing *T* being compressed by two screws *V*, so that it holds the drill *S*. Other tools used in this setting are of a simple nature and need not be described. The facing is obviously done by the transverse movement of the turret.

Cutting Out a Thin Sheet Steel Collar

The illustration in the upper part of Fig. 5 shows a piece of hexagonal plate at *A* from which the thrust washer *B* is to be cut. In this work the center part of the blank *C* is saved and used for other work, but the outside portion is scrapped. The outside of the blank is held in the special jaws *D*, each of which is provided with a spring plunger *G*, a binding plug *F* and a hollow set-screw *E*. One side of the plunger is flatted off with a slight back taper as shown at *H*, so that any tendency to push back is offset by the wedging action of this taper. In operation, the plungers are first pushed down out of the way, and the jaws tightened, after which the plungers are released until they come in contact with the plate. The screws are now tightened and the work is ready for machining. A special tool-holder *O* is secured to the turret by angular gib *P* and screws *Q*. A steel tool-block *L* is mounted on a finished pad and is held in any desired position by the four screws *M*, which pass through the block and the body of the holder and are secured on the other side by nuts and washers. Vertical movement of the block is permitted by the elongated slots *N*, thereby allowing a number of different diameters of washers to be cut with the same tools. The tools *J* and *K* are ground on the sides to fit the slots in the block, and it should be noted that the lower of the tools is set forward slightly in advance of the other so that the center piece *C* will be cut out before the separation of the outer ring occurs.

Turning, Boring and Facing a Thin Steel Drum

The lower illustration in Fig. 5 shows another piece of work in which the same type of jaw with spring plungers is used to support the casting. In this case the jaws are so made that they grip the inside of the shell at *S*, while the plungers *T* come up against the web and assist in supporting it against the pressure of the cut. The same construction is used in the binding plug *V* and the hollow set-screw *U* as in the upper illustration. The facing of the web is performed by the cut-off slide tools while the boring-bar *Z* is cutting out the central portion with the tool *Y*. The forward end of this bar is hardened and ground at *X* to a running fit in the chuck bushing *W*. This piece of work was completed in another setting by holding it in soft jaws which extended in to form a support for the web.

Machining a Thin Ring Pot on the Vertical Turret Lathe

We now come to work of a larger size which can be handled to good advantage on the vertical turret lathe. On this type of machine the work stands vertically, so that there is no overhang of the spindle to contend with as on the horizontal type of machine. Aside from this, the conditions are similar

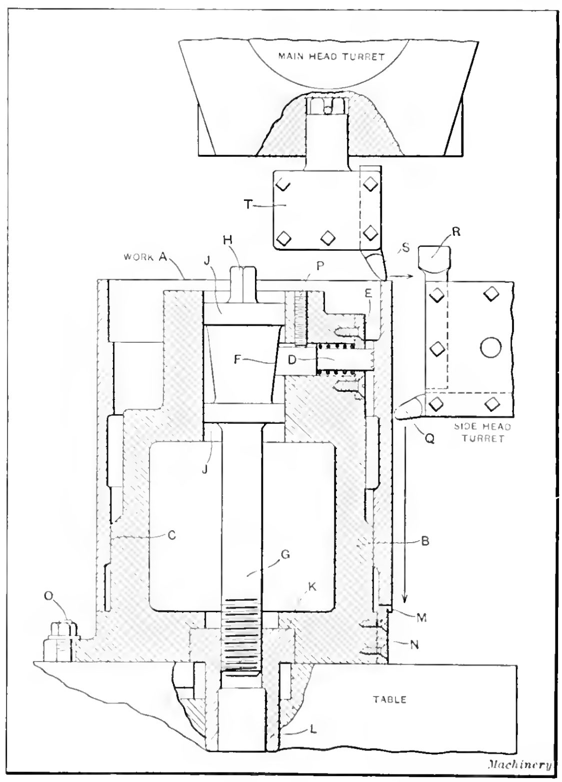

Fig. 8. Second Setting for machining Casting shown in Fig. 7

in both types. As the tools hang vertically, excessive overhang from the turret is not so apt to produce chatter as in the horizontal type of machine.

Fig. 6 shows a cast-iron ring pot from which four thin rings are to be machined. The pot casting A has a beveled flange around its lower end and is reinforced on the inside by web C. The jaws B are beveled to the same angle as the flange at D and, therefore, have a tendency to draw the

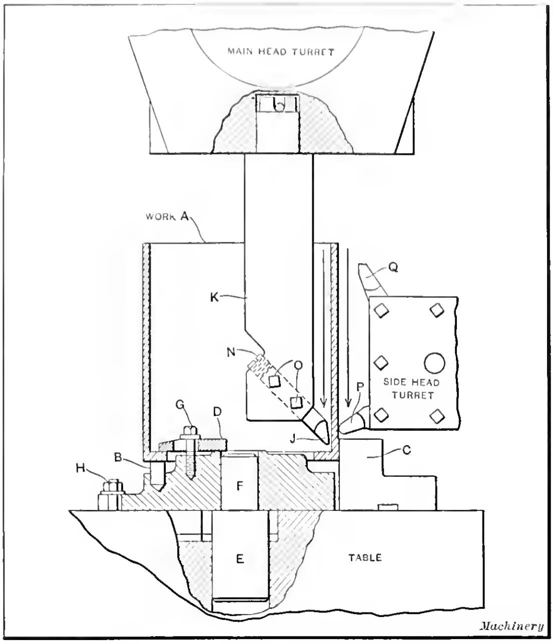

Fig. 9. A Thin Cast-iron Shell finished all over in a Vertical Turret Lathe

work down as well as to center it. The inner web tends to prevent crushing the pot when pressure is applied to the jaws. The bar E is a combination boring and reaming bar (as manufactured by the Bullard Machine Tool Co.), and is provided with slip-cutters and floating reaming cutters. (This type of bar was fully described in an article entitled "Design and Construction of Boring Tools," MACHINERY, March, 1914.) In this particular case the reaming cutters are not used, but roughing and finishing tools as shown at G are used in boring the casting. The shank of the bar fits the turret hole and is prevented from turning by pin F. The side-head turret holds roughing tool H and finishing tool J, these tools being used to turn the exterior of the pot. It should be noted that the boring and turning tools are working opposite each other, in the manner previously described. A special supplementary tool-block is fastened to the opposite side of the side-head turret and carries the three tools K which cut off the rings. These tools are ground on the sides so that they fit the slots in the tool-block, and are held in place by straps tightened by screws L. Attention is called to the fact that these tools are set so that a line passing through their cutting edges forms an angle of 5 degrees with the perpendicular. This is done so that the rings will be cut clean without ragged and broken edges, as only one ring is cut off at a time.

Machining a Piece of Electrical Work

The work A shown in Fig. 7 is a steel casting which is to be bored on the two internal annular pads, faced on the two ends, and turned on the outside. The casting is centered by the lower part of the special jaws K, these being brought up lightly against the casting so that they do not distort it. The screw dogs G on the inside of the work are then tightened until the pointed screws sink into the casting, thus holding the lower end firmly. The pointed set-screws L in the upper part of the jaws are now brought up against the work and tightened, after which the piece is ready for the machining operations. For boring the inside pads a special bar of the same type as that shown in Fig. 6 is used, the bar D being extra long. The shank B fits the turret and is driven by the pin C. A roughing and finishing slip-cutter E does the boring, while tool F in the side-head turret faces the end and turns part of the periphery.

The second setting is shown in Fig. 8, but between the first and second turret lathe operations a slot M is milled across the lower end of the casting to assist in driving. The work is held during the second setting on the special locating fixture B, which is made of cast iron and bolted to the table by the three bolts O, tee-shaped at their lower ends and fitting slots in the table. The centering plug K is a drive fit in the fixture body and is turned down at L to fit the center hole in the table. A steel strip N is fastened to one side of the body and its upper end acts as a driver in the slot M. The lower part of the outside of the body is turned at C to a nice fit in the casting.

The upper portion is firmly held by three expanding pins D which are flatted on one side where the screws P bear against them to prevent turning. The pins are shouldered for the coil springs and are beveled at their inner ends to fit the angle F on the operating rod. Three steel plates E are let into the casting to act as cover plates and hold the springs in place. The operating rod G is of tool steel with its lower end threaded with an Acme thread in bushing K. Two narrow rings on the upper end J are made cylindrical and a square portion is milled to receive a wrench by means of which the mechanism is operated. It will be seen that the purpose of the pins is to steady the upper portion of the casting and prevent torsion which might result under the pressure of the cut. Excessive pressure is not necessary on these pins, as a great amount of the driving is done by the block N at the lower end. The tool S is used for facing the

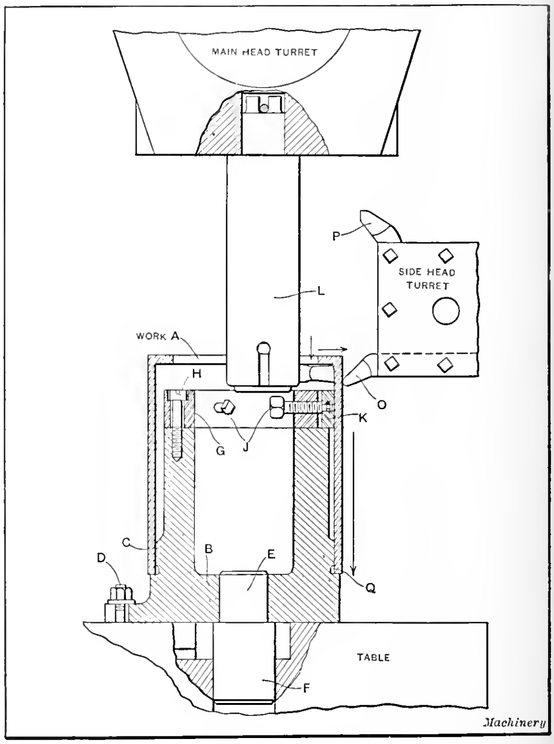

Fig. 10. Illustration showing Second Setting of Same Casting as shown in Fig. 9

end of the casting and is held in one of the regular toolholders T, the shank of which fits the turret hole and is driven by a pin. The side-head holds two tools Q and R which are used for roughing and finishing the periphery.

Machining a Thin Cast-iron Shell

The work shown at A in Fig. 9 is of cast iron and is finished all over, the side walls being only 3/16 inch thick when finished. A cast-iron base is held down on the table of the

machine by the three bolts *H*, which are tee-shaped at their lower ends and fit the table T-slots. A steel plug is forced into the base at *F* and fits the center hole in the table at *E*, thereby locating it centrally. Three hardened steel pins *B* are inserted in the base and act as supporting points for the casting. The three clamps *D* are operated by screws *G* and are slotted so that they can be pulled back, out of the way, when inserting or removing the work. In setting up, the jaws *C* are used to center the work, but they are not set up very tightly for fear of buckling the casting. Two special bars *K* are used for the roughing and finishing boring; tools

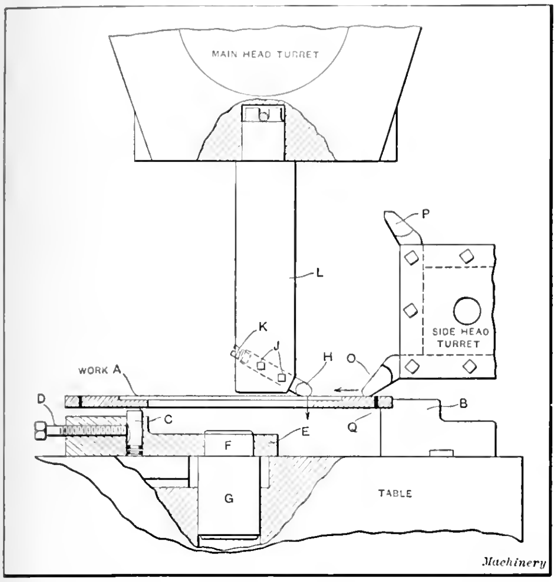

Fig. 11. Machining Steel Sprocket for Automobile Trucks

J are put in at an angle of 45 degrees so that there will be no interference with the clamps when near the bottom of the pot. Two screws *O* clamp the tools in place, and a backing-up screw *N* permits fine adjustments to be made. The tools *P* and *Q* in the side-head are used for roughing and finishing, and when in use are kept directly opposite the boring tools.

The second setting of the same casting is shown in Fig. 10, this operation consisting of boring the hole through the flange and undercutting it, and also approximately matching up the unfinished portion of the inside with that previously machined. The fixture body *B* is made of cast iron and is bolted to the table in the usual manner by the three bolts *D*. A locating stud *E* is forced into the body and fits the center hole in the table at *F*. The lower part of the body is turned at *C* to fit the inside of the bored shell. A shoulder is provided against which the finished end of the work is located, and a groove *Q* is cut so that trouble will not be caused by chips and dirt. A steel ring *G* is fastened to the upper end of the body by three screws *H* in such a way that there is clearance around the body of the screw; thus a floating or equalizing action is permitted. Three steel shoes *K* are let into slots in the ring and are controlled by screws *J* which pass through the ring. It will be seen that this arrangement permits the screws to be tightened sufficiently to perform their function without fear of forcing the work out of true, due to an unequal pressure on the screws, as the floating ring equalizes the strain. The boring-bar *L* used for the work is of the same general type as previously described, slip-cutters being provided for both boring and undercutting the flange. The facing of the flange is accomplished by tools carried in a regular tool-holder as shown in Fig. 8, while the outside turning is done by the roughing and finishing tools *O* and *P* in the side-head turret.

Machining a Steel Sprocket

The work shown in Fig. 11 is rather out of the ordinary. The piece when completed is a steel sprocket, such as used on automobile trucks. Two settings are required to complete the work, but the first one of these is the only one in which we are interested. The pieces from which the sprockets are machined are octagonal in shape and are of rolled steel with a large hole punched in the center. The work is roughly centered and gripped by the outside in the special jaws *B*. A cast-iron spider casting *E* is centered on the table by stud *G*, which fits the center hole in the table and the upper end *F* of which is a drive fit in the spider body. Three spring plungers *C* support the inner part of the plate and are locked in their positions by set-screws *D*. In operation, these plungers are pushed down, out of the way, until the jaws have been tightened, after which they are released and the set-screws tightened. The tooling for this piece of work is not out of the ordinary, bar *L* being similar to the one shown in Fig. 9, except that tool *H* is put in at an angle of 30 degrees instead of 45. The screws *J* hold the tool, and the backing-up screw *K* permits of fine adjustments. The tools *O* and *P* in the side-head are used for roughing and finish-facing. The recess is cut by a tool in the main head, while the final operation of cutting out the work at *Q* is accomplished by a parting tool in the main head.

Machining a Large Pot Casting

The work shown at *A* in Fig. 12 is of cast iron and is machined completely on the inside while the outside is turned as far as the finished pad extends. The work is held by the outside in the standard jaws *B*, supporting the bottom of the pot on the raising buttons *C*. A lug *D* on the outside of the pot acts as a driver against the side of the jaw. A long special tool-holder *J* holds the two tools *E* and *F*, these being held in place by set-screws *K*. These two tools turn the hub and bore the inside of the pot. At the same time that this

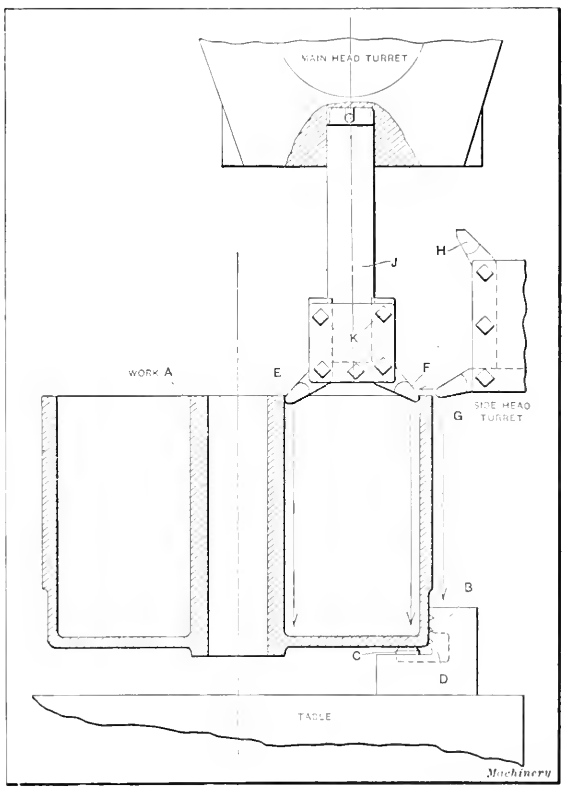

Fig. 12. Another Thin Casting machined in the Vertical Turret Lathe

operation takes place on the inside, tool *G* in the side-head turret is turning the outside diameter. The cutting points of all three tools are in a line. Another long tool-holder holds the tools for the inside finishing while tool *H* in the side-head completes the outside work.

* * *

The use of boron in aluminum-bronze makes an alloy which will not tarnish as readily as a bronze that does not contain boron.

MACHINING DESK FAN PARTS

SPECIAL JIGS, FIXTURES AND TOOLS USED BY THE ROBBINS & MYERS CO., SPRINGFIELD, OHIO

SPECIAL jigs and fixtures that enable interchangeable manufacture to be handled economically and on a satisfactory basis are always of interest to the average mechanic, inasmuch as the majority of these methods can be applied directly to his own work. The manufacture of desk fan parts in large quantities, for instance, requires a special tool equipment that compares favorably with that used in any other line. A number of interesting devices and methods for this work have been devised by the Robbins & Myers Co., Springfield, Ohio, and a description of these will be given in the following.

Fig. 1. Jones & Lamson Double-spindle Flat Turret Lathes at work on Fan Motor Bodies

Machining Fan Motor Bodies on a Jones & Lamson Double-spindle Flat Turret Lathe

Fan motor bodies are made from cast iron and have a particularly thin wall, which makes them extremely difficult to machine, because of the tendency of the castings to spring out of shape when being clamped. Another difficulty is that of making the hole for the motor shaft absolutely true with the counterbore in which the field of the motor rotates. To machine one of these motor bodies satisfactorily, therefore, requires not only a first-class tool equipment for holding and machining, but also calls for great care on the part of the operator. Fig. 1 shows two Jones & Lamson double-spindle flat turret lathes set up and in operation on this class of work. The machine to the left is working on fan motor bodies, while that to the right is at work on the cover or end of the body. The machining operations on the body are the most interesting and therefore will be given here.

Fig. 2 shows a close view of the turret tools, etc., and also the chuck, and Fig. 3 gives a clearer idea of the construction of the chuck and the method used in holding the work. The chucks used are of the ordinary three-jaw type, carrying special cup-shaped housings G fastened to their faces as shown. Around the periphery of these housings are located six knurled headed thumb-screws H. The points of these screws bear lightly against the body of the castings after they have been tightly gripped on the bearing hub by the three jaws of the chucks. The holding and driving is done by the chuck jaws, the housings and knurled screws being used merely to steady the castings. The screws bear against the castings and are tightened just sufficiently to hold them from being shifted out of place by the thrust of the cutting tools. The order (see Fig. 2) in which the operations on this fan motor body are handled is as follows:

First, remove scale from large bore with two tools held in the turret.

Second, index turret; rough-bore and counterbore small holes and rough-bore large holes with tools held at A in the turret.

Third, index turret; rebore small holes with boring tool B.

Fourth, index turret; finish-ream small holes and counterbore with tools C floating; finish-bore large holes with inserted-tooth cutters D and finish-face end of casting with tools F.

While the double-spindle type of machine takes a little longer to set up for various operations, it has the advantage of turning out two pieces in the same time that one could be turned out on a single-spindle machine. As far as accuracy is concerned, the work produced comes up to requirements and, in fact, the Robbins & Myers Co. has found that the double-spindle machine is especially adapted for this class of work, as a product of sixty-eight completed bodies in ten hours should bear evidence.

Two-speed Milling Device

A two-speed milling device for operating two milling cutters of different diameters at their correct peripheral speeds is shown in Fig. 4. The part being machined is a one-horsepower alternating-current motor body which is face-milled and has a slot cut in its base at the same time. Two of these castings A are clamped to the milling machine table at one time and the bases are machined by a large inserted-tooth milling cutter B, driven in the usual manner. The slots are cut with an end-mill C driven by a special arrangement passing through the spindle of the machine and the large cutter.

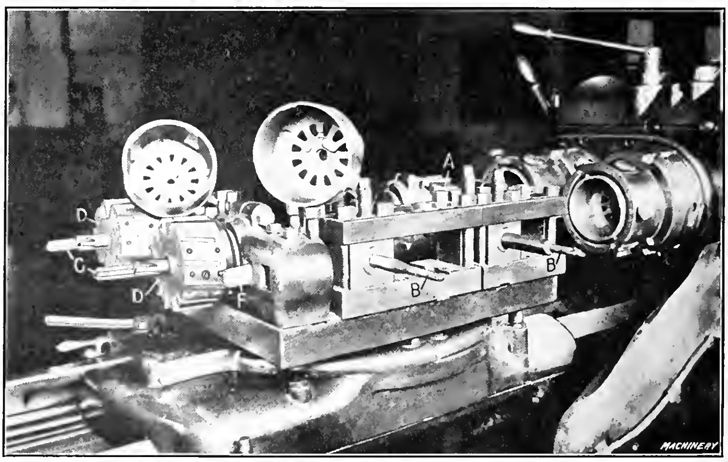

Fig. 2. Close View of Jones & Lamson Double-spindle Flat Turret Lathe showing the Turret Tools, Chucks and Work

A special spindle which passes through the spindle of the milling machine is supported at the outer end by the arm D, generally used for supporting the milling arbor, which, with the milling machine, as can be seen, has been reversed for this purpose. On this spindle a pulley E is located which is driven from the overhead works by a belt as shown.

The end-mill is screwed into the forward end of the spindle

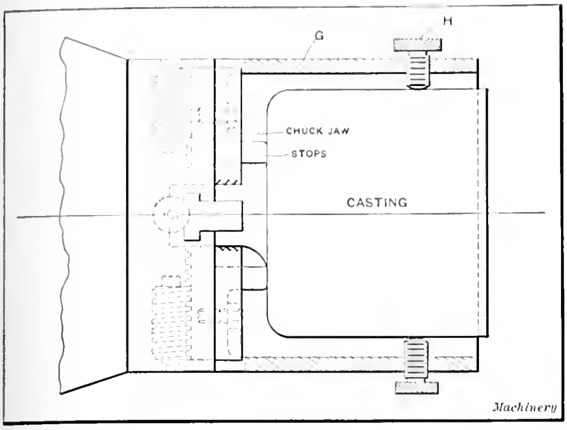

Fig. 3. Detail of the Chuck and Method of holding Fan Motor Bodies in the Two-spindle Jones & Lamson Flat Turret Lathe

and works in a hardened and ground bushing in the end. In the illustration, one of these bushings has been loosened and turned around so that the character of the operations accomplished can be seen and a better view of the cutters obtained. It is evident that it would be impossible to operate the end-mill at the same rate of feed as the large cutter, if the small cutter were rotated at the same peripheral speed. By giving the end-mill a proper peripheral speed, it can be operated at its proper cutting speed and the table of the machine given a rate of feed suitable for the large inserted-

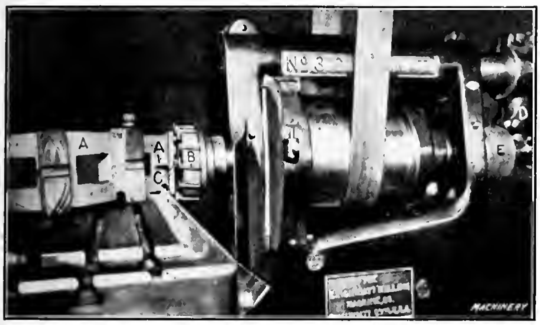

Fig. 4. Two-speed Milling Attachment for machining Alternating-current Motor Body Castings

tooth milling cutter, so that both cuts can be completed at the same time. This method of machining these motor bodies and the use of this special two-speed milling device may appear impractical to some mechanics, but, not having a milling machine of sufficient capacity to take care of the large variety of bodies and sizes, this company has used this method with very satisfactory results. Another method would be to mount the bodies vertically on fixtures on the table of the milling machine, and to use three spiral milling cutters of sufficient width, placing a milling cutter of the proper width for the slot between the two wider cutters. The entire operation could thus be accomplished in one cut.

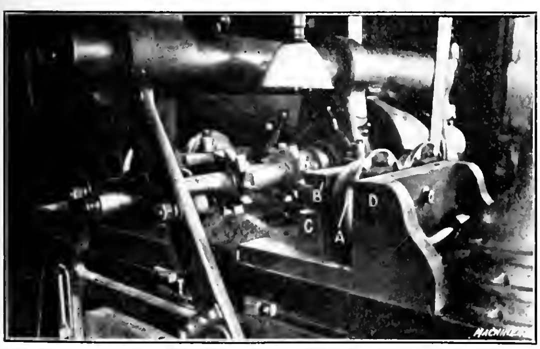

Fig. 5. Reciprocal Milling Attachment for machining the Slot in Desk Fan Bases

A Reciprocal Milling Fixture

Another interesting milling fixture is shown in Fig. 5. This is of the reciprocal type and is used for milling a 1 1/16 inch wide by 1 3/4 inch deep slot in desk fan bases. The spindle of the machine carries two side-relieved milling cutters 7 inches in diameter operated reciprocally on the four castings held in the two fixtures at each end of the milling machine table. While the cutters are at work on the two castings held in the fixture to the left, the operator is loading the fixture to the right and *vice versa*. The circular tapered bodies of the castings *A* are held by clamps *B* in V-grooves in blocks *C*. As the grooves are tapered to correspond with the taper on the work, the action of the clamps forces the base of the castings tightly against the face of the angle-plate *D*, holding them square and rigidly in position. This type of fixture gives very satisfactory results for this work and enables a

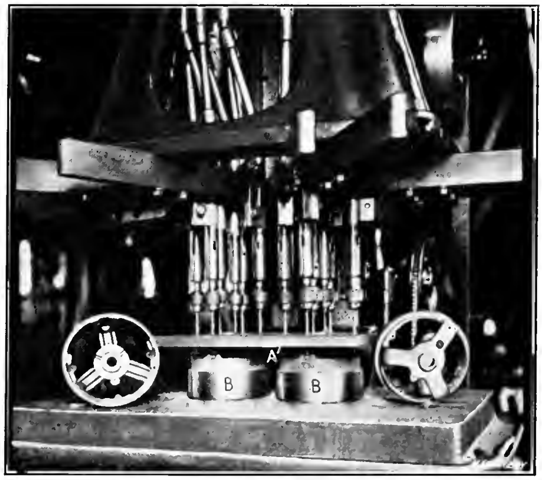

Fig. 6. Drilling Two Alternating-current Motor Bodies in a Pratt & Whitney Multiple Drilling Machine at the Same Setting

production of six hundred castings to be turned out in ten hours.

Gang Drilling on a Multiple Spindle Drilling Machine

An interesting fixture applied to a Pratt & Whitney multiple spindle drilling machine is shown in Fig. 6. This is used for drilling six holes in alternating-current motor bodies *B*, two castings being machined at the same time. The fixture, as Fig. 7 clearly shows, is of simple construction. It consists of a plate *A* which carries the drill bushings for guiding the drills, the motor bodies being located on central

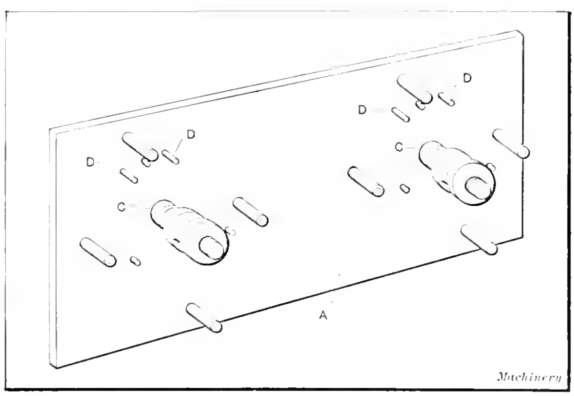

Fig. 7. Detail View of the Fixture shown in Fig. 6

guide studs *C* by two guide pins *D* in the proper positions from one of the arms. This type of jig is of open construction, easily cleaned, and enables the work to be removed and replaced very quickly.

Doubling Production on the Cleveland Automatic

Fig. 8 shows an improvement in tool arrangement on the Cleveland automatic for making the commutator shells shown

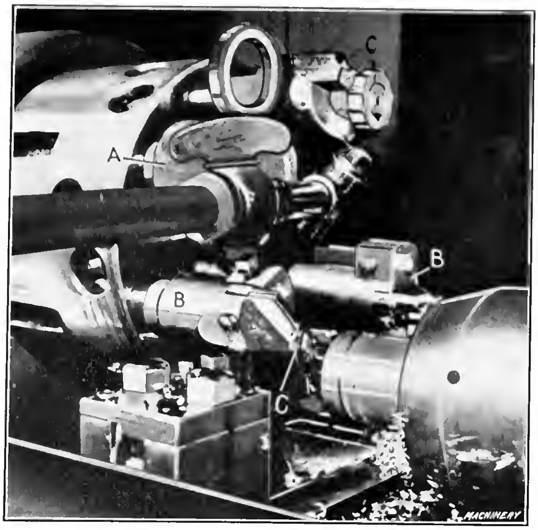

Fig. 8. Doubling Production on a Cleveland Automatic Screw Machine by having two Sets of Tools in the Turret

in Fig. 9, which are used on an automobile electric starter. These parts are made from a 3¼-inch bar of cold-rolled steel, and by the tooling arrangement shown in Fig. 8 the production was increased from 14 to 28 pieces per hour. The tooling equipment consists of two sets of tools carried in the turret and a form tool for producing or shaping two pieces instead of one at each stroke of the cross-slide. The order of operations is as follows: After feeding the stock out to the stop *A*, the hole is drilled and the bar turned by a combination tool *B* held in the turret; then by means of the combination reamer and counterbore *C*, the hole is reamed and counterbored in the front end to the beveled shape shown in Fig. 9. The cross-slide then advances and cuts the first formed piece off, after which the other set of tools comes into operation and forms another piece, two pieces dropping from the machine at every complete index of the turret. This method of doubling up the tools in the turret can be used to advantage on thin work of this type where only a few operations are performed from the turret.

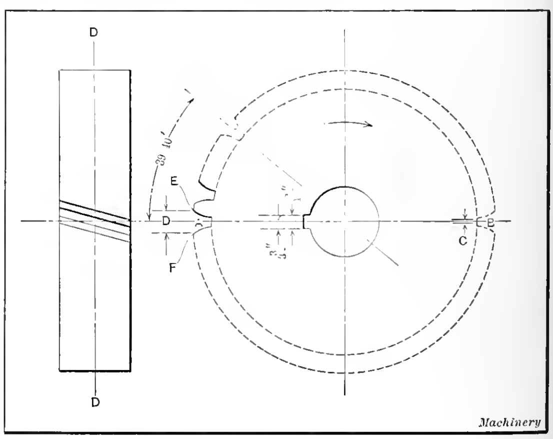
ACCURATE METHOD OF LAYING OUT KEYWAYS IN TIMING GEARS

BY ERNEST A. RUNGE*

Between the crankshaft and camshaft or the magneto driving shaft in an automobile motor, there are many places where errors may occur, the aggregate of which may seriously affect the timing. This makes it necessary—especially when building a model requiring the work to be done without special fixtures—for each keyway in the shaft or timing gear to be located very accurately. We have had quite a lot of this to do on model and special work, and have noticed that otherwise good mechanics have difficulty on this work through the lack of a good method. Believing that there are many others who do not get this kind of a job often enough to have worked up a simple and direct system of their own, I herewith describe the method we have followed with excellent results.

Let us suppose we have a timing as shown in the accompanying illustration, and for the sake of simplicity, let us for the present assume it to be a spur gear, the specifications calling for a 3/16-inch keyway located on the center line of the tooth space. The number of teeth is immaterial. Our first move will be to mount the gear, with the mandrel properly dogged, etc., on the index centers. If we have a true running expanding mandrel that fits in the index spindle, it will be somewhat handier than the solid mandrel. See that the index head is equipped with an index plate, one having a circle with the largest number of holes that will permit division in degrees being preferable for this purpose. With a surface gage having a very sharp pointed scriber, find the center of the gear; this is accomplished by approximating as nearly as possible and then, with the backlash in the index head taken up, scribe a short line near the edge of the gear, say at *A*. Then index the gear through one-half turn, which brings this line at *B*, and scribe another short line at this position with the same setting of the surface gage. If the setting is correct, the two lines will coincide; but should there be a difference *C* as shown, it will indicate that the surface gage scriber is either too high or too low. If this is found to be the case, adjust the scriber to bring the point exactly midway between these lines and repeat the test; when the line drawn on one side of the center coincides with another line drawn on the opposite side—the gear being indexed one-half turn as previously explained—we have found the center. Next we must find the tooth space represented by the distance *D*. With the surface gage scriber at position *A*, set the scriber point so it just touches the periphery of the gear, and index the gear around in the direction of the arrow so that the edge *E* of the gear tooth comes exactly to the scriber point. Mark the position of the index crank with the index sector. Now move the gear around until the edge *F* of the next tooth comes exactly to the scriber point. Count the number of holes passed over in the index plate. Let us suppose we count twelve holes; then the distance *D* requires twelve holes, and one-half of this or six holes will give us the point midway. Now return to *E* and index that number, and we have brought the gear to the position shown in the illustration.

We can now lay out the position of the keyway by adjusting our scriber point 3/32 inch above or below the center, and scribing a fine line from the hole to the left as shown; then indexing the gear around one-half turn, bringing *A* to position *B*; and then with the same setting of the surface gage, scribing another fine line from the hole to the right.



Method of laying out a Keyway in Relation to a Tooth Space

* Address: 110 Boulevard, Hartford, Conn.

The two parallel lines thus obtained mark the location of the keyway. If the keyway is to be cut in the shaper, an additional center line at right angles to *A—B* will be of service in setting the gear in the shaper vise, as by our method we set the gear with this vertical center line parallel to the vise jaw and carefully guide the tool between the lines scribed for that purpose, until we arrive at the proper depth. If care has been exercised in the previous operations, you will have the keyway located as accurately as is possible without an elaborate special fixture. It is assumed that unless you are blessed with unusually good eyesight, you will use a magnifying glass to assist in making these settings. Had the drawing called for a keyway to be located in a position 39 degrees 40 minutes measured counter-clockwise from the center of the tooth space, after we had found the center of the tooth space, we would have indexed the gear that amount in the direction of the arrow, which would bring the tooth space center to position marked *G*. The keyway would then be laid out as before.

In the previous examples we have assumed the gear to be a spur gear. Had it been a helical gear, if the layout for the keyway is shown on the side, our method would be the same as for a spur gear, except that in finding the center of the tooth space we would be obliged to work entirely on the side of the gear. A moment's consideration will show why this must be. The layout may be shown on a plane at the center of the gear width as indicated by the line *D—D*; only one helical cut is represented to avoid confusion. In a case like this, before mounting the gear on the mandrel, we would scribe a line *D—D* on the ends of the gear teeth. Then after the gear is in position, to find the center of the tooth space as in the previous examples, we set our surface gage scriber point exactly on this line *D—D* and find the center of the tooth space as before. Having found the center, scribe the line across the side of the gear and proceed the same as for the spur gear. Had it been necessary to work from the center of a tooth instead of a tooth space, the procedure, except for this difference, would have been the same.

* * *

FIXTURE FOR MILLING CLUTCHES

BY I. W. SPRINK*

The accompanying illustrations show the design and construction of a special form of dividing head used for cutting the clutches on transmission drive pinions and sliding gears.

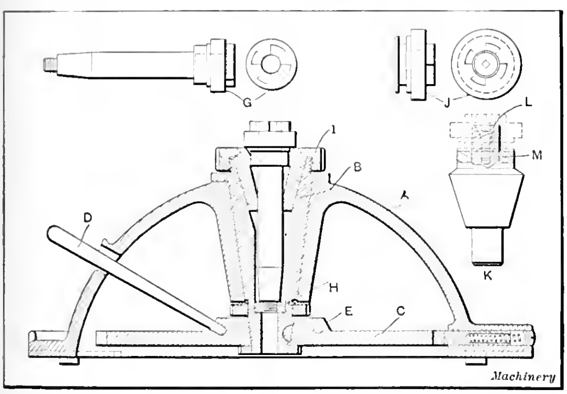


Fig. 1. Cross-sectional View of Fixture for milling Clutches and Details of Work-holding Mandrels

This fixture consists of a frame *A* into which the spindle *B* is fitted. The spindle is designed to serve as a collet chuck on the upper end and is arranged to carry the large index plate *C* at its lower end. The method of operating this dividing head is very simple, the spindle being rotated by means of the handle *D*. The index plate has a series of holes *E* drilled in it at a convenient angle to receive the handle *D*. To turn the spindle, it is merely necessary to withdraw the locking bolt *F* by means of the small lever provided for that purpose, and move the index plate around by means of the handle *D*.

* Address: 3209 McKinley Blvd., Milwaukee, Wis.

The method of chucking the pinion shaft *G* is clearly shown in the cross-sectional view, Fig. 1, and will need little description to make it clear to any mechanic. It will be seen that a small collar *H* rests in a hole at the bottom of the spindle; this collar receives the downward thrust of the work and also serves the purpose of locating the lower end of the work to bring it exactly perpendicular. In using this fixture it is customary to put a sheet-metal washer between the lower face of the pinion and the top surface of the chuck ring *I* in order to keep chips and oil from running down into the dividing head. The collet chuck is cut into three parts and provided with springs between its faces to expand the collet.

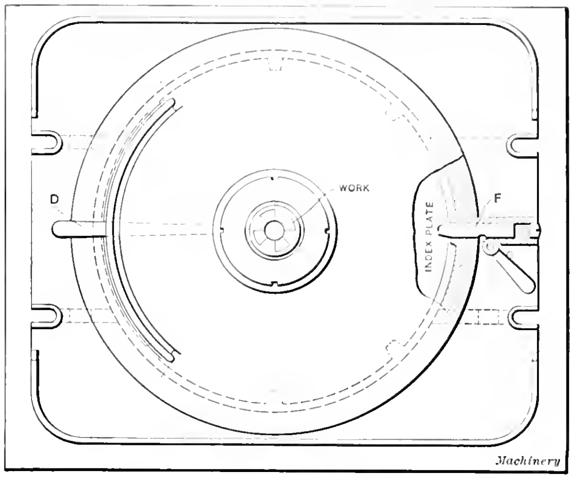

Fig. 2. Plan View of Fixture for milling Clutches

When milling the clutch gear *J* the split collet is replaced by the expansion chuck *K*. The body of this chuck fits into the spindle and is locked in position by the chucking ring *I*. The work is held on this chuck by expanding it by means of the taper headed screw *L*, which is turned by a square key. The hardened steel collar *M* is fitted onto the chuck to provide a good bearing surface and resist wear. The clutch gear is shown in position on the chuck by dotted lines.

It will be evident that eight cuts are required to complete the milling operations on one of these clutch gears, and consequently it is necessary to use an eight-point index plate. A cutter ½ inch wide is used. After setting to bring the cutter to the required depth, the milling machine saddle is moved in until one edge of the cutter registers with a point 0.010 inch to the left of the center; four cuts are then made, completing one side of the clutch teeth. To mill the other side of the teeth, the milling machine saddle is moved out until the other side of the cutter registers with a point 0.010 inch to the right of the center. The head is then indexed ⅛ revolution to mill the side of the first tooth, and then ¼ revolution for taking each of the three remaining cuts. The clutch teeth are cut a little off center in order to give the clutches the required amount of clearance.

All steel parts of this dividing head are carbonized, hardened and ground to make a good serviceable tool. The ideas embodied in the design of this special dividing head may suggest other uses for a tool of this kind where it is required to perform milling, drilling and other operations on work for which the regular milling machine dividing head is not suitable.

* * *

What is claimed to be the largest wind motor in the world has lately been erected at Harlingen, in Holland, for draining a tract of lowland redeemed from the sea by high embankments, the area being nearly 2000 acres. This wind motor is provided with steel sails and is mounted on a steel tower. It has a diameter of 50 feet. It is an interesting fact that while some years ago the wooden windmills of Holland began to be replaced by internal combustion engines, during the last five years the steel windmill has begun to be more and more employed, especially for pumping purposes.

THE PROBLEM OF DISTRIBUTION

The greatest problem confronting society is that of distributing the products of factory, mine, farm, and every industry more efficiently, which means at less cost. Scientific management has done wonders in reducing the cost of manufacture, but it is of little avail to cut the cost of manufacturing products when the great cost of distribution remains practically unchanged. The disparity in the price of farm products in the city and country is notorious. What is needed is some better means of bringing producer and consumer together.

Manufacturers spend money liberally to bring their products to the attention of possible customers, and it must be counted a great achievement of advertising that some great businesses have been developed very largely by its aid. But while it is true, and of course perfectly natural, that a man will read advertisements which describe the tools and materials of his own trade or business, and about anything in particular which appeals especially to him in a personal way, it is true also that the advertising of general products is not habitually read by the general reader as the editorial pages are read. This is one of the great problems of distribution, but we believe it is in course of solution. The old suspicion of advertising claims and statements is wearing away. Advertising has gained greatly, not only in good taste and in the ability to impart information, but also in the reputation for reliability.

The columns of the foremost newspapers, the leading magazines and technical journals are open only to the advertising of reputable people whose claims are scrutinized, and no reader of important journals can now afford to neglect the advertising. Speaking of technical journals in particular, the reader who regularly consults the advertising acquires a great deal of valuable technical information, a knowledge of new developments and considerable trade information which can be acquired in no other way. The day is not far distant, we believe, when the advertising pages of MACHINERY, for example, will rival the reading pages in presenting news of improved practice, materials, machines and designs. Stilted catalogue advertisements devoid of life and drawing power will be entirely displaced, as many of them are now, by masterly argument and convincing claims that will make the silent salesman—the technical journal—an even more potent factor in the great problem of distribution.

HERRINGBONE GEARS FOR HEAVY DUTY

In the beginning of mill construction the gearing was made with wooden teeth, and this form was slowly displaced by cast-iron gears with integral teeth, molded from a full pattern. These cast gears, however, were inaccurate and noisy. The patternmaker might make the pattern with thoroughness and skill, but it was soon warped by rough usage in the foundry and the influences of the weather. A great improvement in cast gears was effected by the molding machine which eliminated the tooth inaccuracies inherent in the full pattern. A pattern of one tooth only, indexed step by step, formed a mold in the sand with precision, and thus eliminated the troubles and expenses incident to the use of the old full patterns. But the requirements of modern machinery construction were not always met satisfactorily in cast teeth, and so the final step in spur gear making was effected when machines were built for forming the teeth from the solid metal by formed cutters or generating tools. Today spur gears twenty-five feet in diameter and larger are machine cut, but this stage, too, is but another step in the evolutionary process.

The spur gear drives its mate evenly or unevenly, depending on whether or not its tooth forms are true shapes. If the shapes are true, if the gears are correctly mounted and if they are not overloaded the angular motion transmitted will be regular, but ideal conditions are difficult to realize in the beginning and almost impossible to maintain.

The inherent defects of spur gearing are being more and more realized as the requirements of machine users become more and more rigid, and designers are specifying herringbone or double-helical gears for positions in which spur gears have proved unsatisfactory. The smooth running characteristic of the double-helical gear is no new discovery. On the contrary, it has been known a long time, and this type of gear has been much used, but only when its higher cost was warranted by the conditions to be overcome. Now, however, the difference in the cost of spur and herringbone gears is becoming less and less as improved processes are being applied to the production of the latter. As some one has aptly remarked, the herringbone gear is to the spur gear what the cut gear was to the cast gear. That, in a nutshell, tells the story of evolution.

* * *

ALLOY STEEL GEARS IN MACHINE TOOL CONSTRUCTION

Considerable experimenting has been done by machine tool builders in an endeavor to follow automobile manufacturers in the use of alloy steel gears in gear-boxes and other power transmitting units of machine tools in order to prevent breakage and stripping of gear teeth. Alloy steel, such as chrome-vanadium and chrome-nickel, has been used with more or less success. Where it is impossible to make a complete analysis of the steel before working it up, it has been found that alloy steel gives far more trouble than ordinary carbon steel. The limits of fluctuation in heat-treatment are much narrower than in ordinary carbon steel, and the material must be handled much more carefully if good results are to be expected. One machine tool builder in the Middle West has tried both chrome-vanadium and chrome-nickel steel for gears which are used in a gear-box transmitting considerable power. Very unsatisfactory results had been obtained, and this manufacturer has gone back to the use of ordinary carbon steel having a carbon content of 0.20 per cent, heat-treating the gears in the most scientific manner known. Since using carbon steel this company has found that its troubles in the way of breakage and stripping of gear teeth are practically eliminated. A more uniform carbon content, in ordinary carbon steel, is obtained; and hence the same heat-treatment on different classes of gears can be employed with very little loss. This seems interesting, since the development, of late, has pointed rather to the use of chrome-nickel and chrome-vanadium for gears that are required to work under severe conditions of load, speed and shock.

FORCED FITS

Periodically, in the transactions of engineering societies and in the technical press, discussions appear with regard to the proper allowances for making forced or pressed fits with full holding power and maximum economy of metal. There seems to be no such uncertainty with respect to shrinkage fits—a confidence which is justified fully by their extensive use in all built-up ordnance. The integrity and safety of every high-powered gun, in all armies and navies, depends upon shrinkage allowances, and the total absence of accidents in recent years through the bursting of the breech in such guns proves that these allowances are adequately proportioned for the stresses which the compound cylinder forming the breech must meet when the charge is exploded. The thickness of these cylinders and their relative "allowances"—that is, the difference before shrinkage between the external diameter of the inner cylinder and the internal diameter of the outer—are always based fundamentally on Lamé's formula for the determination of the stresses in thick cylinders. The derivation and application of this formula have been fully discussed in previous numbers of MACHINERY.

If the allowances for the forced fit are so proportioned that, in pressing home the inner member—axle, shaft or crank-pin—into the outer member—wheel-hub or crank—there occur only expansion of the latter and compression of the former, both within the elastic limits of the metals, then Lamé's formula is fully applicable to forced fits also. Let us consider the effects which, by this formula, are shown to be caused by shrinkage and on the assumption as above by forcing also.

The radial pressure on the contact surfaces of the fit produces a radial, compressive stress in both the inner and outer members. As a result of this stress there are induced in the outer member a circumferential tensile stress or "hoop tension" and also, through lateral contraction, a longitudinal compressive stress which, in wheel or crank-pin hubs, is negligible. The hoop tension diminishes in intensity very rapidly from the inner to the outer circumference of the hub, and hence the critical and dangerous part of the fit lies at the inner layer, that is, at the bore. So long as the tensile stress in this layer does not exceed the ultimate tensile strength of the metal, the hub will not burst, and, conversely, no hub thickness whatever will prevent rupture if the ultimate tensile stress of the metal at the bore be exceeded. Further, as the radial stress decreases so rapidly toward the outer circumference, the influence of wheel-arms and crank-webs on the resultant hoop tension is relatively slight. The allowance per inch of diameter of the inner member depends upon its coefficient of elasticity, the allowable tensile stress at the bore and the quotient of the true compressive stress at the outer surface of the inner member, divided by the hoop tension at the bore. The holding power of the fit is the sum of the total radial pressures on the contact surface, and this pressure is, in turn, affected by the size of the allowances and the compressibility and expansibility of the inner and outer members, respectively, the expansibility depending to some extent on the thickness of the hub. As increased diameter gives augmented contact surface, the allowance per inch of diameter may be decreased if the holding power required does not increase proportionately with this surface.

While the basic principles governing shrinkage and forced fits are the same, the methods of making them differ, and hence there is some doubt, especially with large allowances, as to whether the formulas for a shrinkage fit apply fully to the forced fit. With the latter, in driving the inner member home, the effective allowances and holding power may be reduced either by abrasion or, with unduly large allowances and ductile metal in the hub, by an axial flow of that metal in advance of the entering inner member. There seems no question, however, that with metals of average stiffness, the allowances in forcing should not exceed those for shrinkage, as otherwise there will be at the bore either excessive stress, permanent set or rupture, with ultimate failure of the fit.

OPPORTUNITIES FOR THE MACHINIST

BY F. B. JACOBS*

Anyone who has associated with machinists to any extent cannot help but realize that they are sometimes discontented with their prospects in life. When the machinist compares his wages and outlook with those of his fellowmen who are employed at other vocations, he naturally draws conclusions, which may, or may not be logical. In interviewing a number of machinists, we find some that are satisfied and contented. On the other hand, many claim that their wages are insufficient when compared to the rates paid in other skilled trades, and that life offers no better prospects than uninteresting daily toil for years to come. It cannot be justly claimed that all forms of discontent are harmful, for ambition and discontent often go hand in hand, the one being the direct cause of the other. The dissatisfied machinist has a vague idea that he would like to work at some other calling, but for some unknown reason the majority, when discussing the subject, seem to have a leaning toward vocations for which they have had no training. However, an examination of the ideas advanced shows the same desires: *viz.*, greater compensation for energy expended, less manual labor and more leisure time. We cannot claim that these desires are unreasonable, for they have been, and always will be, entertained by useful citizens in all walks of life. How about the machinist? What chance has he in the competitive struggle? Twenty-five years of close association with machinists and machine shops has convinced the writer that the machinist has a better chance than the average worker and the conclusions drawn are taken from actual experience. The word "worker" is used in this case to designate anyone who is not possessed of an independent income.

In considering the wages paid machinists, we must not lose sight of the fact that they are regulated by the inflexible law of supply and demand. As an illustration, if there are ten open positions at $3.50 per day, and fifteen idle machinists to fill these positions, it is evident that not one of the fifteen could reasonably expect more than the current rate. On the other hand, if there were only five available men, it is evident that some of this number would succeed in getting a higher rate, depending, of course, on their ability to sell what they have to offer—their labor.

When considering the wage question there is another fact that is often overlooked by the mechanic; that is, the close competition that exists between manufacturers whose products are identical. Let it be assumed that two concerns are engaged in the manufacture of machine tools—lathes, for instance. They both buy material in the open market at practically the same prices, the shop management is as efficient as possible, the selling methods are the same, and the combined output goes to the same market. In both cases the selling prices must be practically alike for tools of like design and purpose. It is a well known fact that labor is the most expensive factor in any industry; therefore one concern cannot pay more than the current rates for skilled mechanics and dividends to the stockholders at the same time.

In comparing machinists' wages with those paid other skilled workers, we must take equal conditions, considering carefully the amount of skill involved, the number of available working days per year, the personal risk encountered, and in some cases the physical strength required. A die-sinker receives high wages because his work calls for a combination of mechanical skill and artistic ability. A toolmaker is well paid, as it calls for more than ordinary skill, together with long practice, to work to close limits. An experimental hand, that is one who constructs initial machines from drawings without the aid of jigs, is well paid, as it takes more than ordinary ability to become proficient at this class of work. It is not logical to compare machinists' wages with the rates paid to those employed in the building trades, carpenters, masons, tile setters, structural steel workers, etc., because these trades do not give steady employment owing to inclement weather and off seasons. While the building trades are well paid, their members are seldom better off,

* Address: 838 North Capitol Ave., Indianapolis, Ind.

year for year, than the machinist. Their only gain is too much leisure time. This is a serious setback from a financial point of view, as one always spends more than usual while unemployed, that is if one has it to spend. Structural steel workers are well paid because their work involves the daily risk of life and limb. Perhaps the highest paid skilled workers are the rollers employed in steel mills. They receive from $8 to $15 per day, depending on the material rolled. This work calls for unusual strength, great skill and a sure eye and hand—hence the high wages. In all the callings mentioned it would be comparatively easy to obtain workers at low rates if more than enough men possessing the necessary qualifications were constantly in the ranks of the unemployed. That high priced men find ready employment at the above-mentioned trades is due to the fact that they possess certain qualifications not found in the average person.

On the other hand, the machinist receives better compensation for the time and effort spent than many other skilled workers. As an illustration we can consider the furniture workers of Grand Rapids, Mich., or Evansville, Ind. These are two of the largest furniture manufacturing centers in the country. While the component parts of any piece of furniture have to be accurately machined, the work is of a semi-automatic nature. As it is routine work any man can become skilled in a short time, provided he possesses a certain amount of mechanical ability. For this reason the wages paid are comparatively low, as men who could become qualified and who would be willing to work for moderate wages can easily be obtained.

Coming back to the direct subject: How is the machinist to better his condition to the extent of increasing his compensation? There are many ways. For example, instead of being an ordinary hand on uninteresting routine work, why not be an expert all-around man? The work is interesting and the wages good. While the way to success is somewhat rocky, it has been traveled by many and the skill attained is sure to be recognized sooner or later. When a machinist has once earned the reputation of being a skilled and reliable workman, the fat pay envelope becomes a reality instead of a dream. There are three primary qualifications, good health, mechanical intuition and the love of adventure. It is an acknowledged fact that shop practice varies greatly, not only locally, but all over the country. For this reason, it is necessary for the man who desires to become an expert to follow the wanderlust for a period of years. This involves working on all sorts of machine work in many localities. The scene of activities often includes every large city in the country. The life is hard in many ways, calling for a cast-iron constitution. Days of misery are sure to be encountered; there will be times of sickness among total strangers, or what is worse, no money. It is well to mention these facts in passing; otherwise one might form the opinion that the life of the roving machinist is a bed of roses. It is worth while, however, as the experience gained by travel and association is invaluable. After a machinist has worked in thirty or forty shops he should be a good mechanic if it is in him to be one.

No system of training is without its drawbacks, and the schooling received by the wandering machinist is no exception. Often times the wanderlust is irresistible to one who has once answered it. This is especially true during the first balmy days of spring. The stay-at-home hears the same call, but he lacks the courage or initiative to answer it. The result of answering the call is that many mechanics never settle down. This is true of the minority only, for the roaming machinist is very like his stay-at-home brother in one respect; he cannot, or at least does not, resist the feminine charms. Thus he generally marries, and home ties eventually compel him to settle. He is careful where he settles, however, as experience has taught him to compare conditions and to form accurate decisions as to what constitutes fair treatment, wages, etc. His varied training has developed initiative. Therefore he knows how to proceed in selling his labor to the best advantage. Those who have been trained in the school of experience seldom try to stir up trouble when unfair shop conditions, real or fancied, are encountered. If dissatisfied they remedy the situation very simply by following the line of least resistance—they seek employment elsewhere.

It is sometimes argued that under present conditions a varied training is not necessary, that we are in an age of specialization, etc. Perhaps we are. Nevertheless the fact remains that men who have had the varied training on actual work invariably succeed in obtaining responsible positions at good wages. There are several kinds of varied training. The college trained mechanical engineer is one example. That he is college trained is due to the fact that his parents were financially able to not only support him, but pay expensive tuition fees during a period of his life when his earning power was absolutely nil. We respect the college man because he has had a varied training along theoretical lines. Thousands of dollars have been spent on his education. Why was this done? To fit him for his life work and to make him a useful member of society. The practically trained man is respected because he has shown ability to fight his own way, thus making possible a varied training. He has asked no favors of anyone. Not only has he made his success possible, but he has also been a producer the meanwhile. Who deserves the greater credit, the one who had the way paved for him, or the other who fought his own way?

It is sometimes claimed that the machinist's opportunities for betterment would be greater if his labor organization were stronger. If the test of time is of any value, it would appear that this theory is not well grounded. To be sure, card men are conspicuous in the Western and Southern states; indeed a non-union man finds it almost impossible to obtain employment in these sections. The South and West, however, contain comparatively few manufacturing centers. Taking the country as a whole, the majority of the employers of machinists run strictly open shops. If one happens to be a card man he is not molested. On the other hand, card men are not permitted to intimidate or cajole their fellow workers who are not organized. As a matter of fact non-union men often receive higher wages than those paid under the rates set by the union scale. Organized labor automatically adjusts itself to conditions; we do not have to consider it theoretically, as known results give us the base on which to frame our arguments and draw our conclusions. The wandering machinist is always a card man; necessity compels him to be. However, at the same time, he generally favors the open shop, whether he acknowledges it or not, as it is there that he receives the highest compensation.

Is the machinist better off, financially and otherwise, in the city or country? This question must be viewed from many points. That the city offers greater opportunities for employment cannot be denied. The cost of living in cities is, of course, greater, but to offset this wages are higher. Many live in the suburbs, traveling back and forth daily. This consumes time and incurs an extra expense, but it is argued that the advantages gained by living away from crowded districts outweigh the extra time and expense. If one is employed in a comparatively small town, the cost of living is much less than it is in the city. On the other hand, one is practically tied down, especially if he happens to be a property owner. Under these conditions the shop management is in a position to exercise a dictatorship even to the extent of controlling the political rights of the workman. In the small town the union does not set the rate—the shop management does. Thus one might be ever so skilled or efficient and yet find it impossible to obtain more than the fixed rate.

One reason for this, and a logical one, too, is that in a comparatively small town everybody is acquainted with their neighbors' affairs. Let it be assumed that Bill succeeded in getting an increase of twenty-five cents per day. Naturally he tells Mrs. Bill, for ten chances to one she would find it out anyway, and if he had not enlightened her at first there would be domestic warfare for the time being. Now Mrs. Bill is very much pleased. An extra $1.50 per week that was not looked for will go a long way. She may get a new hat, who knows? She cannot resist the feminine tendency for gossip to the extent of keeping Bill's good fortune to herself.

She tells Mrs. Jim and what is the result? Mrs. Jim, of course, tells Jim when he comes home to dinner. He gets peeved and thinks that he, too, deserves a raise. He may get it, and again he may not. However, it soon gets noised around that Bill has had his pay raised, and the first thing the management knows they are confronted with a general demand for more money. This could not happen in a city, for city people are master hands at attending to their own affairs; indeed they seldom know their next-door neighbors. In a small town, the shop management is shrewd enough to realize that the workman cannot, or at least does not, care to incur the expense of moving to another locality. Another reason why many hesitate to locate in country towns is that there is very little to offer in the way of recreation, aside from a moving picture show or two. All work and no play makes Jack a dull boy; therefore the machinist cannot be blamed for working in places that have at least the appearance of being lively.

After all is said, the machinist has as many opportunities as any other worker, if he will take steps to turn chances into success. No one can reasonably expect to succeed by waiting for fortunate chances—these have to be sought.

COOPERATION OF THE FACTORY MACHINE SHOP WITH THE TRADE SCHOOL*

BY JAMES F. JOHNSON†

In the present move toward supplying the demand for trained mechanics through trade education departments, it is timely to note the important part that can be played, and really should be played, by factories having trade apprentices. The apprenticeship system has about passed out of existence. Because of the general trend of manufacturing competition, every effort is brought to bear upon production and the idea of taking the time of a valuable producer to instruct young apprentices who are not producers of any great worth does not usually appeal to the manufacturer. Because of this state of affairs, the apprentice is obliged to learn his trade as well as he can. The result is inevitable, and surely cannot be considered valuable in building up the trade.

The opportunities offered by the trade school at Bridgeport, Conn., have brought about cooperation with the manufacturers that has proved an excellent way of dealing with this important problem. What has been done there should encourage other industrial centers to make an effort in this direction. In order that those young men who are at work daily might enjoy the benefits of a trade education, there was opened up in the trade school a department for those apprentices who are employed in the shops outside. These young men attend the school five hours per week, fifty weeks in the year, during the length of their apprenticeship in the factory, and are paid by the factory while they are at school.

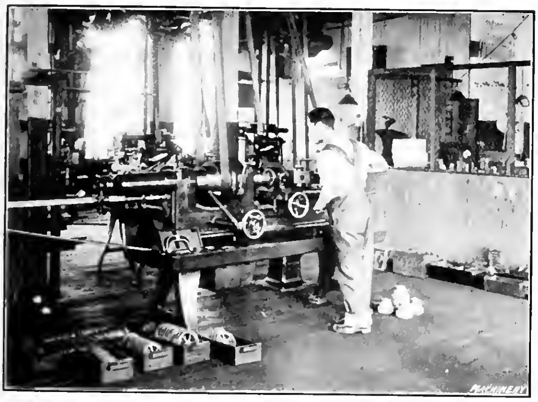

Fig. 1. An Apprentice learning to set up and operate a Hand Screw Machine

Instruction is given in those branches directly related to their trade but which cannot be given in the factory. The scheme is a praiseworthy one and those manufacturers cooperating in such a cause are to be complimented. The work as it is carried on for the machine apprentices is of most interest to the readers of MACHINERY and is here described. Fig. 1 shows an apprentice being instructed in screw machine operating, and Fig. 2 shows one of the ten divisions of machine apprentices coming from different shops. These are instructed in blueprint reading (the blueprints of the respective shops being used), shop drawing and shop mathematics. Besides this, a portion of each session is set aside for the reading of trade literature, or for shop talks. Little if any instruction is given in actual machine work, as their respective shops will furnish enough of that—but what is needed most and what the factories do not give is what is taught in the school. The work is in charge of a thorough tradesman who appreciates the needs of the machinist.

Fig. 2. A Class of Apprentices employed in Factories, who attend School One-half Day a Week

Each week this instructor visits the shops where these boys are employed and secures such information as may be of value to him in his work. The great value of this instruction to the coming tradesman is daily illustrated in the places where the boys are employed. It is not an unusual thing to see one of them and the assistant foreman or the foreman with their heads together talking over features of a design shown on a blueprint. When there is doubt about a calculation in the shop, the student-apprentice is consulted, or rather he is given the work to do.

The spirit of cooperation between the tradesman and the apprentice is growing. The old hand at the trade smiles at the youth and slaps him encouragingly on the back, and he is given his place among the workers, for he is becoming an intelligent mechanic. This training carried on for the length of his trade apprenticeship is sure to have a very desirable effect. Besides being a machinist, he knows the whys and wherefores of things and is a more valuable man to himself and to his employer. As a result there will be among the coming machinists a group of young intelligent workers who thoroughly understand their trade and its relation with allied trades, and realize their position in the manufacturing world. The effect of this is undeniably good. It means a better workman, a better product, increased production, and better working conditions.

* * *

A New Zealand correspondent writes that he considers it a serious mistake on the part of advertisers of American machine tools not to quote prices when advertising, and that the names of foreign agents or dealers handling their goods are seldom given. As a result the larger part of New Zealand business goes to English agents in New Zealand, much of which might be secured by American concerns if they displayed a little more enterprise in advertising, giving prices, the names of foreign representatives, and other specific information.

MAKING CON-ECCENTRIC TAPS*

METHOD USED IN CUTTING RELIEF ON TAPS LEAVING PART OF THREAD CONCENTRIC

BY SERVER

I HAVE been particularly interested in reading the articles which have appeared in MACHINERY on machine relieved taps, and feeling that a brief discussion of the method of machining this relief would be of interest to others, I have prepared the following article. In conducting this operation, certain difficulties are met with in connection with "picking up the thread" preparatory to relieving the lands of the taps, and in connection with a description of the method of conducting this operation I propose to explain a few short-cuts which greatly simplify the work. A number of tap-makers seem to have recognized the con-eccentric relief for taps as most satisfactory, and apparently each of these manufacturers has been using this method secretly in the belief that his product was the only one embodying this valuable feature. Under the pressure of business competition, this fallacy has been exploded, thus meeting the fate of the majority of such business and trade secrets. The information given in this article applies particularly in cases where special or small lots of standard taps are put through. The methods described are in no sense representative of standard practice in the manufacture of taps on a commercial scale, as plants engaged in this line are equipped with more or less special machinery for cutting the threads. Machines used for this purpose are semi-automatic in operation, the operator being merely required to set the work up in the machine and to see that it operates properly.

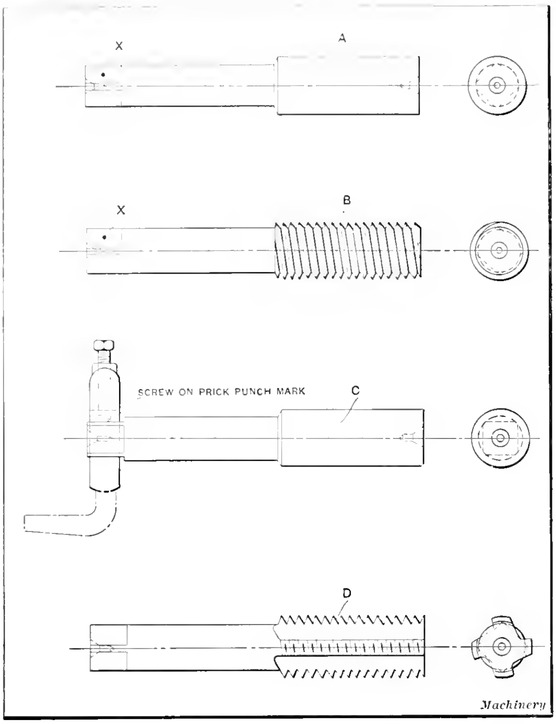

Fig. 1. Operations in Tap Making which precede cutting the Relief

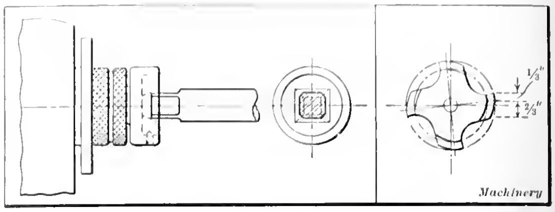
Fig. 1 shows the preliminary operations involved in making a tap according to the methods which are outlined in the following. Previous to cutting the thread and relief, the taps are first machined to the form shown at *A*, with the square cut on the end of the shank. Before starting to cut the thread it is a wise precaution to place a prick-punch mark or other point of reference on one side of the square, as indicated at *X*. This mark comes under the screw of the dog, as shown at *C* in Fig. 1; and the reason for observing this precaution will be explained in a subsequent paragraph. Each tap is next placed in the lathe to have the thread cut in the usual way, no attention being paid to the matter of relief. After the threading operation has been performed on each of the taps, they are set up on the milling machine to have the flutes cut, which brings the work to the condition shown at *D*. In performing this operation care is taken to have the prick-punch mark previously referred to, in line with a suitable mark on the spindle of the indexing head, if a center similar to the one shown in Fig. 2 is used. In case the work is mounted on centers and driven by a dog, the screw of the dog is brought down on the side of the square having the index mark. The reason for always placing the dog on the square is the necessity of having the flutes on each tap in the same relation to the thread. If there are either four or eight flutes on the tap, however, it is unnecessary to follow this method as the relation of the flutes to the helix will be the same on each tap regardless of the position of the prick-punch mark. In any case, the reference mark would be placed on one side of the square, as it is used again in a subsequent operation.



Figs. 2 and 3. Centers used for the Fluting Operation and End View of Finished Tap showing Con-eccentric Relief

So far as their appearance goes, the taps are now finished. In order to make them cut more freely, however, it is the practice to make them with one-third of the land concentric and two-thirds eccentrically relieved. Fig. 3 shows an end view of one of these con-eccentric taps, from which the method of relief will be readily understood. To machine this relief, the taps are returned to a lathe fitted with a special relieving attachment connected to the cross-slide. The drive is obtained by gears and a shaft which actuates a cam that causes the cross-slide and threading tool to move in on each land to produce the eccentric relief, and then come out again ready to engage the next land. The general arrangement of the relieving attachment is shown in Fig. 5. In machining the relief, the cross-slide moves in the direction of the arrow, this movement being controlled by the cam on the driving shaft; the cross-slide is held in contact with

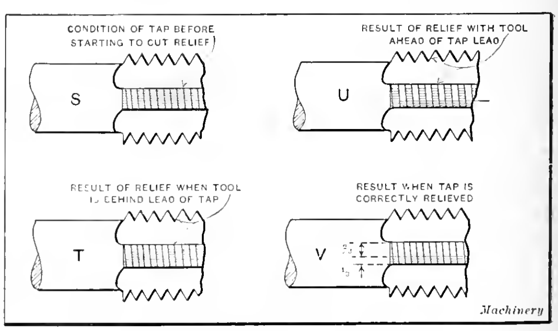


Fig. 4. Illustrations showing Various Conditions of Relief

* For additional information on the relief of taps, tap making and allied subjects published in MACHINERY, see also "Relief of Taps," January, 1914; "Relief of Taps," December, 1913; "Tap Fluting Cutters," March, 1913; "Special Shanks for Taps," February, 1913; "New Standard Dimensions for Taps," January, 1913; "Notes on the Early History of Tap Making," December, 1912; "Manufacture of Taps," January and February, 1909; "Testing the Lead of Taps and Screws," January, 1908; "Remarks on the Making of Hand Taps," June and July, 1907; "Formulas for Determining the Proportion of Taps," January, 1907; and "Proportions of Hand Taps in Sets," December, 1905.

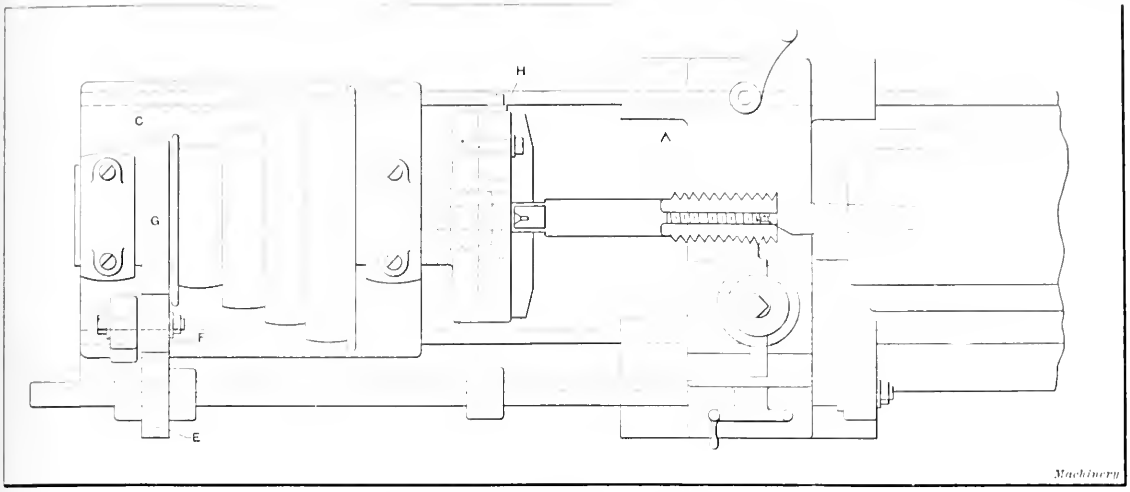

Fig. 5. Design of the Relieving Attachment for cutting Con-eccentric Relief

the cam and pulled back through the action of a counterweight. In some cases it is found advisable to substitute a spring in place of the counterweight. Power is transmitted to the driving shaft through the gears *E* and *F*, which, in turn, are driven from the gear *G* carried on the lathe spindle. The gear *E* is a change gear, different gears being substituted according to the number of lands on the tap. The relieving attachment is operated at a speed four times that of the lathe spindle in the case of taps with four lands to be machined, six times as fast if there are six lands, etc.

Before proceeding to machine the relief on the taps, they are taken to the hardening department and heated in a lead bath, after which they are allowed to cool gradually in the air. This leaves the surface a dark blue in color, as indicated by the shade lines in Fig. 4. When one of these colored taps is set up on the relieving lathe, the first thing to do is to have the reference mark on the square come under the screw of the two-jawed chuck *H* in Fig. 5. After screwing the tailstock center up to hold the work in place, tighten the chuck on the square end of the tap. This chuck is used in place of a driving dog in order to avoid lost motion which would cause the tap to "thump" when each land of the tap came in contact with the relieving tool. This would be disastrous to the tool and ruin the finish of the work. A detailed illustration of the special chuck used for holding the taps in the relieving lathe is shown in Fig. 6, where it will be seen that the jaws are operated by a single screw *J*. The jaws float in the slot *K* in order to eliminate any tendency to throw the tap off center, which might otherwise exist. It will be seen that the chuck is made in two parts *L* and *M* which are held together by two screws *N* which fit in elongated slots. The purpose of this construction will be explained in a subsequent paragraph.

With the tap set up on the lathe in the usual manner for threading, we proceed to pick up the thread. Particular care must be observed at this point, and the following outlines a little kink which facilitates the performance of this part of the work. A piece of white paper is placed on the cross-slide so that the space between the tap thread and the point of the threading tool can be clearly seen. In this way the operator knows just how far and in what direction the tool is out of lead with the tap. This will be better understood by referring to Fig. 7, where the amount that the tool is out of lead with the tap is shown by the space *O*, this space being clearly shown by the sheet of white paper *P* placed under the work. In order to get the tool into lead with the tap, the lever *Q* in Fig. 8 is thrown over to disengage the gears *R* that drive the screw-cutting attachment. The spindle is next turned and the gears re-engaged at another point which, in the operator's judgment, will give the correct lead. After allowing the lathe to turn through a few revolutions, the tool is once more tried with the thread to see if it engages properly with the lead of the tap, this procedure being repeated until the tap thread and tool match up as nearly as the eye can judge. A trial cut is then taken along the thread, and the manner in which the relief is being cut can be determined from the amount of colored surface that is removed. The result of this trial cut may produce either of the conditions illustrated in Fig. 4. In this illustration *S* shows the tap before starting to cut the relief, in which all of the color produced by treatment in the lead bath is still on the surface of the tap, this color being indicated by the shading. At *T* a tap is shown where the relief was cut with the travel of the tool behind the lead of the tap, this condition being indicated by one side of the thread having more of the coloring removed than the other. At *U* the tool is a little ahead of the lead of the tap, this being the reverse of the condition shown at *T*. Where the difference in lead is so slight that it can only be noticed by this method, it would not be possible to correct the error by throwing the gears out of mesh and re-engaging them at another point, as this is too coarse an adjustment. By tightening or loosening the tailstock center, however, the lead can be corrected very accurately, with the result that the tap is relieved correctly, as shown at *V* in Fig. 4. Referring to this illustration, it will be seen that the amount of coloring left on the surface of the tap and the amount removed are in the ratio of one-third to two-thirds, as they should be.

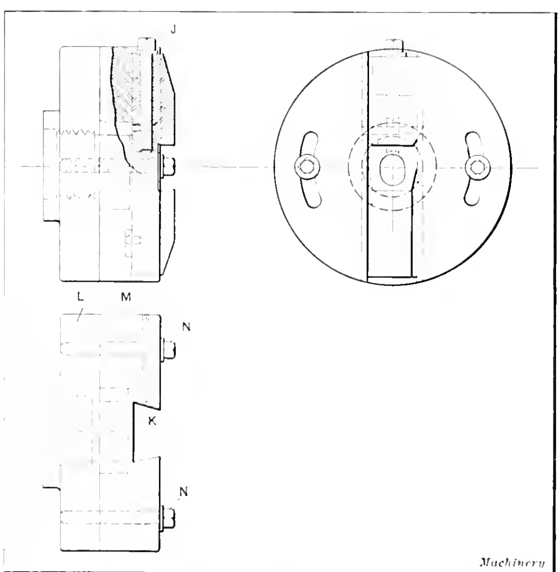

Fig. 6. Design of the Special Form of Chuck used

After the first tap of a given size has been set up and properly relieved, the remaining taps will come so near to being in lead with the tool that there is no need to bother with the method of throwing the gears out of mesh to obtain the proper position. Slight variations can be taken care of by manipulating the tailstock center as previously mentioned, and provided the prick-punch mark on the square was placed under the jaw with the screw in it, satisfactory results will be obtained. Should the lands or the helix of the thread vary greatly in their relation to the square with the prick-punch mark on it, this is evidence that the operator on one of the previous operations failed in properly locating the tap in the machine. This can sometimes be corrected by chucking on one of the other squares, if the error is in the fluting, or possibly the operator will have to disengage the gears in picking up the thread, in order to bring the tool into lead with the tap. It is necessary to start up the machine in order to take up any back-lash; then stop it and try the tool in the thread to see if everything is as it should be.

While this method holds good for V-threads, in machining taps with other types of threads, the tool will also be required to machine the top of the thread. Tools of this class for machining Acme and Whitworth threads are illustrated in Fig. 9. In connection with Fig. 6, it was mentioned that the chuck is made in two parts which are held together by screws fitting in elongated slots. The purpose of this construction is to enable the operator to move one part of the chuck independently of the spindle in order to bring the lands of the tap into correct relation with the cam of the relieving attachment. Although this may appear to be a somewhat complicated process, the operator will soon become proficient in following it. In fact, the method is much quicker than filing the relief, and as the equipment used is simple and does not interfere with the use of the lathe for other operations, there is a great advantage as compared with machines which can only be used for a single purpose. It must not be forgotten, however, that for making standard taps where it may be required to machine hundreds at a time, a special machine with cams of the required form, automatic feed for the cross-slide, and an automatic trip for operating the cross-slide —thus enabling the threading and relieving to be finished at the same time—will be far more economical. In using such machines, the flutes are milled last, so that care must be taken that they are milled in exactly the required place. This is provided for by using the reference mark placed on one of the squares on the tap shank.

Remember there is always work for skilled hands.

STANDARDIZATION OF PIPE THREADS*

Pipe was first generally used in the latter part of the eighteenth century, when the invention of illuminating gas required some means to convey it from place to place. At about this time the long-continued war which had been in progress between France and England came to a close and a large quantity of gun barrel stock remained on the market. The first gas pipe was, therefore, made from gun barrels, and as these were made tapering, it was a simple matter to screw the small end of one into the large end of the next, thereby making a threaded socket joint. Thus, threads were used to connect pipe from the earliest time of its employment. There is no information as to what kinds of threads were used in the early days of gas pipe lines. The present standard for pipe threads in general use in the United States is named after Robert Briggs, who was active in gathering information regarding thread systems both in this country and in England. He had considerable engineering and manufacturing experience, and was for several years superintendent of the Pascal Iron Works, and later engineering editor of the *Journal of the Franklin Institute*. He did not originate the thread which bears his name, but standard gages for pipe threads were made under his supervision while he was with the Pascal Iron Works. These gages were used as master gages and were the standard employed by Messrs. Morris & Tasker, owners of the Pascal Iron Works, since they started the making of pipe about 1830. This firm was the first large manufacturer of pipe in the United States.

The cutting of taper threads on pipe or bolts was first accomplished in the lathe. The first record we have of a taper thread that could be cut by dies is in the invention of P. W. Gates, Jr., who, in 1847, patented a taper die. The adoption of taper dies soon became general, and the Crane Co., of Chicago, then known as the Northwestern Mfg. Co., as early as in 1866 listed taper taps and dies in sizes up to three inches.

However, few manufacturers adhered closely to the Briggs standard until 1885. At that time a committee was appointed by the American Society of Mechanical Engineers to confer with the manufacturers of pipe dies and fittings, with a view of bringing about and maintaining a uniformity in pipe threads by the use of gages which should definitely represent whatever standard was adopted. This committee issued circular letters to various manufacturers of pipe, boiler tubes and fittings, and in due time each manufacturer of pipe fittings or dies sent to the Pratt & Whitney Co., Hartford, Conn., a sample piece of pipe of each size, 6 inches and

* Abstract from an article by A. M. Houser and C. A. Olson of the Crane Co., Chicago, in the "Valve World."

smaller, threaded on one end according to their own standard. These samples were tested by the Pratt & Whitney Co. with Briggs standard gages, and a report was made to each manufacturer as to the state of his gages compared with the Briggs standard. In examining these samples certain variations from the Briggs standard were found to exist, but they were not great enough to warrant any departure from the Briggs gages, and it was, therefore, decided that the Briggs gages should be recognized as standard. This gave a standard for male threads for pipes or fittings, but no standard was adopted for female threads, and it has been the practice of manufacturers to tap female fittings so as to allow a certain number of turns of the male standard plug gage before binding. The number of threads "turn" adopted by various manufacturers varied somewhat. Because of this difference, therefore, a definite standard for ring pipe gages has now also been adopted. (Details of this standard were given in the May number of MACHINERY.)

BLANKING DIES FOR PUNCHING SAW-TOOTH SECTIONS

It is a recognized fact among diemakers that punchings with extremely sharp corners or points of a very acute angle are hard to produce, the difficulty being in the upkeep of the punch and die. The Nelson Tool Co. of New York City was recently called upon to make a punch and die for the piece of work illustrated in Fig. 2. This is a saw tooth section that is riveted on the edge of a cotton gin wheel. It was formerly the practice to make these cotton gin saws solid,

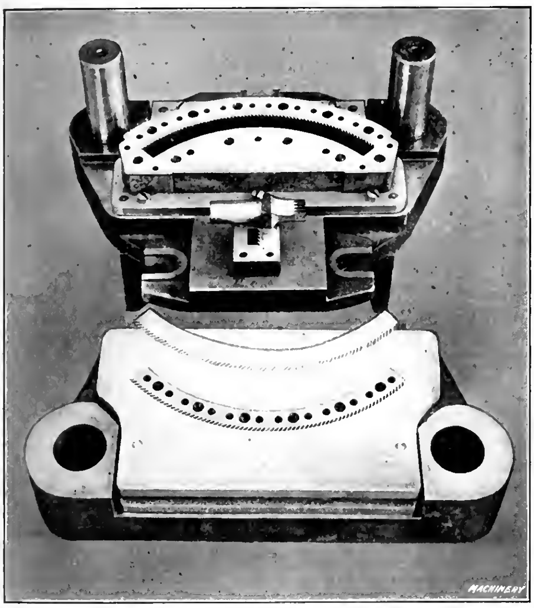

Fig. 1. Punch and Die and Trial Tools for making Blank in Fig. 2

indexing and cutting the teeth on a machine similar to a gear cutter. But as the teeth wore out rapidly it was found very expensive to keep replacing the saws, and so it was decided to make a punched segment that could be placed around the rim of a saw blank. The sheet steel, 0.017 inch thick, is a high carbon steel, capable of being hardened.

Before attempting to make the punch and die proper, a punch and die covering a small section was first made; this may be seen between the large punch and die in Fig. 1. The object of making this trial die was to punch enough of the steel to see how the points would stand up and thus determine whether it was practical to make the die or not. After 15,000 blanks had been run off on the small trial punch and die, and the corners of both punch and die had stood up in good shape, it was decided to make the die. Referring now to the punch and die shown in Fig. 1, the most difficult part is, of course, the making of the sections of the punch and die in which the teeth appear. It will be seen that these parts are composed of six sections, each of which is located by means of two dowel-pins and a screw. The sections may be followed by observing the groups of three holes, of which there are six on each of the curved tooth sections.

Observing carefully the shape of the teeth in Fig. 2, it will be seen that they are not straight but curved. This, of course, would render the shaping of the teeth by filing a very difficult job; therefore, the teeth in both punch and die were formed by milling. The teeth are spaced at a pitch

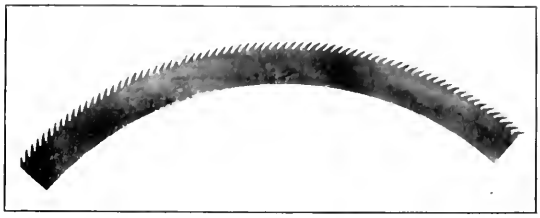

Fig. 2. Toothed Blank made in Punch and Die shown in Fig. 1

that would give 288 teeth in a complete revolution; therefore, the first thing to be done was to provide a means for indexing 1/288 of a revolution for each tooth. Fig. 3 shows how the blocks were mounted by dowel-pins on a master block, which, in turn, was clamped to the circular attachment of a Brown & Sharpe milling machine. The blocks were positioned with reference to a central arbor which may be seen in the foreground of this illustration, and the tooth section was therefore located at the proper radius from the arbor. Next, the collar on the rotating screw of the circular table was graduated with twenty-four divisions. As each revolution of the rotating screw turns the table one degree, it was necessary to move the rotating handle through thirty of the graduated lines or one and one-quarter revolution to get 1/288 part of the circumference.

A special cutter-base was made in which inserted teeth were placed, and while in place they were turned to the proper shape to cut the tooth shape in the punch or die section, as the case may be. Each of these sections was slightly relieved on the cutting edge for a distance of about $\frac{1}{2}$ inch; this left the remaining $\frac{5}{8}$ inch for the wearing life of the die. The sections were not mounted directly on the subpress parts, but on separate plates that were removable to facilitate grinding. The main reason for making the die in sections was, of course, to obviate the shrinkage and distortion that might occur in hardening. Fitting the punch and die was particularly difficult because of the delicacy of the tooth outline. When the die was completed it fitted so well that thin paper was cut without leaving any burr. C. L. L.

STATE LAWS ON ACCIDENT PREVENTION

SAFETY DEVICES AND CONDITIONS OF OPERATION REQUIRED BY LAW

BY MANCIUS S. HUTTON*

It has only been within the last five years that a factory owner or company about to purchase a machine has taken the time and trouble to look at the danger points and see whether or not they are properly safeguarded before deciding upon what make to buy. This change of attitude upon the part of the purchaser has been brought about through the passage of the workmen's compensation laws and the state factory investigations, resulting in the passage of more exacting laws in regard to the requirements of safety devices that must be provided in factories, work shops and mercantile establishments in the different states. If the manufacturer should not furnish an adequate guard which will meet the requirements of either the state or insurance company's inspectors, he may be asked to make the necessary changes in his shop before shipping, or the purchaser may have to provide the guards after receiving the machine. In either case there will be a delay before the machine can become productive. The cost in placing the guards on the machine after it has been assembled will in all probability be more than if they were put on while being built. At the present time, a machine will be given greater preference from the purchaser if it can be shown that it amply protects the workman against injury and will meet every requirement of the state labor-law enforcing body and the insurance companies.

The American Bridge Co. has the following words stamped on every letter sent out by their purchasing agent in pursuit of material or machines: "Provisions for safeguarding workmen should be brought to our attention, as we will consider them in selecting new machinery and equipment." Another company having its factory in New York State has the following note made a part of each order and contract: "This order for machinery is accepted with the understanding that it will in all requirements absolutely comply in every particular with the New York state laws as laid down for the preservation of life and limb, and of machine operators, or any persons whose duties may call them around the machine, as such laws may be interpreted by the New York state inspector. Unless the machine is received in this condition, we reserve the right to return it at once without notification, charging the transportation charges to the maker, or to make such changes as may be necessary to make it satisfactory to the New York state inspector, and take the same from the price formerly agreed upon." Other companies have given notice to the manufacturers that safety is one of the most important things that will be considered when purchasing new machines.

One of the crying needs of today is uniformity of practice in the matter of safeguards, *i. e.*, what is to be guarded and how. On account of the varying conditions to be met in the different shops throughout the country, those who are in the factory inspection departments say that it is impossible to draw up a definite set of rules which can be applied to all conditions. Some of the large companies and railroads which have a large number of plants situated in the different states have, however, decided upon a certain standard of safety which is used in all their factories.

Out of the forty-eight states in the union the following eighteen have no laws concerning safeguarding machinery: Alabama, Arizona, North and South Carolina, North and South Dakota, Delaware, Florida, Georgia, Idaho, Kentucky, Mississippi, Montana, Nevada, New Mexico, Texas, Utah and Wyoming. In Louisiana, Maine and Maryland there are only laws regarding sanitation in factories. Again in Arkansas, Missouri, and New Hampshire the laws are not of the kind that either the manufacturer or the purchaser is interested in. This leaves the following twenty-four states which have laws of interest to the readers of this journal: California, Colorado, Connecticut, Illinois, Indiana, Iowa, Kansas, Massachusetts, Michigan, Minnesota, Nebraska, New Jersey, New York, Ohio, Oklahoma, Oregon, Pennsylvania, Rhode Island, Tennessee, Vermont, Virginia, West Virginia, Washington and Wisconsin. Undoubtedly before very long the twenty-four states which have been backward in protecting their industrial workers will step to the front and become the leaders in the safety movement.

A glance at this list of twenty-four states reveals the fact that practically all of them are either agricultural or mining states and that with the exception of four these states do not have more than 100,000 industrial workers. In nearly all of the large mining states such as Arizona, Pennsylvania and West Virginia there are laws for the protection of miners which are not included in this article. These laws are enforced by a different set of inspectors who are usually expert miners.

When the states labor laws were first framed the question of whether a guard was to be placed over a certain machine or a part of a machine was left entirely to the judgment of the commissioner of labor or his assistants. The wordings of the laws have changed in this respect in a number of states latterly by making it mandatory upon the owner or person in charge of a factory to provide safeguards upon the machines or machinery mentioned in the laws. Machines may sometimes be so placed in the shop that no known guard could be used, in which case the law says that a guard must be used "if practicable." A list of the states which still leave to the discretion of the inspectors the question of safeguarding a machine or machinery are the following: Indiana, Michigan, Rhode Island, Tennessee and Vermont.

In an examination of these laws it will be found that a large number of them were written before the advent of the safety movement and have not been changed since that time. They merely mention the names of some of the machines and machinery or part of it that must be guarded, giving very little information as to how or how much of it must be guarded, this being left to the owner and inspector to decide.

The laws in the twenty-four states which are of interest to both the manufacturer and the purchaser can be divided into three groups which, again, can be subdivided. The groups are: 1. transmission machinery; 2. productive machines; and 3. hygiene and sanitation.

TRANSMISSION MACHINERY

Mechanical

1. *Belt Shifters.*—"Belt shifters or other mechanical contrivance for the purpose of throwing on or off belts or pulleys while running." This expression is found at present in the laws of the following fifteen states: Colorado, Indiana, Iowa, Kansas, Michigan, Minnesota, Nebraska, New Jersey, New York, Ohio, Oklahoma, Oregon, Pennsylvania, Washington, and Virginia. In Wisconsin the industrial commission has made the following rulings: All loose pulleys must be furnished with a permanent belt shifter, so located as to be within easy reach of the operator. All belt shifters must be so constructed as to make it impossible for the belt to creep and must be equipped with a lock or some other efficient device which will prevent the shifter from being accidentally shifted. Illinois also mentions the fact that the belt shifter must be placed within easy reach of the operator.

2. *Loose Pulleys.*—"Wherever practical all machinery shall be provided with loose pulleys." In Illinois it is only on machines which are required to be started and stopped frequently that loose pulleys must be used. In place of the loose pulley a clutch or other disengaging device can be provided. In Wisconsin the loose pulley or clutch is required on all machines that are not individually motor driven. The number of states requiring loose pulleys is eleven. They are the same as those that require belt shifters, with the exception of Colorado, Iowa, Nebraska, Ohio, Oklahoma, Oregon and Washington.

Drums.—"Drums,—etc., shall be guarded." The word drum appears in the text of the laws of nine states, namely:

* Address: 257 W. 86th St., New York City.

Connecticut, Illinois, Massachusetts, Minnesota, New Jersey, Rhode Island, Tennessee, Vermont and West Virginia.

3. *Belting, Shafting and Gearing.*—"All cogs, gearing, belting, shafting and machinery of every description shall be properly guarded." This is practically the wording in the text of the laws of twenty-one states with the exception of New York and Wisconsin which are given below. The names of these states are the same as those given under belt shifters with the addition of Connecticut, Massachusetts, Rhode Island, Tennessee and Vermont. According to the New York law all belting and revolving shafting within seven feet of the floors must be protected on its exposed surface by being encased so as to effectively prevent any part of the body, hair or clothing of all persons from coming in contact with such belting or shafting. The wording of the rules in Wisconsin are as follows: "All belts, ropes or chain driving machinery or shafting exposed to contact, except those which are so small or those which move so slowly that there is no possibility of danger, must be guarded. In all cases the point where the belt, rope or chain runs onto the pulley, sheave or sprocket must be guarded. All horizontal belts, ropes or chains driving machinery or shafting seven feet or less from the floor, where exposed to contact, must be guarded. Note:—In guarding overhead belts or rope drives, unless so guarded that persons cannot pass under them, the width of the guard should not be less than the width of the belt or rope drive and the length should not be less than the distance between the outer faces of the two pulleys. It should cover the outer faces of the two pulleys or sheaves and extend upward to such a point and be attached in such a way that in case the belt breaks it will withstand the whipping force of the belt." "All gears where exposed to contact must be entirely enclosed or equipped with a flange guard which must enclose the teeth of the gears. All arm or spoke gears and all web gears with holes in the web, which are over eighteen inches in diameter, where exposed to contact, must be entirely enclosed." "All transmission shafting in work-rooms or in passageways leading to work-rooms and located less than six and one-half feet from the floor, where exposed to contact, must be guarded." Besides Wisconsin, Minnesota mentions rope and chain drives as requiring to be protected in the state.

4. *Pulleys, Clutches, Friction Drives and Sprockets.*—These are only mentioned in Wisconsin, where the rules say that pulleys near the shaft hanger must be provided with a guard placed adjacent to the pulley to prevent the belt from leaving the pulley and also that all pulleys over eighteen inches in diameter, which are exposed to contact, must be guarded. Again, all clutches and sprockets must be guarded especially when exposed to contact. The contact faces of all arm or spoke friction drives and all web friction drives with holes in the web, when over eighteen inches in diameter and exposed to contact must be entirely enclosed.

5. *Flywheels.*—"All vats, pans, saws, gearing, shafting, flywheels, etc., and machinery of every description shall be guarded." This is the wording in the states of Illinois, Minnesota, Ohio and Pennsylvania. In Wisconsin the rules state that all sections of flywheels, with spokes, which are six feet or less from the floor and which are exposed to contact must be guarded. Flywheels which run in pits must be provided with toe boards around the pit. The guard around the flywheel of an engine located in the engine room may be in the form of a railing. This railing must not be less than thirty inches in height and must be constructed of two rails, the bottom one being not less than eighteen inches from the floor.

6. *Conveyors.*—These are merely mentioned as requiring to be safeguarded in the states of Colorado and Washington.

7. *Mechanical Stop for Machines.*—A loose pulley, clutch or other adequate device must be placed within easy reach of the machine operator in the states of Nebraska and Wisconsin so that any machine can be stopped instantly. In New Jersey the law calls for friction clutches to be provided in order to stop machinery. In Illinois where the machines are direct-connected to the prime mover, where arranged in groups and power supplied by the prime mover located in the confines of such group, or where arranged in groups with prime mover located without the group, the power being received through a main shaft or lineshaft; a switch, throttle or other power controlling device shall be furnished and placed within easy reach of the operators affected, so that all shafting, transmission machinery and machines of such group can be simultaneously shut down in case of need or accident.

Electrical

The guarding of the electrical transmission wires in a factory or work-shop is mentioned in the laws of Illinois and Minnesota.

PRODUCTIVE MACHINES OR MACHINERY

Before taking up the individual machines as a whole it will be advisable to refer to certain parts which need to be protected.

1. *Set-screws, Keys and Bolts.*—These are mentioned as in need of protection in seventeen states, of which fourteen casually mention them in the same class as belting. These states are the same as those given under belt shifters with the exception of Minnesota, Oregon and West Virginia. In New York and Ohio the law states that all set-screws, keys, bolts and all parts projecting beyond the surface of the revolving shaft shall be countersunk or provided with a suitable covering. In Wisconsin the meaning is the same as regards set-screws as in the New York law but the wording is different. As regards keys and keyseats, the latter state says that all projecting keys or keyseats, where exposed to contact, must be guarded. An exception is made with keyseats on machines which are impossible to guard or fill without interfering with the operation, or where they are in shafts that are so small or run so slowly that there is no danger.

2. *The Shuttle of a Loom.*—In Illinois and Massachusetts a guard must be placed to prevent the shuttle from flying out at each end of its travel. Massachusetts also forbids the use of a shuttle which requires the operator to use his mouth or lip to thread it. This is a hygienic precaution rather than a safety regulation.

3. *Counterweights and Balance Gears.*—The covering or fencing in of these is required in Minnesota.

4. *Line Rollers.*—The need of some kind of protection for the employes working around line rollers is mentioned in the laws of Colorado, Illinois, Nebraska, Oregon and Washington.

5. *Ovens, Furnaces, Forges and Tables.*—Why Illinois should mention these as especially requiring a guard is not very clear, but such is the case.

6. *Woodworking Machinery.* In Illinois saws, planers, shapers and sandpapering machines, in Ohio saws, planers and shapers, while in Wisconsin saws, planers, shapers and stickers must be guarded. The other states which require saw and planer guards are Colorado, Indiana, Iowa, Kansas, Michigan, Nebraska, New Jersey, New York, Oklahoma, Oregon, Pennsylvania, Vermont, Virginia, and Washington. Trimmers are required to be guarded in Colorado and Washington. In practically all the states, with the exception of Wisconsin, these machines are mentioned in the same sentence as belting, gearing, vats and pans. In Wisconsin the rules of the industrial commission are that all hand jointers or planers must be equipped with a safety cylinder head and have a guard placed over the knives. Also that all band saws, both the upper and lower wheels and the saw itself, except that part below the saw guide, must be covered. Circular saws, besides being guarded, must be provided with a splitter. In general, all knife heads, wood shapers, stickers, planers, when exposed to contact, must be guarded. West Virginia alludes to a corner machine as one on which a safety device must be placed.

7. *Laundry Machinery.*—All laundry machines in Illinois are considered dangerous and therefore will be required to be safeguarded. Besides Illinois, mangles are required to be protected in Colorado and Washington.

8. *Hydro-extractors.*—A screen must be placed over hydro-extractors in Illinois, Nebraska and New York.

9. *Power and Foot Presses.*—This class of machines causes, next to the saws and planers, the greatest number of accidents, yet it is only given in the law of one state—New Jersey.

10. *Paper Machines.*—An inspector knows from experience that certain machines to be found in paper mills should be fully protected, yet it is a fact that Illinois is the only state to mention this class of machines.

11. *Corn Shredders.* Corn shredders or husking machines are not allowed to be sold or offered for sale in Minnesota and Wisconsin unless provided with reasonable safety devices to protect the operator from accidents from the snapping and husking rollers, and these guards must be so designed as to compel the operator to stand a safe distance from the rollers while feeding the machine.

12. *Electrical Apparatus and Appliances.*—All dynamos, motors, switches, fuses, etc., must be guarded in Illinois and Minnesota.

13. "*Machinery of Every Description.*"—This phrase is to be found in sixteen of the state laws. It simply means that dangerous machines or machinery which are not definitely stated in the law can be required to be guarded if the inspector considers it desirable to do so in order to prevent accidents. In certain states such as Minnesota, the following sentence is to be found: "All dangerous parts of machinery ———— shall be fenced, boxed or otherwise protected." While the wording is different, the meaning is exactly the same as the above.

HYGIENE AND SANITATION

Dust-Creating Machinery

1. *Grinding and Buffing Machines.*—"Exhaust fans of sufficient power shall be provided for the purpose of carrying off dust from emery wheels and grindstones and dust-creating machinery from establishments where used." This is the wording in the states of Indiana and Minnesota. The meaning of the law in Iowa is the same as that expressed above with the addition that the exhaust system must be carried outside the building or to some receptacle placed so as to receive the dust. In Connecticut an exhaust system must be installed in any process which generates an excessive amount of dust. In this state tripoli, rouge and corundum wheels are mentioned besides emery. The Colorado and Washington law is very similar to that of Connecticut. In Wisconsin the dust-creating machinery must be equipped with either an exhaust or water system which will remove all particles of dust that are light enough to float in the air. In New York the exhaust fan which operates the exhaust system must be of sufficient capacity and power and must be kept running constantly while the machines are in use. In Massachusetts, Michigan, New Jersey, Ohio and Pennsylvania emery belts of either leather, leather covered, felt, canvas, paper, cotton, or wheels or belts rolled or coated with emery or corundum, or cotton wheels used as buffs besides the solid emery wheels, shall be provided with an exhaust or blowers placed over, beside or under the wheels or belts, arranged in such a manner as to carry off the dust arising from or thrown off the same while in operation. Massachusetts also has a law requiring an exhaust system on this class of machines. The laws of Connecticut, Indiana, Iowa, New York, Minnesota, Washington and Wisconsin require exhaust systems or other efficient dust-removing means on all dust-creating machinery. There are a number of cases in which grinding wheels are exempt from these requirements in certain of the states. These exemptions are as follows:

a. Grinding machinery upon which water is used at the point of grinding contact.

b. Small emery wheels which are used temporarily for tool grinding.

c. Solid emery wheels used in woodworking establishments.

d. Wheels or belts which are not used continuously more than three hours in the twenty-four.

e. Small shops employing not more than one man at work upon an emery wheel.

f. Emery wheels which are in general use by all employes, in common, for touching up tools or castings or for sharpening saws.

g. Emery wheels six inches or less in diameter used in establishments where the principal business is not emery wheel grinding. The exemption under *a* is found in the states of Iowa, Massachusetts, New Jersey, New York, Ohio and Pennsylvania; *b* in Iowa, Massachusetts, New Jersey; *c* in New York; *d* in Pennsylvania; *e* in Ohio; *f* in Wisconsin; and *g* in Massachusetts. In the laws of Michigan, New Jersey, Ohio and Washington, the material of which the hood or hopper of the wheel is made, the size of the exhaust pipe and the capacity and power of the exhaust fan are laid down definitely; while in New York the same data has been collected and published by the State Department of Labor in book form. In Massachusetts, New York and New Jersey the plans of an exhaust installation must be submitted to the proper state department for approval before commencing work.

2. *Tumbling Barrels or Rattlers.*—These are mentioned specifically in Iowa and Wisconsin.

3. *Flint Grinding.*—The flint grinding mills of Maryland are required to be equipped with an exhaust system to carry the flint dust away from the place where the men have to work.

4. *Hair Picking Machines.*—In the upholstering or mattress establishments or other factories in Michigan where hair, moss, tow or cotton is used for filling, the hair picking machines shall be placed in such a position as to carry away the dust thrown off by the machines while in operation directly to the outside of the building or to some other receptacle established to receive and confine the dust.

5. *Industries or Processes in which Lead is used.*—In order to prevent lead poisoning the laws of Ohio and Pennsylvania require that the crushing, mixing, shifting, grinding and packing of all the lead salts or other compounds shall be so conducted as to keep the air in the work-room in which the process is carried on free from the dry lead dust. This is done by requiring all hoppers, chutes, conveyors, elevators, vents from separators, dumps, pulverizers, chasers, dry pans or other apparatus for drying pulp lead, dry pan dumps and all barrel packers and cars or other receptacles into which corrosives are emptied to be connected with a dust collecting system. Also all vessels or containers in which dry lead in any chemical form is being conveyed from one place to another within the factory shall be equipped at the places where the same are filled or discharged with hoods having connection with an air-exhaust. Such exhaust system should be regulated by the discharge of air from a fan, either through a cloth dust-collector having an area of not less than one-half square foot of cloth to every cubic foot of air passing through it per minute, the dust collector to be placed in a separate room which no employe shall be required or allowed to enter except for essential repairs while the works are in operation, or by any other apparatus which will efficiently remove the lead dust from the air before it is discharged into the outer air.

Machines and Processes Giving Off Fumes

1. *Vats and Pans.*—"Shall provide and maintain in use reasonable safeguards for all vats, pans, etc." This is practically the wording in Colorado, Indiana, Kansas, Michigan, Minnesota, New Jersey, Oklahoma, Pennsylvania, Vermont, Virginia, Washington and Wisconsin. The words "giving off fumes or vapors which are irritating, obnoxious or injurious to the health" are added in the Wisconsin rules, while the words "containing molten metal or hot or corrosive fluids" have been added to the Colorado law in Illinois, Maine, Rhode Island and Tennessee. In New York every vat or pan which is so located that the top is on a lower level than the operator's elbow shall be protected with a cover which shall be maintained over the same while in use in such a manner as to prevent the operator or other persons falling in or coming in contact with their contents. Should it be necessary to remove the cover from the vat or pan while it is in use it shall be protected by a railing placed around the same.

2. *Linotype and Type Casting Machines.*—In Louisiana every newspaper or printing concern using three or more linotypes or other type casting machines is required to install an exhaust fan or other device sufficient to keep pure air circulating and to expel the fumes. They must also install a vent pipe on each machine running from the metal pot to a flue or other aperture. Iowa has the same provision.

3. *Industries or Processes in which Lead is used.* The two states that require exhaust systems to carry off the lead dust also require that the lead fumes be carried out of the room in which the employes work.

General Ventilation and Sanitation

In several of the states such as Connecticut, Colorado, Massachusetts, Maine, Oregon, Rhode Island, Tennessee and Vermont the state inspector can order changes to be made in a factory should he consider either the heating, lighting, ventilation or sanitary conditions to be injurious to the health of the workmen. Under this general clause a commissioner of labor or his inspectors in these states can order an employer to install a vacuum system on all dust-creating machinery and a vent for receptacles containing molten metal or hot liquids which give off obnoxious fumes.

In what has preceded no mention has been made concerning what was required in the way of safeguarding the employes in the state of California. The reason for this is that on the first of this year the inspection of factories and the issuing of rules in regard to protection became a part of the duties of the industrial accident commission which was created in 1911 to handle the operation of the workmen's compensation law. The commission has not, as yet, made rules for the guidance of the employers of the state and its own inspectors. There is no doubt but that this state will place itself in the very forefront of the safety movement. The commission is given very liberal powers and the new law expressly states in Section 52 that "every employer shall furnish employment which shall be safe for the employes therein and shall furnish a place of employment which shall be safe for employes therein and shall furnish and use such safety devices and safeguards and shall adopt and use such practices, means, methods, to render such employment and place of employment safe and shall do every other thing reasonably necessary to protect the life and safety of such employes."

According to the secretary of state of North Carolina there is a common law in that state which requires that employers shall furnish reasonably safe appliances for their employes. But it can be seen that this law would become a dead letter in this state, as the commissioner and his deputy are not required to examine industrial plants except those against which a complaint has been lodged. The only qualifications that the commissioner has to have is that he be a practical printer.

Section 5 of the safety law of the state of Minnesota requires that "whenever practicable the point of danger in any machine or mechanism shall be securely guarded by the maker and the manufacture or sale of any machine or mechanism not so guarded is hereby prohibited." At the present time this is the only state which is prohibiting the manufacture and sale of unguarded machinery.

The industrial commission of Wisconsin has determined upon the following standards regarding safeguards:

1. No safeguard required which cannot be proved to be practical.
2. No safeguard required which the commission cannot show how to install.
3. Homemade safeguards which as far as possible can be constructed and installed cheaply in the shop.

As a part of the safety laws in Colorado, Indiana, Minnesota, New Jersey, New York, Ohio, Oklahoma, Oregon, Pennsylvania, Virginia, West Virginia and Wisconsin, it is stipulated that should a machine or any part of it be found in a dangerous condition or not properly guarded the commissioner of labor or one of his inspectors may prohibit the use of the machine until the same has been made safe. He is required to attach a notice to the machine while it is in the unsafe condition calling attention to the same.

In Illinois, Indiana, Minnesota, New Jersey, New York, Pennsylvania and Virginia no person is allowed to remove or make ineffective any safeguard while working at the guarded machine except for making immediate repair, and after being repaired it should be promptly replaced.

The interpretating and enforcing of the labor laws is done through a state department or commission consisting of a chief inspector and a number of assistants. The inspectors have the right of entry into a factory of the state during regular working hours as often as they may consider it necessary for the purpose of inspection. The salary paid the state factory inspector in most of the states is never higher than $2000 and in most cases is in the neighborhood of $1200 to $1500 a year. The chief inspector or commissioner of labor receives a salary varying from $1800 to $8000

In twenty-eight states the inspectors are not required to pass a civil service examination nor is any practical experience or technical training required of them, while in five states that have no civil service requirement the inspectors are required to have some practical experience. In nine states the inspectors must pass a civil service examination before being appointed.

In three states—California, Ohio and Wisconsin—the state factory inspection department has been absorbed by the industrial commission which now has charge of the inspection of factories as well as the administration of the workmen's compensation law.

In New York and Pennsylvania there has been created an industrial board consisting of the commissioner of labor and four associates. In Massachusetts the state board of labor and industries and the industrial accident board, sitting jointly, act in the same capacity as an industrial board. They have the power to obtain the services of experts upon their committees. These persons serve without pay. The board in each of these states has the power to draw up rules and regulations regarding the installation, position, operation and use of machines and machinery, the furnishing and use of safety devices and appliances for machines and of guards to be worn upon the person and other cognate matters, whenever it finds such regulations necessary in order to provide for the prevention of accidents in factories. These rules and regulations after a public hearing become the same as law. All meetings of the board are open to the public. The industrial commissions spoken of above have also the same power as regards the making of rules which eventually become laws. Besides the making of laws, they have the right to make exceptions to existing laws where they see that the letting down of the bars will not increase the number of accidents.

* * *

INCREASING THE EFFICIENCY OF THE CUTTING TORCH

Experiments recently conducted in cutting with oxy-hydrogen and oxy-acetylene cutting torches show that a marked increase in the rate of production is effected by increasing the temperature of the oxygen. The most favorable results secured in this connection show that the increase of speed obtained by preheating the oxgyen is 18 per cent, while the saving in the amount of oxygen used was 55 per cent. As an increase in temperature means a corresponding increase in the pressure of the oxygen, it seemed possible that merely increasing the pressure would have the same effect. Experiments along this line proved that this reasoning was correct. Where the pressure was steadily increased, it was found that the rate of cutting increased in direct proportion. It was found, however, that the higher pressures had a tendency to round the upper edge of the cut. A pressure of 35.5 pounds per square inch seems to be about the maximum amount with which perfect work could be produced. With very low pressures, the rate of cutting was not only very slow, but the cut itself was defective. Experiments were also tried in changing the ratio of hydrogen to oxygen, and it was found that where this ratio was 15 to 4 instead of the customary 4 to 1, the rate of cutting was exceptionally high in cases where the pressure of the oxygen was about the maximum of 35.5 pounds per square inch.

* * *

Careful measurements were made during the past year by means of which it was determined that the soot fall in Pittsburg ranges from 595 to 1950 tons per square mile per year. London has been considered one of the "gloomiest" cities in the world, yet the soot fall in London is only 426 tons per square mile per year.

CRANKSHAFT GRINDING*

PRACTICE OF THE REO MOTOR CAR CO.

BY ROSS HOLMES†

THERE is in existence a great deal of valuable data relative to feeds, speeds and depths of cut for the best modern lathe practice. Knowing the depth of cut, it is possible to determine the best relation of speed and feed, by reference to this data which has been collected in the form of charts and tables. In attempting to do the same thing in connection with grinding methods, I was unable to find any information on the subject. Work of that kind had been arranged by cut-and-try methods, the production being recorded

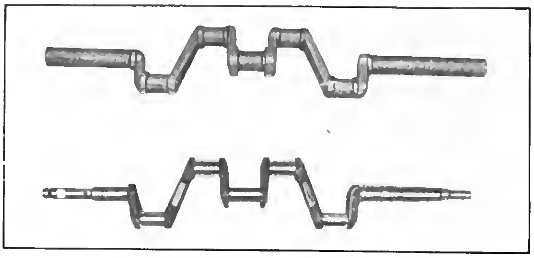

Fig. 1. One of the Finished Crankshafts and the Rough Drop-forging

and the maximum speeds obtained in that way. To obtain such data, the crankshaft used in the "Reo the Fifth" motor was chosen for observation and time study. It is drop-forged from manganese steel and heat-treated. The crankpins are ground from the rough, while the bearings and pilot ends are rough-turned on a lathe. The rough forgings are first sawed to length and centered, and then the center bearing is ground for a space somewhat narrower than the bearing. This is to provide a bearing for the steadyrest on the lathe. The end bearings are now rough-turned and the pins are next rough- and finish-ground. Then the bearings are finish-ground, and also the end pilots, the tapering portion on which the flywheel is forced, and the "gear fit" which is so called since it receives the timer gear. The next operation is on a lathe, which cuts the gear fit off to the exact length and cuts the threads on it with a Geometric die. Holes are drilled in the centers of the crankpins to roughly balance the crankshaft and an emery wheel grinds the shaft to a perfect running balance. A flat spot and a keyway are

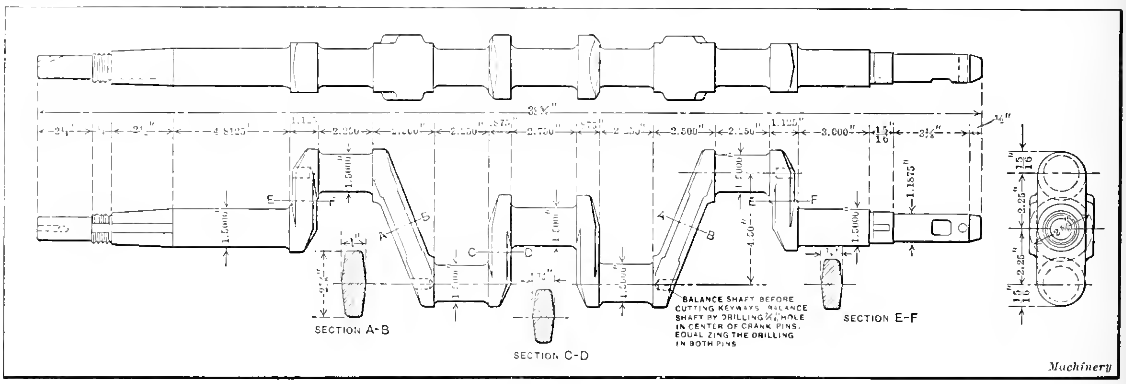

Fig. 2. Important Dimensions of the Crankshaft shown in Fig. 1

next milled out, and a keyway is cut for the flywheel key. A drill press completes the series of operations by drilling the oil and pin holes.

In this investigation the roughing speeds on the pins and the first grinding operation on the center bearing were found to be within 2 per cent of each other, while the material handling and adjustment times varied less than 5 per cent. The first of the grinding operations—spot-centering the bearing—is done on a 14 by 50-inch Norton grinder with a Norton 24-N flanged wheel. This wheel is dressed by a diamond, using the hand motion and not the traverse. Such a dressing is required for every four shafts, and gives a good roughing wheel surface which is square but not too smooth. A driver similar to the one illustrated is a time-saving substitute for the grinder dog. The feed is by hand, the wheel being advanced every revolution as nearly 0.02 inch as possible.

The cutting time averaged 1 minute 48.75 seconds and the changing time 27 seconds. The time required for dressing the wheel was 66 seconds, which, distributed over the four crankshafts, gives an average of 16½ seconds. This gives a total of 2 minutes 32.25 seconds each as the fastest continuous speed that it is possible to maintain. It is possible to hurry the work for short intervals and reduce the cutting time from 108.75 seconds to about 90 seconds, but this soon leads to the belts crowding off and when this occurs it involves about 100 seconds to readjust the machine and have the wheel gather up the requisite speed, which more than counterbalances the reduced cutting time. At the time of this observation, the wheel was 19⅝ inches in diameter, which at 1170 R. P. M. gives a surface velocity of 6020 feet per minute. The bearing is 1.73 inch in diameter and must be ground down to 1.52 inch. With the work turning at 27 R. P. M., a surface velocity of 12.3 feet per minute is obtained. The approximate volume of metal removed is 0.105 (depth of cut) by 2.75 (width) by 1.625 inch (mean diameter) which gives a volume of 1.48 cubic inch or 0.415 pound.

Following this spot-centering operation, the shaft goes to the shouldering lathe, shown in Fig. 3, which is an engine lathe fitted with a turret on the tool-slide and also two additional tool-slides. The center tool machines the center bearing to the correct width, while the other two tools are run in just outside of the crank throws to leave the rough fillet on the end bearings ready for the grinder. The turret tools are split, thus being accurately adjusted for width. The end or line bearings are rough-turned on the lathe shown in Fig. 4. This lathe uses a side-cutting tool with a broad blunt nose instead of the customary round-nosed tool. This avoids any tendency to "draw in," and at the same time it can take a cut the full length of the tool, making it possible to rough-size the bearing in one cut instead of needing two or three to reduce it to the correct size. This tool, shown in the foreground of the illustration, is ground flat on top, with a groove parallel to one side made with the corner of the wheel, allowing clearance for the steel shaving. The cut of this tool is square with the work, and it is for this reason that the two narrow, round-nosed tools are used in the previous operation to round the fillets and mark the end of the cut.

† Care of Reo Motor Car Co., Lansing, Mich.

The other rough-grinding operation, namely on the crank-pins, is done with a 24-inch Grade O wheel which requires dressing for every third crankshaft. This wheel was 23½ inches in diameter at the time of the test, the exact width of pin 2¼ inches and the speed 955 R. P. M., which gives a surface speed of 5890 feet per minute. The standard Norton offset for crankshafts which was used was removed and set up by a helper. In setting up, use is made of a metal-balancing plate which has tapering wedges that force the pins equidistant from a surface plate; and this locates the crankshaft centrally in the offset, so that the same amount of stock is removed from all the pins. In placing this work in the grinder, a gage is put on the shaft and the work shifted until the wheel touches the gage. It is now in position for grinding the first pin. A standard spacing bar is set from this position and the other pins are thus accurately spaced. On the first revolution of the work 0.02 inch is cut from the forged fillet before the work gathers up motion. The hand feed is about 0.02 inch per revolution of the work. In operating the machine, two pins on a line are first ground; and then the offset is shifted to the other center and the other two pins are ground. The time required is as follows:

Grinding time per pin.........	1 minute 26.375	seconds
Change centers	29	seconds
Change work	1 minute 23.50	seconds
Dress wheel	2 minutes 2	seconds
Dress wheel, per shaft.........	40.66	seconds
Total time for grinding four pins, changing and dressing wheel	8 minutes 18.6	seconds

The volume of stock removed is approximately 1.625 inch (mean diameter) by 2¼ inches (width) by 0.105 inch (depth

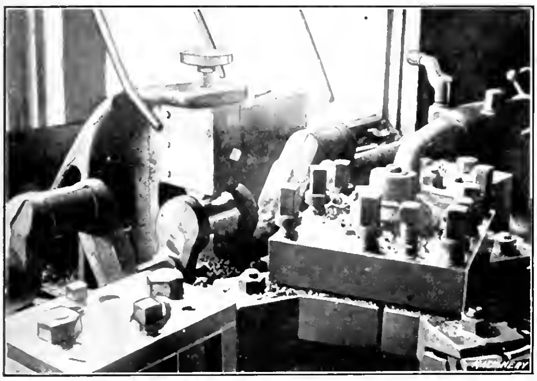

Fig. 3. Facing up Crankshafts to provide the Necessary Wheel Clearance

of cut) which gives a volume of 1.210 cubic inch. For the four pins the volume of metal removed is 4.840 cubic inches or 1.35 pound. From this data and the total cutting time for four pins of 5 minutes 45.4 seconds, the time required to remove one cubic inch of metal is found to be 71.4 seconds. Doing the same for the spot-centering operation on the center bearing, the time per cubic inch of metal is found to be 73.5 seconds. These calculations are based on cutting time only. In the first case, 40¼ per cent must be added to the cutting time to get the total time. In the second case, 44½ per cent must be added. These percentages represent the average of many sets of data, which, however, run surprisingly uniform, so much so as to establish 45 per cent as the limit of the ratio of "lost time" to "cutting time."

It was found that with the shortest finishing operations, such as took a total of thirty to forty seconds, elementary standards were impractical. These operations were performed so quickly that the changing and calipering occupied from 70 to 90 per cent of the time, and so only standard totals for these operations on the crankshaft were arrived at, which are as follows:

Grinding taper	42.5 seconds
Grinding gear fit	33.4 seconds
Grinding short pilot on flywheel end.......	31.4 seconds
Grinding long pilot on front end..........	43.6 seconds

In fact, the finish-grinding is found to be quite different from roughing. The amount of metal left for this operation was 0.040 inch on the diameter. However, the depth is so small and the surface covered so carefully in order to produce the finish that it is area rather than volume which must be considered. The finishing operations involving a larger area were found to have a nearly constant handling time ratio. An allowance of 77½ per cent was added to the actual grinding time on the pins and 71 per cent on the bearings. These are well within the 5 per cent limit of variations, though they are much larger than the additions to

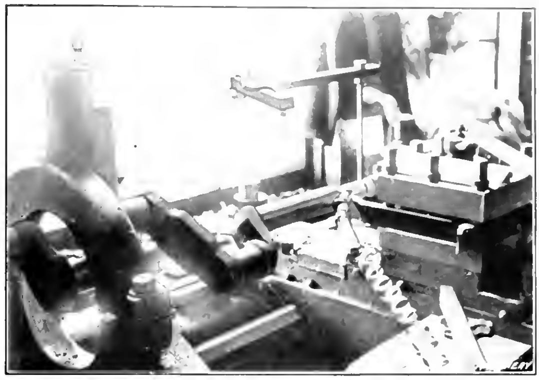

Fig. 4. Roughing out the End Bearings on the Lathe

the roughing time. This is undoubtedly due to the additional care necessary in grinding to the quarter thousandth limit placed on this class of work.

As to the cutting time, those operations involving no longitudinal motion of the wheel were found to require considerably more time per unit of area than those where the wheel could be run in to a certain depth of cut and then the whole length of bearing reduced to that finished dimension by a longitudinal motion. The first class of operation, such as finish-grinding the pins, is done on a 14 by 50 inch Norton grinding machine with a 24-N wheel. At the time of the test, the actual diameter was 23¼ inches, and when running at 955 R. P. M. a surface speed of 5820 feet per minute is attained. The work is revolved at 316 R. P. M., which, with a diameter of 1½ inch, gives 124 feet per minute as the surface speed. After grinding six shafts it is necessary to dress the wheel. A "Star" dresser is used to rough-dress it, since the wheel must be cut down half the depth of the 3/16 inch fillet in the angles. The surface is finished by a diamond held in the traverse. Finally, the fillet is hand-finished with the diamond until a test made by grinding a thin piece of board exactly fits the templet. This takes 10 minutes 12 seconds or 1 minute 42 seconds per shaft. The average

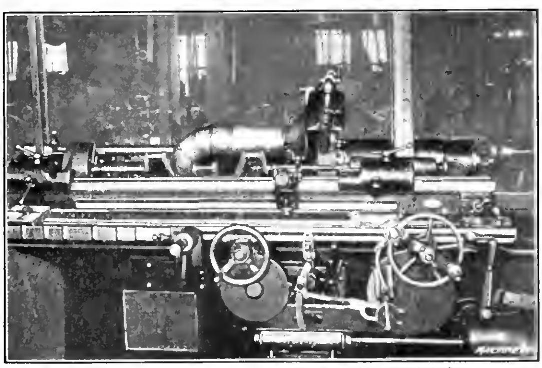

Fig. 5. Grinding the Gear Fit on the Norton Grinder

cutting time per pin was 1 minute 11.25 seconds, making a total of 4 minutes 45 seconds. The total time including changing the work and wheel dressing was 8 minutes 26 seconds. Each pin is 2¼ inches long by 1½ inch in diameter, which gives a surface of 10.6 square inches. This gives a cutting time of 6.73 seconds per square inch for finish-grinding to a depth of 0.020 inch. For this operation, no spacing bar is used, since the lateral limits on the position of the bearings are not close.

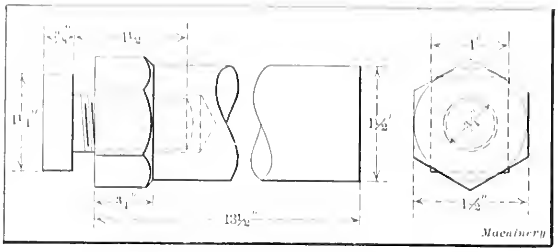

Fig. 6. Detail of the Driver shown in Operation in Fig. 5

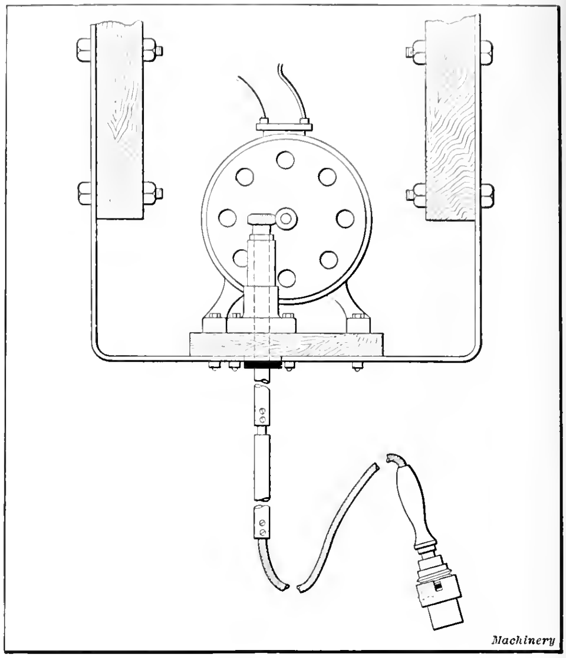
The other finishing operation is made up of both of these types of work. The wide end bearings are finished by moving the work lengthwise in front of the wheel. The center bearing involves the "running in" cut, but here the lateral limits of position are close and so it becomes necessary to work much more carefully. A standard cutting time of 7.93 seconds per square inch is the best speed consistent with good workmanship. The bearing is 2¾ inches long and 1½ inch in diameter, giving an area of 13 square inches. This work is done on a 10 by 50 inch Norton grinding machine, using an N grade wheel 18¾ inches in diameter revolving at 1170 R. P. M. or 5745 feet per minute. The work is 1½ inch in diameter and runs at 150 R. P. M., which gives a surface speed of 58.8 feet per minute. The wheel is dressed every ten shafts and the time required is 9 minutes 21 seconds.

If the forgings are coming very regular a somewhat different procedure is followed: Twenty-five shafts are ground and then the wheel is dressed for the fillets and the whole twenty-five shafts are then re-run to check up the fillets. This reduces the wheel cost and dressing time per crankshaft and gives fully as good a fillet. A grinding dog is used in this operation and the feed is by hand. The cutting time on the center bearing is 1 minute 43 seconds. For the end bearings, the times are 59 seconds and 49 seconds, respectively. The long one is 4.8125 inches long and the other 3 inches long. The total area is 7.8125 inches in length by 1½ inch in diameter or 36.9 square inches. The time is 1 minute 48 seconds or 2.93 seconds per square inch. The reason this time per square inch is so much less than the other standard is that the longitudinal motion covers the area far more quickly. The total time for grinding the three bearings, including changing and dressing the wheel, is 6 minutes 7.5 seconds.

The total time involved in machining each of these crankshafts is approximately 69 minutes, the time being distributed as shown in the accompanying table. Those times given in minutes and fractions are averages for irregular operations where the work varies for each individual crankshaft. Those given in minutes and seconds are for operations of a uniform character, which allow an exact duplication of motions in performing the work on each shaft. It may be of interest in this connection to mention the diamond cost which was $0.02375 per crankshaft; the wheel cost which was $0.075 and the scrap cost, which was $0.06927. These figures are arrived at by dividing the average seasonal cost by the average seasonal production. During all this test, no attempt was made to speed the work beyond limits which could be kept up indefinitely. The whole endeavor was to determine a standard rate for grinding surfaces and to observe the conditions under which this is done.

AN ELECTRICAL NUT SETTING ARRANGEMENT

In assembling the Witherbee igniter in the company's factory at Springfield, Mass., an ingenious arrangement is employed for setting the nuts on the hard rubber cases by power. The illustration shows the method of mounting the ¼ horsepower electric motor from the ceiling. This motor is speeded to 1800 R. P. M. and from the end of the armature shaft a worm meshes with a worm-gear on a vertically positioned shaft that extends down toward the floor. From the end of this shaft is extended a flexible shaft, and at the end



Electrically-driven Nut-setter

of the flexible shaft is an Errington nut setter. This nut setter works on the friction principle, so that when the nuts have been set up to the correct tension, the friction slips. With this device a man is able to do a large number of nuts per day, and in addition to being faster, the work is more thoroughly done and there is no danger of cracking the hard rubber plates. C. L. L.

PRODUCTION TOOLS FOR REO ENGINE CYLINDERS*—1

SPECIAL JIGS AND FIXTURES, AND MACHINING METHODS USED BY THE REO MOTOR CAR CO., LANSING, MICH.

BY DOUGLAS T. HAMILTON†

No better example of interchangeable manufacture and the development of special jigs and fixtures is obtainable than can be found in the production of automobile engine cylinders. When we consider the number of operations necessary on an automobile engine cylinder casting and the exactness to which the various surfaces must be machined, it is little short of marvelous that this work can be accomplished in such a short time and at such a low unit cost. The methods and jigs and fixtures employed by the Reo Motor Car Co., Lansing, Mich., are described in the following. The manufacturing steps from the time that the casting is received from the foundry until it is ready for assembling in the completed engine are described in detail. Fig. 1 shows the automobile engine casting. It is of the two-cylinder *en bloc* type and is used in a four-cylinder 30-horsepower engine.

Preliminary Operations on the Automobile Engine Casting

The first operations on the automobile engine casting after it is received from the foundry are inspecting, snagging and removing all objectionable fins. After it has passed through these preliminary operations it is placed in a testing fixture and given a water test at a pressure varying from 200 to 210 pounds per square inch, which exceeds, by about 175 pounds, the normal pressure in the water jacket when the engine is in use.

Milling Top and Bottom Faces of Casting

The preliminary machining operation, which consists in milling the top and bottom faces *O* and *P* of the cylinder casting, see Fig. 1, is accomplished, as shown in Fig. 2, in a Pratt & Whitney Lincoln type milling machine. Two castings *A* are held in this fixture at a time, but it is not of the reciprocal type. Fig. 3 shows in detail the construction of this milling fixture, and by referring to the latter illustration, the method of holding the cylinder castings will be clearly understood. The casting is located between four jaws *B* and *C*, which are operated by left- and right-hand screws, actuated by two handwheels *D*, only one of which is shown. The base of these jaws slides in T-slots formed by machine steel strips which are fastened to the top face of the base casting of the fixture, and the vees of these jaws grip the cylinder casting around the circular portion, as indicated in Fig. 2. To prevent the thrust of the cut from loosening the jaws, a special clamping strap *E*, operated by the lever *F*, as shown in Fig. 2, is provided. This is put in place and tightened after the casting has been located and clamped in the fixture.

The milling is accomplished by two $5\frac{1}{2}$-inch diameter inserted-tooth high-speed steel milling cutters which take a depth of cut varying from 3/16 to 1/8 inch. The cutters are rotated at a peripheral speed of 30 R. P. M. and the table travels at a rate of 1/16 inch per revolution of the cutters. The jigs held on this table are of the individual type, and in operating it is necessary to mill the two castings before starting on a second cut. However, the time of operating is reduced by unloading the first casting that is milled while the second one is being operated upon, and loading the second

† Associate Editor of MACHINERY.

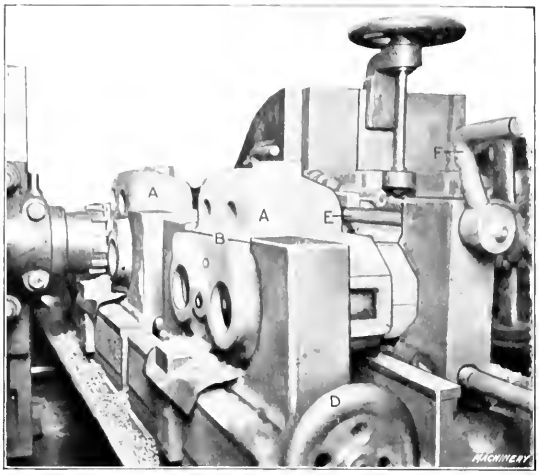

Fig. 2. Milling the Top and Bottom Surfaces of the Cylinder Casting

fixture when the casting in the first one is being machined. The casting in the first fixture, however, cannot be replaced until the table of the machine has been brought back to the starting point. Nevertheless, very little time is lost in operating, as a production of one hundred and thirty-four completed castings in nine hours evidences.

Drilling and Reaming the Flange Holes in the Base of the Cylinder Casting

Upon the completion of the milling operations just described, the next step is to drill the holes in the flange, through which the bolts pass that fasten the cylinder castings to the crank-case. These holes also act as locating points in all subsequent operations. Although this operation is of a simple character, the method of accomplishing it is rather interesting, as Fig. 4 will show. The drilling and reaming of the six flange holes *R* (Fig. 1) is accomplished progressively in a Baush multiple spindle drilling machine. The type

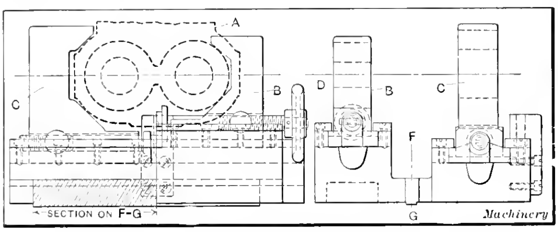

Fig. 3. Milling Fixture used for holding the Cylinder Castings in the Machine shown in Fig. 2

of fixture used is not only of novel construction, but incorporates some points in design that facilitate interchangeable manufacture. As will be seen upon reference to Fig. 4, this fixture is of open construction and consists primarily of a frame *A*, to the top faces of which two rails *B* are fastened. Sliding upon these rails are the work-holding fixtures to which the cylinder is clamped bottom side up.

A more detailed view of the construction is shown in Fig. 5, to which reference should now be made. Upon referring to this illustration, it will be seen that the cylinder casting *D* is held to the bottom face of the sliding portion *E* of the jig by two long clamping bolts *F* and a cross-bar *G*, in which a clamping screw *H* is located. This screw is used to hold the cylinder casting up tight against the bottom face of the jig. The casting is located in the proper relation to the bushings in the top face of the jig by two jaws *I* operated by means of a left- and right-hand screw that receives motion from the handle *J*. These jaw members slide on the top edges of the jig, and have under ledges on which the flange of the cylinder base rests.

Referring now to Fig. 4, the method of operating the fixture is as follows: three work-holding jigs of the type illustrated are in use. The operator first places one jig under the six drills which are 1/2 inch in diameter, and are rotated at 220 R. P. M. The machine is then operated and the drills pass through the 5/8-inch flange. This first jig is then shifted over into the reaming position and the second jig put into place. The machine is again operated and while the holes in the second casting are being drilled the holes in the first casting are reamed by six reamers 17/32 inch diameter; these are

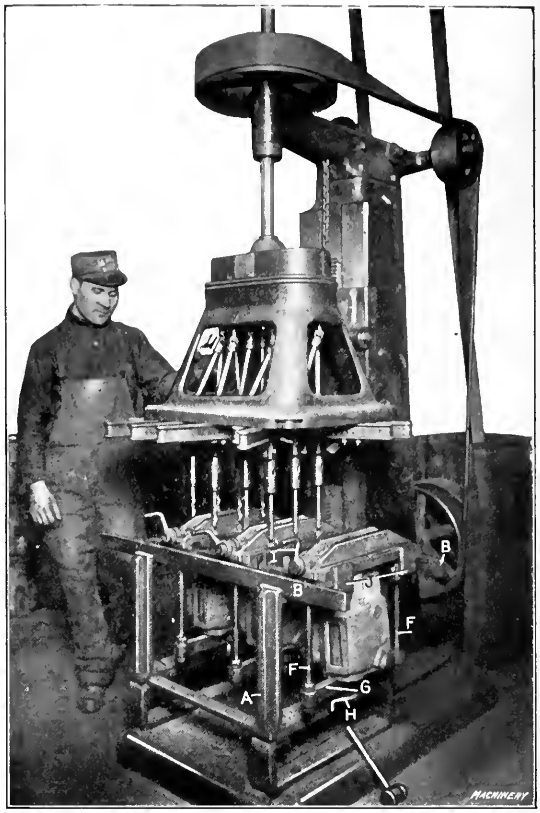

Fig. 4. Progressive Drilling and Reaming of Flange Holes in the Base of the Cylinder Casting

rotated at 220 R. P. M. and the downward travel of the head is 0.005 inch per revolution of the reamers. The third or extra jig is then brought into position and the operations repeated. When the fixture has once started to work in this order, a casting is drilled and reamed at each downward movement of the head. The third jig enables the operator to remove and clamp another casting in position while the machine is

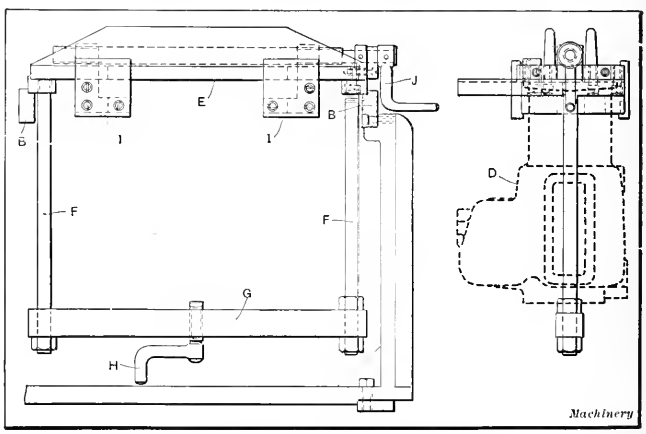

Fig. 5. The Progressive Drilling and Reaming Jig

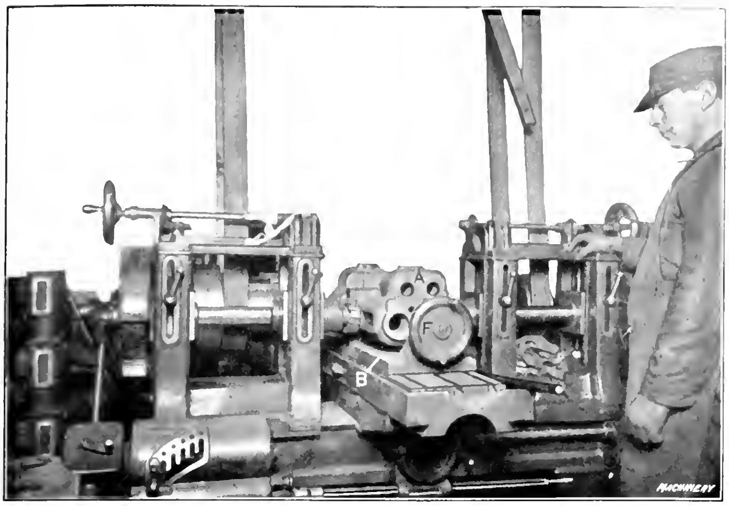

Fig. 6. Reciprocal Milling of Bosses for Waterjacket Plates

in operation, so that the drilling and reaming of the castings is practically continuous. The production from this machine is high, averaging about 210 completed cylinder castings in nine hours. The method of handling the work is, of course, largely responsible for this production. The jigs are provided with removable bushings so that they can be run along progressively on the rack and allow the drilling and reaming operations to be accomplished through the same jig simply by changing the guiding bushings.

Milling Bosses for Water Connection Plates

Following the drilling and reaming of the six holes in the flange of the cylinder casting, the next operation is to face

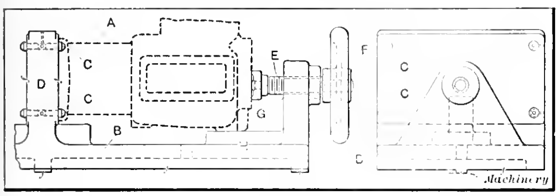

Fig. 7. Detail of Reciprocal Milling Jig shown in Fig. 6

off the bosses *S*, Fig. 1, for the water connection plates. There are two surfaces machined on each casting and this work is accomplished in the Lincoln type milling machine shown in Fig. 6. Two high-speed steel inserted-tooth milling cutters are used for this purpose, and two castings are machined at one setting. This fixture is of the reciprocal milling type, enabling the milling operation to be carried on practically continuously. Fig. 7 shows the type of fixture that is used, and upon reference to this illustration it will be seen that the bed of the fixture consists of one casting *B* which is fastened to the table of the milling machine. The cylinder casting is located in the correct position by four hardened studs *C*, fitting in the previously reamed holes in the flange, and is held tight up against the center bracket *D* of the fixture by the screw *E* operated by handwheel *F*. The forward end of this screw is provided with an adjusting clamping head *G* which accommodates itself to the surface of the cylinder casting, holding it tight against the machined face of the fixture. The casting *A* also rests on a projecting boss *H* on the fixture. As this fixture is worked on the reciprocal principle, it is evident that the production will be greater than that shown in Fig. 2. In this case 140 of these castings are machined in nine hours as against 134 in the first milling operation. The depth of cut taken from each side varies from 1/8 to 3/16 inch and the length of surface milled on each casting is approximately 6 1/16 inches.

Rough- and Finish-boring Cylinder Operations

In order to avoid the difficulties that would result from striking hard and soft castings when boring, the Reo Motor Car Co. has followed the plan of testing all the castings before boring with a scleroscope. The average run of castings strike between 30 and 40 on the scleroscope, and any that strike higher than this are laid aside, marked as hard and machined separately. By following this plan, it is possible to get an average product from the machine each day without running up against any serious difficulties because of hard cylinders. The operator also has less trouble with the cutters because he knows before he puts the casting in the machine whether it is hard or of a uniform density. The same operator who runs the Foote-Burt cylinder boring machine shown in Fig. 8 also tests the cylinders for hardness before clamping them in the jig. The boring machine illustrated is of the four-spindle construction, and machines two cylinder castings or four bores in one setting. On an average, 5/16 inch of material is removed from the diameter of the cylinder bores *T*, Fig. 1, at a rate of feed of 0.063 inch per revolution, leaving it 3.965 inches in diameter by 10 inches deep.

The type of fixture used for holding the castings while rough-boring the cylinders is shown in Fig. 9. Referring to this illustration, it will be seen that the fixture *A*, which consists primarily of a cast frame, is of open construction and is provided with work-holding slides *B* which fit in V-ways provided in the top part of the frame of the fixture. The cylinder castings are located on these slides from the previously drilled and reamed holes in the flange, and are held in position by heel-clamps *C*. The slides *B* are then pushed into the fixture and located by the plug *D* that fits in a bushed hole in the slide and serves to locate the slide in the correct relation to the boring spindles of the machine. In order to provide a support for the casting at its lower end, two tapered wedges *E* and *F* are added to the fixture which assist in holding the casting tight against the slide, and prevent any twisting action due to the boring tool shifting the casting when the bore is eccentric. The top part of this fixture is tied with a tie-bolt *G*, which holds the slides rigidly and prevents any side motion. The nuts on these tie-bolts are released when removing the work-holding slides.

Fig. 8. Rough-boring the Cylinder in a Foote-Burt Cylinder Boring Machine

This rough-boring cut is extremely hard on the machine and cutters because of the large amount of material removed, and also because of the fact that the skin material or surface is much more difficult to cut than the interior or softer metal. Considering this, 124 completed cylinder castings in nine hours shows that the method of machining is about as complete as it could be. Four work-holding slides are provided for this machine so that while the machine is in motion the operator can be removing two finished cylinder castings and clamping two rough ones on the extra slides, thus reducing to a minimum the time that the machine stands idle between loadings.

The second rough-boring cut is accomplished on a Moline four-spindle cylinder boring machine which is equipped with a fixture similar in construction to that shown in Fig. 9. In this case, a cut 0.105 inch on the diameter is taken, and the fixture instead of being loaded from the front as was the case with the rough-boring fixture shown in Fig. 8, is loaded from the end. The production from this machine is 134 completed cylinder castings in nine hours. Before taking the finish-boring cut on the cylinder, the other operations on the valve seats and similar parts are performed and the finish-

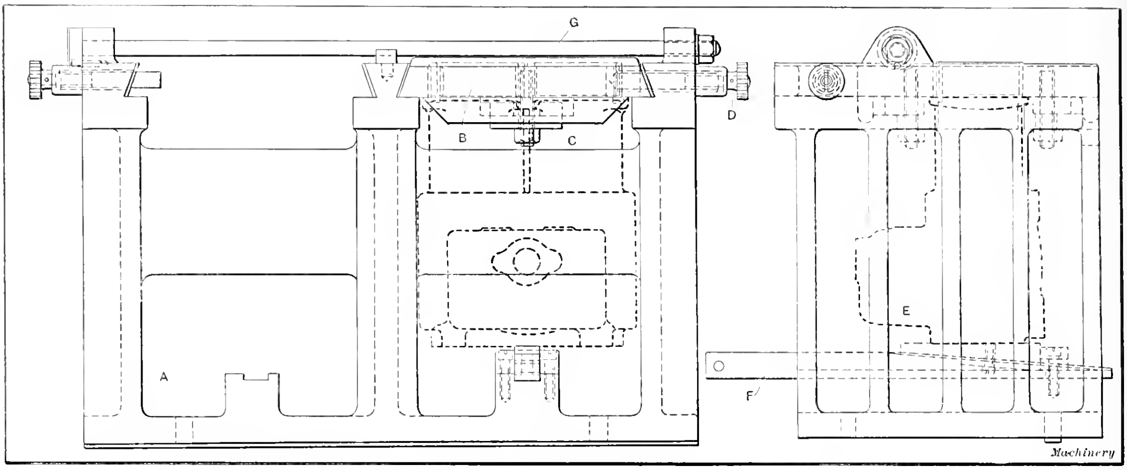

Fig. 9. The Rough-boring Jig which carries Two Cylinder Castings and is used in the Machine shown in Fig. 8

boring is left until last before the castings are taken to the cylinder grinding machine. These operations will be described in a following article.

METHOD OF SECURING CELLULOID TO WOOD

BY G. G.

I recently had occasion to fasten pieces of sheet celluloid to some narrow strips of wood. One side of these strips was completely covered with fine graduation lines and figures so that it was impossible to use small brads to secure them in place. I tried several different kinds of mucilage and glue but met with little success, as the best glue that I found only held for two days.

If the reader ever happens to run across a job of this kind he need not give up hope, as it is quite an easy matter to deal with if you know the proper way to proceed. The method I finally hit upon is as follows: After scraping the wood and celluloid absolutely clean, heat some grain alcohol to the boiling point. As alcohol boils at a relatively low temperature and is very inflammable, it should be held at a considerable distance from the source of heat. When the alcohol has been warmed to the desired point, it is applied to the under side of the celluloid with a small brush. The celluloid is then pressed down on the wooden strip to which it is to be secured and held tightly in place for about two minutes. After that time, nothing except fire will ever make the celluloid come off. The same method may be used for sticking celluloid to celluloid, celluloid to hard rubber and celluloid to glass.

HOW SOME UNUSUAL JOBS WERE HANDLED

BY W. D. FORBES*

In every machine shop in the country there are certain jobs which can be done more or less rapidly and more or less well, as they present no great difficulties. For instance, a pair of parallels 2 inches square could be gotten out so that they would be perfectly serviceable and parallel by any shop that has a planer, as, of course, the work would be accomplished by planing up a long strip and then parting it. This, of necessity, would produce two similar pieces. But when it comes to certain classes of work, the question of how it is done or whether it can be done at all in the shop is interesting.

How many shops could produce a strip of steel ½ inch wide by 0.0015 inch thick and do it commercially? I once tried this very job and made a big failure of it as far as the commercial side went, although I managed to get a couple of strips down to the 0.0015 inch dimension. I had just installed a new surface grinder and felt that I could grind anything that could be ground, so I accepted the job of making two of these thin pieces. I made a cast-iron block and planed it up, filed off the two ends to an easy curve and stretched the strip, which was about 0.0025 inch thick, across it. I thought this would work all right, but after several trials found that, even with a good supply of water, the heat generated was too great. Finally I resorted to hitching a stout spring to one end of the strip, that is, the end where the emery wheel left the work, and by putting a tension on the spring and on the strip, I finally managed to get a couple of pieces down to size at a cost of about eight or ten times what I got for them. Upon telling a friend of my experience, he said that my grinder should have been replaced by a pair of rolls, and that if I had used these I could have gotten down to size without any trouble. This may be perfectly practical for those who understand rolling metals, but it isn't really a machine shop job.

Another job which would puzzle a machine shop would be to put a ⅜-inch hole through a piece of steel 28 inches long, and have the hole true and to size; yet any gun barrel maker would do this without difficulty. Probably everybody who has run a machine shop has had a customer tell him that he is quite privileged to suggest any change in the work which will reduce the cost of machining. This really means that the change will allow the person wanting the work done to make a little more money and the manufacturer, himself, to get less work as a result. It is most magnanimous, of course, but the manufacturer usually rather fails to see the point.

A certain firm required a number of cross-head guides, which were to be used in some horizontal air-compressors, and the job was being estimated on by a shop that was very

* Address: New London, Conn.

anxious to get the work. The privilege of suggesting changes in the design was offered, and after considering what could be done, the shop put in a bid and was successful in obtaining the work. The following alteration was made: The castings weighed about forty pounds each and were of a channel form; they had to be planed off on the top to receive the gibs, and down in the channel to receive the cross-head shoe which was of composition. The original design had oil pockets at each end of the channel, which the draftsman had shown with a lip projecting above the bottom of the channel. This would have made it necessary to machine these cross-head guides singly if a planer was used as, of course, these lips interfered with a continuous cut when several of the cross-head guides were set up together on a planer. These oil pockets were cut off the pattern and a separate pattern made; the pockets were then screwed into position on the finished guides. It is clear that by stringing the cross-head guides along the table the planer tool could sweep through the whole group, making them all alike and saving considerable time, the planer having to be reversed only once for half a dozen guides for each cut. Just as many reversals would have had to be made for each guide had the oil pocket been left as originally designed, to say nothing of the multiplicity of measurements when handling the cross-head guides singly.

Now how is it that a machine shop is so often confronted by just such a condition as the one here noted? It will be admitted at once that, when looking over the men in most drafting offices, you will see very few gray heads; and while gray hairs are a great objection they do, at times, denote experience, and that is of value. The young draftsman usually comes from a technical school and can make good drawings, but his lack of shop experience seems to me to give a clear reason why impractical designs are so often met with. Yet where is the chief draftsman? What is the superintendent doing to allow designs to be gotten out by inexperienced men without thoroughly overhauling them with a view of obviating unnecessary work? Most superintendents and chief draftsmen will say in answer to this question that if they were twins they might be able to look over all the details; in other words, that they have no time to properly consider the work of those they employ. This is all well enough in a way, but in every machine shop there are bright men, not necessarily young, who know all the tools in the shop, just what can be done on them and what is a good practical way to do it.

Another illustration in connection with these very cross-head guides: The gibs were designed to have countersunk fillister head screws to hold them in place and the tapped holes in the cast-iron cross-heads were shown to go down about seven-eighths into the cast iron for tapping. A quarter of an inch more drilling and there would have been a through hole. Now everybody knows that a through hole can be more quickly drilled than a depth hole and that it can also be more quickly tapped. Some will not quite agree with this but the practical man who is doing the work will. He will tell you that, with all care, stops on a drill-press slip and that tapping machines sometimes don't reverse just when they should. The countersinking for fillister heads was quite unnecessary, as there was nothing to interfere with the use of cap-screws which saved counterboring and such screws are infinitely handier than the slotted head affairs.

Speaking of slotted heads in screws, I have always wondered how it was that an English patent on screw-heads never became popular. It was shown me years ago by Mr. T. A. Weston, of differential pulley-block fame, and in my opinion he ought to have a monument erected to him for his invention. This screw-head would be more generally used for wood screws than for machine screws. Instead of having a single slot cut across the head, it had two slots at right angles, forming a Greek cross. If this was all it would not have amounted to much; but these slots converged toward the center and were sunk deep in the screw-head, the slots themselves tapering in width from the center to the edge of the screw-head. The screw-driver was of a form to fit down into these recesses, and as they were tapering and converging one size of screw-driver answered for several sizes of screws. You could put a screw on a screw-driver held vertically and the screw would not drop off; and a screw could be gotten out or else the entire body twisted off. Mr. Weston told me that these slotted screw-heads were made by being struck up in the machine that made the head and at the same time the head was formed. I never saw the machine work but I saw samples of this screw and I certainly wish that it had come into existence. Perhaps some of the readers can shed further light on what seems to be the sidetracking of a valuable idea.

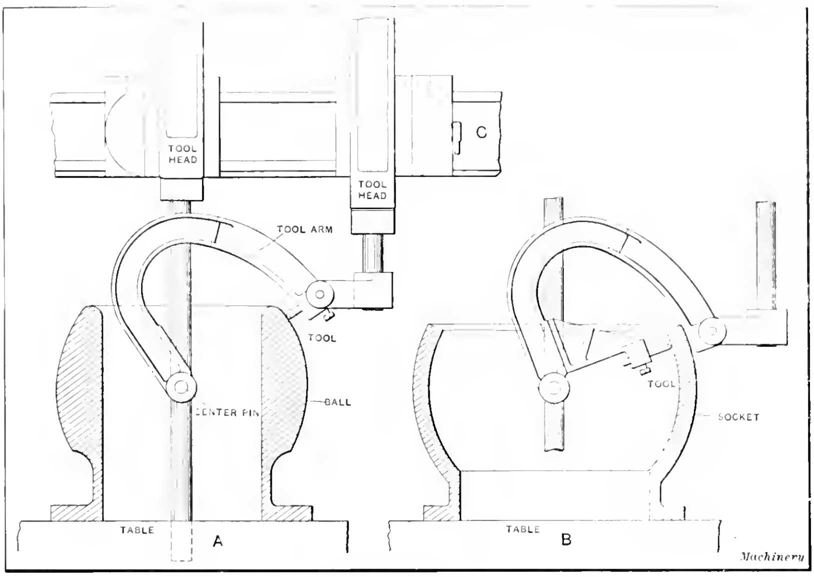
BALL AND SOCKET TURNING DEVICE

BY L. D. PEIK*



Device for turning a 36-inch Ball and Socket on the Boring Mill

In the shop where the writer is employed the operation of turning a ball was one which usually gave considerable trouble, and this was especially true of balls of any considerable size. In the accompanying illustration *A* shows the ball and *B* the socket for a ball and socket joint 36 inches in diameter, which was used on a suction pipe line. This ball and socket were both finished on a boring mill by means of the device which forms the subject of this article. The left-hand tool-head holds the bar which centers the tool-arm, this bar being supported at its lower end by a bushing in the table. It will be seen that the center pin holds the split tool-arm, the opposite end of this arm being supported by a yoke fastened to the right-hand tool-head. The right-hand tool-head is loosened slightly on the saddle and the screw *C* is removed to give the feed motion a free swing on the saddle, to allow it to follow the arc described by the tool-arm.

The proper arc of the ball is made by feeding down the right-hand tool-head while the left-hand head remains stationary. The socket is bored in a similar manner by means of a tool-holder bolted to the arm on the inside as illustrated at *B*. This device has been in use for some time and the writer has found that there is very little chattering of the tool on the finishing cut if the bolts on the saddle are kept adjusted.

COMPOUND STRESSES

ELASTIC LIMIT WITH COMPOUND STRESSES, AND THE MAXIMUM SHEAR THEORY

BY SANFORD A. MOSS*

The elastic limit of a material is found by subjecting it to direct tension or compression in a testing machine. It gives a value which must be borne in mind in using the material in engineering structures. It is obvious that the conditions must be the same as existed in the testing machine, that is, there must be simple tension or compression. Examples of such stresses are found in the bursting stresses in thin pipes, centrifugal force stresses in rotating thin rings, tension on wire ropes and bending stresses in beams near the places where the stresses are maximum. In each of these cases the conditions are exactly the same as in the case of a specimen in a testing machine, so that the values of elastic limit are directly applicable. These are cases of simple stress.

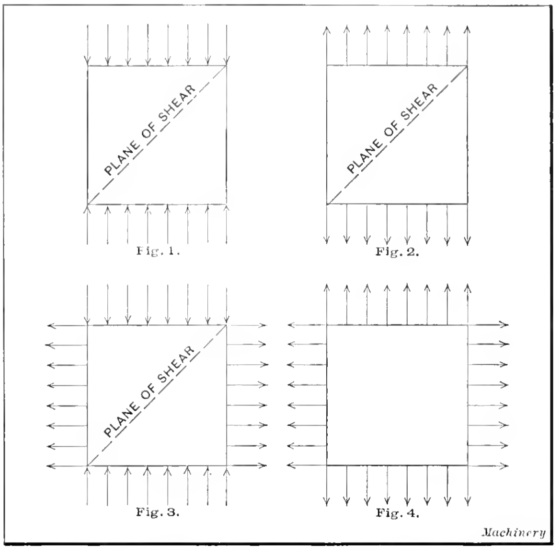

Fig. 1. Shear due to Compression. Fig. 2. Shear due to Tension. Fig. 3. Shear due to Combined Tension and Compression. Fig. 4. Tension in Two Directions. Maximum Shear is inclined at Angle of 45 Degrees to Plane of Paper

Another class of cases arise, however, in which there are stresses in two or three directions at the same time. These are called compound stresses. An example of this is found in a long thin cylinder closed at each end and subjected to internal fluid pressure. There is a tangential stress which tends to burst the cylinder along a line parallel with the axis, as well as a longitudinal stress, due to pressure on the heads, which tends to tear the cylinder apart in a plane perpendicular to the axis; that is to say, a small square in the wall of the cylinder is subjected to stress in two directions, each at right angles to the other. Examples of similar cases are found in stresses due to combined bending and twisting in a shaft, stresses due to centrifugal force in a rotating wheel disk, and stresses in a hub pressed on a shaft.

The Elastic Limit Question With Compound Stresses

The question then arises, What is the criterion for safety in the cases above, equivalent to the value of the elastic limit in cases of simple stress?

A very unfortunate thing in engineering has been the fact that it has not been realized until very recently that there is any necessity for a criterion. Two different classes of engineers have each tacitly assumed a certain criterion, discussed later as the "maximum stress theory" and the "maximum strain theory," without realizing that they have made an assumption in the matter, supposing that their ideas were *apriori* correct, and that there was no other possibility. As an actual fact, no *apriori* assumption is possible, and the matter is one which must be made the subject of very careful experiment. It has only been in very recent years that such experiments have been made. Most engineers who have studied the existing experiments carefully have agreed that neither of the old theories is correct, but that a new one, the "maximum shear theory," must be adopted. The fundamental principles at the root of the whole matter are not popularly understood, and it is the purpose of this article to go into details regarding them. In the writer's opinion, it is completely settled that the maximum shear theory is the proper one for ductile materials such as steel. The writer believes that any engineer who will take the time to investigate the matter completely will be convinced of this. Many engineers use the older theories for the reason that they have started out this way, and have never realized that there was any question in the matter.

Cross Contraction and Net Strain

A simple tensile stress causes elongation in its own direction, as given by the modulus of elasticity. That is, if E is the modulus of elasticity, the total elongation l produced in a piece of length L by a stress S is given by the well known law:

$$E = \frac{S}{l \div L}.$$

Not only does the stress in the given direction produce the extension mentioned in the direction of the stress, but there is also produced a contraction in each direction at right angles to the stress. That is, if we have a square bar stressed in the testing machine in the direction of its length, so that the length increases according to the above formula, there is a contraction in each opposite direction, which produces decrease in the thickness of the bar. The ratio of the contraction at right angles to a stress, to the direct extension, is called Poisson's ratio. For ordinary kinds of steel this has a value of 0.3. If the direct stress is a compressive stress, so as to cause decrease of length in the direction of the stress, then there will be an expansion in each direction at right angles equal to 0.3 times the compression. Suppose we have a bar 1 inch square, in compression, with such stress that every inch of its length is compressed 0.001 inch. Due to this compression the thickness of the bar will be increased in each direction 0.0003 inch.

This action of extension in one direction and contraction in the other, due to a simple tensile stress, exists for each such stress. When there are stresses in two directions at once, that is to say, when we have compound stresses, each of the individual stresses produces its deformation regardless of the existence of the other stresses. The total deformation produced is due to the sum of such individual deformations. Consider the case of a hub pressed onto a shaft. There is a stress in the radial direction which compresses the fibers in this radial direction. Due to this radial compression, there is extension in the tangential direction. There is also a stress in the tangential direction which tends to burst the hub across the diameter. This stress produces extension in the tangential direction and also compression in the radial direction. Consider now the material in that portion of the hub immediately next to the bore. This is a thin ring of metal the circumference of which is increased directly by the tangential stress. However, the compressive radial stress also tends to produce extension in the tangential direction, so that the total increase of circumference exceeds that produced by the tangential stress, if acting alone, by an amount which is 0.3 of the direct compression produced by the radial stress acting alone. Similarly, there is a decrease in thickness of the ring due to the radial stress directly, and a further decrease in the thickness due to the tangential stress.

In the case just considered one of the stresses was a tensile stress and the other a compressive stress, and the deformation in each direction was greater than that pro-

* Address: 36 Sachem St., Lynn, Mass.

duced by each stress acting alone. We may, however, have both stresses in the same direction, as in the case of a rotating disk, where there are both radial and tangential tensile stresses. The tangential stress tends to increase the circumference of any thin ring in the interior of the disk, but the radial stress, which causes extension in the radial direction, causes contraction in the tangential direction, so that the net increase in circumference is less than that due to the tangential stress acting alone. Similarly, the net increase in the thickness of any thin ring is less than that produced by the radial stress acting alone. If we have a direct stress S_1 it produces a deformation or increase in length in each unit of length, called "strain," amounting to $\frac{S_1}{E}$. If now we have another stress at right angles to the stress S_1 amounting to S_2, this stress produces, in its own direction, an extension in unit length, or strain, amounting to $\frac{S_2}{E}$. At the same time, this stress S_2 produces in the direction of the stress S_1 a contraction equal to $\frac{0.3\,S_2}{E}$. Hence the total extension per unit length, or strain, in the direction of the stress S_1 is:

$$\frac{1}{E}\,(S_1 - 0.3\,S_2).$$

If there are stresses in a third direction, we have to subtract still another term to get the net strain. If the three stresses are equal and of the same kind, the net strain is $(1.0 - 0.3 - 0.3)$ or 0.4 times that due to one stress.

In order to produce the same deformation in unit length, or strain, due to the stresses S_1 and S_2, we would have to have a simple stress equal to $S_1 - 0.3\,S_2$. Such an equivalent simple stress which would produce the same strain as the actual strain existing at any point due to the actual compound stresses, used to be called the "true stress." The actual stresses which we have been discussing and which are given directly by the forces acting on our material were then called the "apparent stresses."

Shear

When a short specimen is compressed in a testing machine, it fails by sliding of the upper part on the lower part at an angle of 45 degrees; that is, the direct compressive stress produces a tendency for the two parts to slide one on the other as shown by Fig. 1. This tendency to slide is called a shearing stress. A tensile stress also causes a tendency to slide. If a tension break in a homogeneous material is closely examined, it will be seen that the actual failure has been due to sliding at an angle of 45 degrees along a number of different faces, some inclined one way and some inclined another. In other words a tensile stress produces a tendency to slide, as shown in Fig. 2. Suppose now that we have in the same cube both tensile and compressive stresses at right angles. Then there is a combined tendency to slide, as shown in Fig. 3. If these stresses are both the same, the tendency to slide is double that produced by either stress if acting alone. It is obvious that in any case of a tensile stress in one direction and a compressive stress at right angles, there is a tendency to slide equal to that produced by a simple stress of an amount equal to the sum of the two existing stresses. That is to say, the shear produced by two stresses of opposite kinds in directions at right angles, is equal to the shear produced by a simple stress which is equal to the sum of the two stresses. When there are three stresses the shear is computed in a similar way which we will discuss later.

Stress Computation

The mathematical theory of elasticity, as it has existed for years, gives means for computing the actual stresses existing at any point of a body, or the "apparent stresses," as they are sometimes called, as well as the simple stresses which would produce equivalent strains, or the "true stresses," and the simple stresses which would produce equivalent shears. There is no difference of opinion about such computation. There are many matters in the theory of elasticity which are difficult of solution but such problems as can be solved are universally agreed upon. Hence, the matters which are not generally handled satisfactorily are not matters of theory of elasticity computation.

Criterion for Equivalent Simple Stress with Compound Stresses

If we had only to deal with simple stresses we would raise no question as to just what happens when the elastic limit is reached. The elastic limit and the beginning of failure may be a matter merely of the stress, or it may be a matter of the strain, or it may be a matter of the shear. However, conditions would be just the same in a piece in which we are interested as they are in the testing machine, so that we know that the beginning of failure, whatever it may be due to, would occur when the testing machine stress is reached. In the case of compound stresses, there is quite a different condition. We may have in a piece in which we are interested a stress which is safe in the testing machine and which would be safe if it existed alone. However, we have in addition stresses in other directions. If it were the direct stress only which counted, and if the existence of stress in other directions did not cause weakening in the direction of the greatest stress, such stress in other directions would be immaterial. On the contrary, if the limit of safety is fixed by the amount of strain or deformation which is permissible, then we would have to take account of stresses in all directions, since each of these produces a strain in any given direction. We would then have to compute the net strain in a given direction, due to all of the stresses taken together.

Suppose that if we had a direct tensile stress of 30,000 pounds alone, we would just be at the elastic limit. If now we have in addition a tensile stress at right angles, this would diminish the strain produced by the first stress, so that the net strain would be less than that corresponding to a simple stress of 30,000 pounds. Hence if net strain counts, our material would be strengthened by the existence of this second tensile stress at right angles to the first. On the contrary, if the second stress were a compressive stress, it would cause a strain which would have to be added to the original strain, so that weakening would result. A similar situation exists if it is shear which we have to attend to. A direct stress produces a certain shear and the existence of a stress at right angles produces additional shear which is to be added to or subtracted from the first, according to the direction of the second stress. The strain produced by two equal stresses at right angles, one tensile and one compressive, is 1.3 times the strain produced by either stress alone, while the shear produced by two such stresses is twice that produced by either stress alone.

It is obvious then that we must decide just what sort of action causes failure and just what conditions we are interested in, whether merely the stress itself, the strain, or the shear. Having decided this question, the theory of elasticity gives us more or less easy means for determining the value of a simple stress which in a testing machine would produce the same conditions as those existing in any case of compound stresses.

Maximum Strain Theory

The theory that has in the past been generally accepted is the maximum strain theory. So far as the writer knows there were never any experiments made to demonstrate its validity. It was probably reasoned out by some of the older elasticians purely as a matter of abstract philosophy, and probably considered by them as self-evident. The theory thus crept into use in an unobtrusive way without realization that there had been made an assumption that was not axiomatic. This theory is used in most of the older textbooks and writings, without discussion. This theory supposes that the thing which causes failure and which must be used as a criterion for safety is the amount of deformation or strain. With a modulus of elasticity, E, of 30,000,000, there is a deformation or strain of 0.001 inch in every inch of length with a simple stress of 30,000 pounds. If now 30,000 pounds is the elastic limit, then when we have compound stresses, failure will begin to occur whenever the net strain due to the action of all the stresses together becomes 0.001

inch per inch. This will occur, for instance, with a tensile stress of 39,000 pounds in one direction and a tensile stress of 30,000 pounds in a direction at right angles. Due to the first stress there will be an extension or strain in its own direction of 0.0013 inch in every inch of length. The stress of 30,000 pounds in the opposite direction will produce an extension in that direction of 0.001 inch per inch of length, and hence a contraction in the direction of the first stress equal to 0.3 of this, or 0.0003 inch. The net extension or strain in the first direction will therefore be 0.0013—0.0003, or 0.001. This is the same strain as produced by a simple stress of 30,000 pounds. In the same way a tensile stress of 24,000 pounds in one direction and a compressive stress of 20,000 pounds in an opposite direction may be shown to produce a strain of 0.001 inch in every inch of length. That is to say, according to the maximum strain theory a simple stress of 30,000 pounds per square inch is the stress equivalent in the results produced, so far as failure is concerned, to tensile stresses at right angles of 39,000 pounds and 30,000 pounds, or to a tensile stress of 24,000 pounds in one direction and a compressive stress of 20,000 pounds in the other direction. The well known formulas for stresses in a gun or thick tube, due to Clavarino for the case where there are heads in the end, and to Birnie for the case where there are no heads, are examples of formulas based on the maximum strain theory.

Maximum Stress Theory

The maximum stress theory supposes that failure and elastic limit are purely matters of stress in a given direction regardless of the existence of stresses in other directions. That is to say, if a stress of 30,000 pounds is the elastic limit for a simple stress in a testing machine, it will also be the elastic limit in any case of compound stresses if the stress in one direction is 30,000 pounds and regardless of the existence of lesser stresses, whether tension or compression, in directions at right angles. The formula attributed to Lamé for a thick tube or gun is an example of the application of the maximum stress theory.

Maximum Shear Theory

As a result of some brilliant experiments published in the *Philosophical Magazine*, May, 1900, Mr. J. J. Guest formulated the maximum shear theory. This publication formed an epoch in this subject, and the paper will undoubtedly go down in history as a classic. Mohr, in Germany, reached similar conclusions at about the same time, his publication being in the *Zeitschrift des Vereines deutscher Ingenieure* in January and November, 1900. Since this time, many explanations and discussions have been published on this subject in Great Britain.*

This theory states that the cause of an elastic limit and the criterion for the beginning of failure is the sliding of particles past each other due to shear, and that failure in ductile materials is due to this sliding and not to direct tension. Hence, any case of direct tension or compression produces a tendency to slide and the failure is due to this. A compression failure illustrates this directly. A tension failure if carefully examined will show the same point. It was also known for many years before Guest's publication that at about the time the elastic limit was reached in a tension specimen, lines at an angle of 45 degrees began to appear. It has been shown that this is the indication of failure by shear. The evidence presented by investigators seems to the writer conclusive that this theory must be adopted to the exclusion of the maximum strain and maximum stress theories. It shows that failure by tension and failure by compression are really only different aspects of failure by shear. Failure means the beginning of sliding which is not recovered when the stress is removed and gives permanent set, thus indicating the "elastic limit." It follows, therefore, that the elastic limit will be the same for tension as for compression. This is true for steel and other ductile materials and is in itself a point of evidence in favor of the maximum shear theory.

Cast iron has no elastic limit and the actions referred to do not occur, so that elastic failure does not exist in cast iron as called for by the maximum shear theory. As is well known, the action of cast iron is quite different in tension and compression. Some experimental work on cast iron indicates that rupture with compound stresses occurs when the maximum stress reaches the value causing rupture with simple tension. This, of course, may not mean that a safe compound stress with cast iron occurs when the maximum stress reaches the safe value for tension.

As an example of computation of equivalent simple stress by the maximum shear theory we will take the case of Fig. 3, supposing equal tension and compression stresses of 20,000 pounds per square inch. The equivalent simple stress is 40,000 pounds per square inch. This may be compared with the equivalent simple stresses by the maximum stress and strain theories, respectively, which are 20,000 and 26,000 pounds per square inch. In the case of Fig. 4, the maximum shear theory gives as the equivalent simple stress 20,000 pounds per square inch, and the maximum stress and strain theories give 20,000 and 14,000 pounds per square inch, respectively.

According to the maximum shear theory, a body compressed equally in three directions at once will never fail, no matter how great the stress, since the shear is zero. Some experiments seem to indicate the accuracy of this theory, and the inaccuracy of the maximum stress or strain theories, which call for failure with stresses equal to, and 2½ times, the elastic limit, respectively.

Use of Maximum Shear Theory

From the discussion above of computation of shear, the following rules for computation of the simple stress equivalent to any case of compound stresses follow directly, and these rules should be used in determining failure according to the maximum shear theory. When there are stresses in two directions at right angles, with no stress in the third direction, and with both stresses of the same kind, that is, both compression or both tension, the equivalent simple stress is equal to the greater of the two stresses. In this case the maximum stress theory gives exactly the same results.

When there are stresses in two directions at right angles, with no stress in the third direction, and with the stresses of opposite kinds, that is, one tension and one compression, the sum of the numbers giving the two stresses gives the equivalent simple stress. That is to say, if we have tension of 10,000 pounds in one direction and compression of 5000 pounds in another direction, the situation so far as failure is concerned is exactly the same as if we had a simple stress in a testing machine of 15,000 pounds per square inch.

When there are stresses in all three directions at the same time and all of the same kind, that is, all tension or all compression, we subtract the minimum from the maximum of the three stresses to obtain the equivalent simple stress.

When there are stresses in three directions at the same time, one or more tension and one or more compression, the sum of the numbers giving maximum compression and maximum tension stress gives the greatest equivalent simple stress.

In the case of a beam at the point of maximum stress there is usually stress in a single direction, so that this stress is a simple one and we need make no use of the maximum shear theory. In case of a rotating shaft subject to bending and twisting at the same time, that bending moment which, if existing alone, would give the same conditions so far as failure is concerned, is the square root of the sum of the squares of the actual bending and twisting moments. This is also equal to that twisting moment which, if existing alone, would give the same conditions so far as failure is concerned. In the case of a rotating wheel, such as a turbine disk, there are radial and tangential stresses which are both tensile stresses. Hence, the greater of the two gives the equivalent simple stress, the same as if the maximum stress theory were used. For the case of a thick tube or cannon with

* See "Engineering," July 10, August 21, September 4, October 23, November 6, November 13, November 20, and November 27, 1908; February 5 and August 20, 1909; December 15 and December 29, 1910; "Report of the British Association," Section G, 1913; "Philosophical Magazine," July and December, 1906; "Proceedings of the Physical Society of London," Volume 20; "Proceedings of the Royal Society," Volume 49.

internal fluid pressure P, and ratio of outside to inside diameter R, the maximum equivalent simple stress is

$$\frac{2PR^2}{R^2-1}$$

If a hub is pressed on a solid shaft of the same material, the original difference in diameters being Y inch per inch of bore, with modulus of elasticity E, the maximum equivalent simple stress is EY.

WORK-HOLDING FIXTURES FOR THE VERTICAL SURFACE GRINDER

The Ritter Dental Mfg. Co. of Rochester, N. Y., makes extensive use of the vertical surface grinder for machining operations in the factory. Some of the work done is quite unusual, yet with the fixtures which have been provided the vertical surface method of finish-grinding has worked out well.

Fig. 1 shows an installation of the Blanchard vertical surface grinder in the shop, and the operator is shown surface-grinding the halves of ball-and-socket joint sections for the Ritter dental engine. These pieces, which are drop-forgings, are held by catching the front ends in V-blocks at the central part of the fixture, while the outer ends are clamped by the hand clamps seen in front of each piece. These act on simple levers, clamping the pieces inward and downward at the same time. After the forgings are located, it is an easy matter to grind them to an even bearing surface, the finish of which is much better than could be obtained by ordinary milling methods. Especially is grinding advantageous as the scale due to the drop-forging operation is difficult to mill.

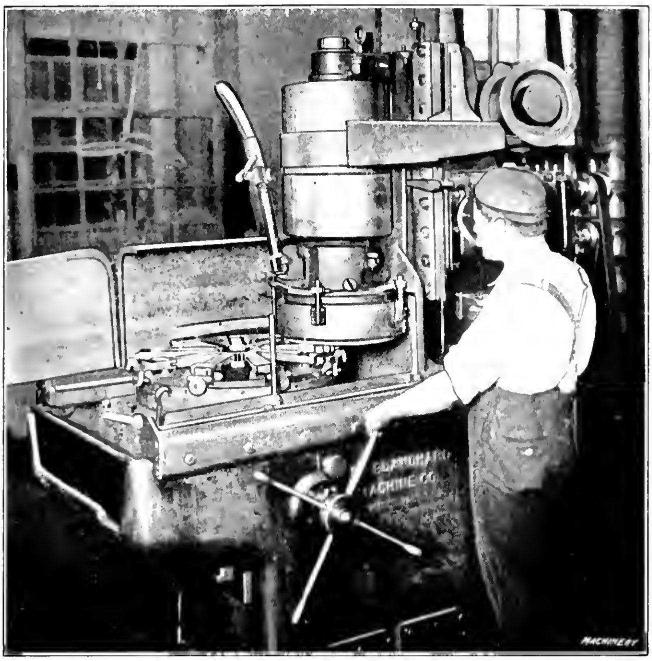

Fig. 1. Facing Forgings on a Vertical Surface Grinder

In Fig. 2 are shown six other grinding fixtures used upon the vertical surface grinder. At A is a fixture for holding small sections of extruded brass. Because of the fact that this metal is extruded, the outlines are all exactly alike; therefore they can be held by the pin method as shown. The pins are located so that several different sizes may be held on the same fixture. In the illustration only a few of the parts to be ground are shown in place, but these are sufficient to illustrate the principle involved.

At B is an unusual fixture for a surface grinder. On this plate there are provisions for holding ten engine castings so that the ends of the cylinders may be faced off. The castings are located with four pins each and are clamped at the sides to hold them firmly down against the fixture.

At C is shown the only magnetic fixture in this lot. This is for holding small thin disks. The disks are made of steel and are grouped in the channels provided on the plate. After one side has been faced off they are turned over and similarly treated on the other side.

At D is shown a fixture for holding the engine bodies in inclined positions for facing off the section which may be seen in the vertical plane on the casting shown on the fixture. This fixture provides for holding six castings, and the method is the best and quickest way of finishing this surface on the casting.

A similar fixture is shown at E. This, however, provides for holding the cylinder castings in a reverse position from that shown in the fixture at D, and is for the purpose of grinding the bases. Ten of the castings are held on this fixture, being bolted with straps between each two pieces.

The fixture shown at F is also for holding extruded brass sections, being of the same design as the fixture illustrated at A. Here, again, a few of the sections are shown in place, only enough being shown to illustrate the principle. C. L. L.

SOME RECENT IMPROVEMENTS IN CASEHARDENING PRACTICE*

MATERIALS USED FOR CARBURIZING—ACTION OF DIFFERENT MATERIALS—MEANS OF CONTROLLING HEATING FURNACES AND MEASURING HARDNESS OF WORK

THE experiments in casehardening practice referred to in the following were for investigating the materials used for carburizing, the action of different materials, and the means of controlling the heating furnaces, and of measuring the resultant hardness of the work. The experiments began at the furnace end of the problem. At first it was decided to install pyrometers, but this was not done, owing to the high cost of an efficient pyrometric outfit for a battery of thirteen muffles; moreover, it was thought that such an outfit might be too expensive to keep in working order. There was also doubt as to whether thermo-electric and resistance pyrometers would be suitable for a system starting with a hot furnace full of cold work or for ascertaining the temperature of an isolated article.

Optical Pyrometers

Finally, after considerable experimenting, an optical form of pyrometer was adopted containing a dye solution capable of absorbing the rays emitted by the hot steel at various

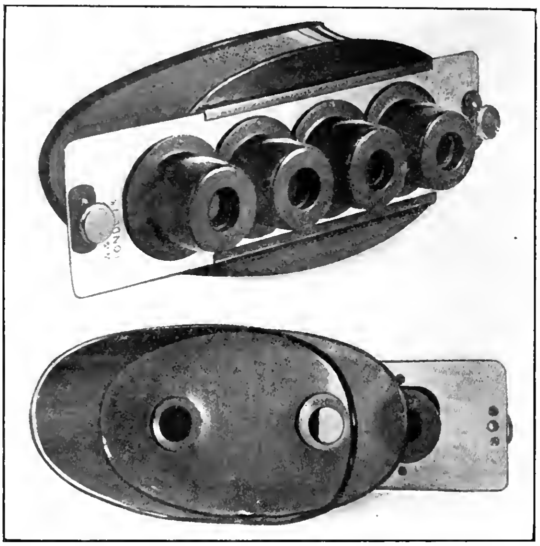

Fig. 1. Front and Rear Views of an Optical Pyrometer having Two Pairs of Cells containing Dye Solution through which Heated Work is observed

temperatures. Front and rear views of one of these pyrometers are shown in Fig. 1. It has an eye-shield to guard the eyes from extraneous light, and instead of two lenses, there are two pairs of dye solutions well protected by caps which also serve to keep out the light. This form is suitable when some particular temperature is required. For instance, the casehardening temperature is controlled by means of an instrument like this, having one pair of cells containing dye solution adjusted to 900 degrees C. and another pair adjusted to 925 degrees C. If the pots containing the parts to be casehardened are visible through the 900-degree pair and invisible through the 925-degree pair, the temperature is considered correct. There is no need to remove the eyes while the pairs are being changed, as the aluminum carrier can be shifted from one side to the other.

For reheating work, and for hardening tools, a single pair is all that is necessary. The hardening temperature is attained as soon as the work appears just visibly red. For double reheating two pairs are, of course, necessary. The cells can be interchanged and are readily detachable, so one instrument can be used to ascertain any temperature, provided the object be visibly red hot. The actual container is a glass tube less than one inch long, with accurately fitting glass ends held together on rubber rings by two telescoping brass tubes. In form, the cell is much like a short polarimeter tube. The caps on the aluminum slides are provided with springs to prevent the cells from falling out.

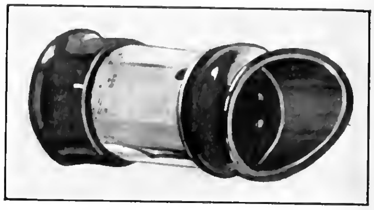

Fig. 2. Adjustable Form of Optical Pyrometer for Temperatures over 400 Degrees C.

In another form the instrument is adjustable and is either monocular or binocular. The dye solution is contained in expansible cells, and a range of absorptive powers is obtained by altering the length of the column. The first pyrometer of this form was made with two thick glass ends and a length of inner tube from a bicycle tire. On squeezing the glass ends together, the rubber sides bulge outward. This is an example of the present form seen in Fig. 2. The actual container is enclosed in the tube, which is provided at one end with an eye-piece, and at the other with a screw which serves to lengthen the cell until the added part is sufficient to just absorb the light. The temperature is indicated by a scale engraved on the tube. This form of pyrometer is perhaps not quite so accurate as the form with each cell especially made to one temperature. According to a National Physical Laboratory report the error may be ± 10 degrees C. The form shown in Fig. 2 is three inches long by one and one-half inch diameter and is very convenient to use.

The method of determining temperatures is a zero method and is, therefore, more accurate than one involving a comparison of colors; furthermore, the critical point occurs when the eye is shaded from extraneous light, that is, when the pupil is dilated and the retina is in its most sensitive condition. In judging temperatures by the unaided eye errors are caused by (1) extraneous light falling on the eye; (2) the difficulty of remembering close shades of color; (3) errors of judgment in comparing the image of the color observed with a series of mental images of colors previously seen.

All these chances of error are eliminated by an instrument of the kind shown in Figs. 1 and 2. No extraneous light falls on the eyes and no recollection is required; the hardener has simply to look through, wait about half a minute until his eyes have become accustomed to the darkness, and then see whether the object is visible as a dark red patch or invisible. Hardeners seem to prefer to use their eyes for telling the temperature, and these instruments provide pyrometric equivalents for limit gages and micrometers, and at the same time screen the eyes from the

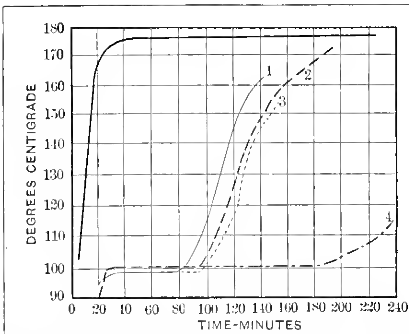

Fig. 3. Curves showing Rise of Temperature in Casehardening Pots filled with Granular Charcoal of Various Sizes containing 6 Per Cent Moisture

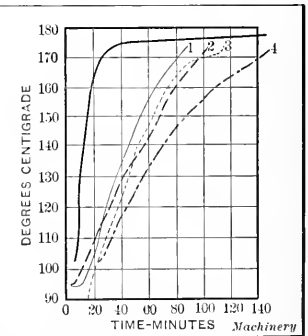

Fig. 4. Rise of Temperature of Dry Charcoal of Various Sizes—compare with Fig. 3

* Abstract of a paper presented before the Iron and Steel Institute, London, by Henry L. Heathcote.

glare and heat of the furnace. The readings are admittedly dependent on the sensitiveness of the eye; if this varies with different workmen, the temperature readings will vary accordingly, being lower the more sensitive the eye. These variations, however, do not greatly affect the accuracy, and from actual experiments it is believed that the variation in sensitiveness, under the actual working conditions of these instruments, is not nearly so great as might be expected.

If the object be a large one, it is advisable to interpose a perforated screen between it and the instrument. One way to make an observation is to adjust the instrument to a lower

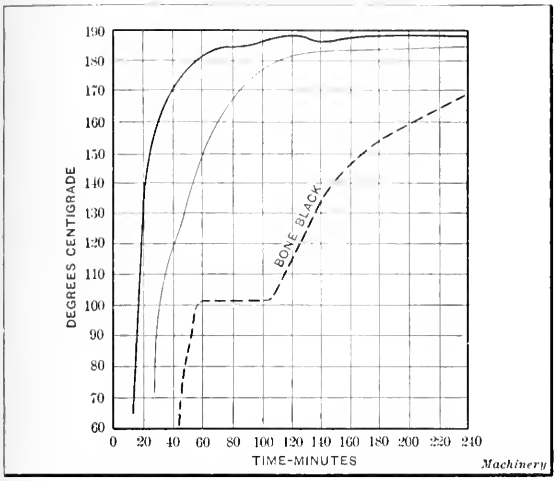

Fig. 5. Comparison in Rise of Temperature of Soda-ash Charcoal Mixture and Bone-black Bone-dust Mixture

temperature than that expected, and then, by sliding darker cells into position, or by unscrewing (if of the adjustable form), darken the image until it just ceases to appear colored. The temperatures engraved on the cell or the body of the instrument will then indicate the temperature of the hot body, provided the conditions of the test are as nearly "black body" as those obtaining when the calibration was effected. These instruments have been applied with satisfactory results to the heat-treatment of steel, carburizing, reheating, annealing, and hardening tools of all kinds.

Casehardening Composition

Having provided a simple and effective device for ascertaining the temperature of red-hot bodies, the nature, mode of action, and effect of casehardening compositions were next investigated. Obviously for carburizing to occur (1) the heat must first penetrate to the steel and raise it to the proper condition; (2) it must liberate and maintain a supply of the carburizing ingredients; (3) the peripheral layers of the steel must combine with (or dissolve) these ingredients; (4) the carbide must diffuse from the periphery inward.

The composition of casehardening materials varies very widely. The following table shows the range of variation in seventeen commercial compositions tested:

TABLE I. VARIATION IN CASEHARDENING COMPOSITIONS

	Per Cent
Moisture	2.68 to 26.17
Oil	0.17 to 20.76
Carbon (organic)	6.7 to 54.19
Calcium phosphate	0.32 to 74.75
Calcium carbonate	1.2 to 11.57
Barium carbonate	nil to 42.0
Zinc oxide	nil to 14.5
Silica	nil to 8.14
Sulphates (SO_3)	trace to 3.45
Sodium chloride	nil to 7.88
Sodium carbonate	nil to 40.0
Sulphides (S)	nil to 2.8

When these experiments were begun the mixture of barium carbonate, 40 per cent, and charcoal, 60 per cent, suggested by Guillet was not in use, and it was usual to use casehardening compositions once only or perhaps twice. Another drawback experienced in commercial operation, for instance, with pots ten inches high by ten inches in diameter, was the difference in the depth of penetration near the middle and the outside of the pot. Some compositions showed as much as 150 degrees C. difference in temperature between the inside and the outside. The author accordingly set out to improve: *Permanence*, and to obviate loss of activity and consequent wastefulness; *permeability* to heat, and to obviate unequal heating and casing.

The supposition that the loss of carburizing power was due to loss of nitrogenous constituents was confirmed by early experiments. Spent hardening mixture may contain 12 per cent organic carbon (total carbon less carbon in carbonates), and yet, under similar conditions, have far less carburizing power than fresh material containing less carbon. Such spent mixture gives indication of only traces of nitrogen.

Experiments extending over a considerable time and range of composition have confirmed the following suppositions: (1) the depth of case depends chiefly on the temperature the steel attains and the duration of the hot condition. On these factors depend the rate and extent of the diffusion of the carbon or carbide. (2) The concentration of the carbon in the case depends chiefly on the "activity" of the mixture, or rate at which it or its products part with carbon to the steel. The concentration of carbon in the surface layers may increase or decrease with temperature, but usually increases as the temperature rises and with the time. (3) The duration of the hot condition for a given time of heating depends chiefly upon the permeability to heat of the casehardening composition.

Comparative depth of penetration has been the subject of a number of investigations, but is so much dependent on factors other than the casehardening composition that the author has sought for some other test. The one finally adopted is to take a known volume of the composition and ascertain the volume of the "case" that can be obtained from it without replenishing.

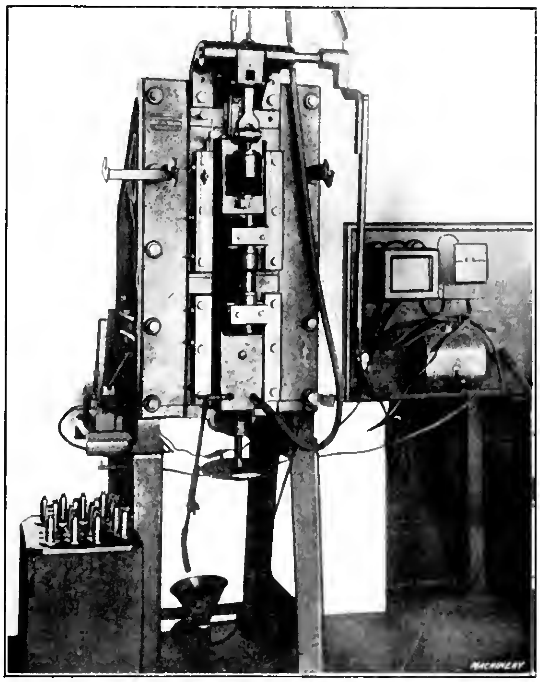

Fig. 6. Electric Welder arranged for tempering Casehardened Articles

The ratio of total volume of case to initial volume of casehardening material affords a good indication of the efficiency of the composition, and is not so dependent as a single penetration measurement on other factors such as size of pot, number and size of the articles it contains, loss of heat from furnace walls when the pot is introduced, etc.

The results of testing some experimental mixtures showed that wood charcoal impregnated with soda ash gave a ratio of 0.116. This mixture is eminently suitable on the score of

permanence, and can be used over and over again indefinitely, provided that the inevitable waste involved in commercial usage is made up from time to time with fresh composition and that the ingredients are well incorporated and in the proper proportions.

Permeability to Heat

Having found a composition far more permanent in its properties than any then in current use, the author proceeded to investigate the factors concerned in permeability to heat. Most commercial mixtures consist of or contain a large proportion of small particles which it seems reasonable to expect will block up all the interstices and prevent the free passage of heat, for it has been shown that the heat conductivity of insulating materials depends chiefly on their air spaces. To test this point, granular charcoal was employed, and two model casehardening pots, 5 inches high, 3.7 inches in diameter and 0.04 inch thick, were made of sheet steel and welded together. One contained the charcoal under investigation, and the other was used empty. A thermometer bulb was placed at the center of each pot and the apparatus placed in an oven at 180 degrees C. Fig. 3 shows the rise of temperature with time. The curve on the left shows the temperature at the middle of the empty pot; those on the right, numbered 1, 2, 3, 4, refer to charcoal of various sizes, each containing approximately the same proportion of moisture and taken from the same sack.

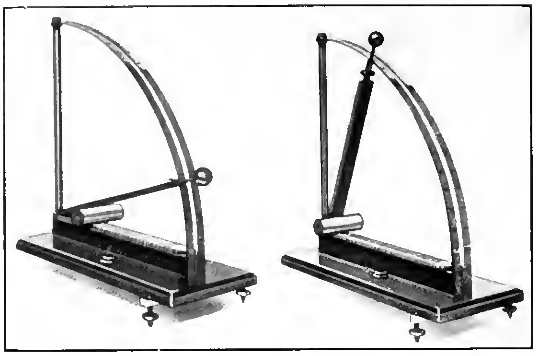

Fig. 7. Quadrant Sclerometer for testing Hard and Soft Bars—Two-file Form

Two striking points are brought out by these results: First, the arrest of temperature at the center at about 100 degrees C. while moisture is being driven off; and second, the effect of size of grain and particularly of dust upon the duration of the arrest. When the same samples were again heated the temperature rose much more quickly (see Fig. 4). The absence of any arrest is, of course, due to the moisture having been expelled during the previous tests.

A mixture which can be used over and over again possesses the great advantage that moisture, oil and other volatile constituents have, for the most part, been already expelled by the previous heatings. This is illustrated by the results plotted in Fig. 5. The curve on the right refers to a mixture of bone-black and bone-dust; and the middle one to the soda ash and charcoal mixture (consisting of three parts used to one part not used) freed from all small particles and dust by means of a sieve with round holes 0.08 inch in diameter. The two mixtures were heated at the same time. The curve on the left shows the rise in temperature of a similar empty pot.

To see if these results represented anything of commercial importance, some tests were made with pots ten inches high by ten inches in diameter, with coarse and fine mixtures having the same composition. The same number and kind of articles were packed in each pot, and test-pieces, 1½ inch by ½ inch square, were placed near the top and bottom and at the middle of the pot. The pots were then heated together for five hours, the maximum temperature being about 925 degrees C. These test-pieces were reheated to 760 degrees C. and quenched in water to show the depth of the case. The following table represents the results:

TABLE II. COMPARATIVE DEPTHS OF CASE WITH FINE AND COARSE MIXTURES

	Top	Middle	Bottom
Fine	0.025" to 0.03"	0.02" to 0.025"	0.03" to 0.03"
Coarse as No. 3	0.045" to 0.05"	0.04" to 0.04"	0.045" to 0.05"

Composition of the Case

Having secured a considerable improvement in both permanence and permeability to heat, it remained to ascertain whether this composition imparted a suitable percentage of carbon and gave uniform results from day to day. W. T. Flather, who has made a great number of determinations of carbon in the successive layers of the case, carburized some bars of "Ubas" steel in his standard pot and under his standard conditions, but using the dust-free charcoal impregnated with soda ash (three parts used to one part fresh). The bars were ⅝ inch in diameter and 6 inches long, and were carburized four hours at 925 degrees C. Successive layers, 0.0025 inch thick, were turned off and the carbon content of each layer determined. The surface layer contained 1.050 per cent of carbon; the twentieth layer, 0.440 per cent; and the fortieth layer, 0.205 per cent. The even gradation of the carbon content from surface to core was noteworthy.

In a test on a commercial scale, extending over twenty-nine days, test-bars one inch in diameter were carburized along with ordinary work at 900 degrees to 925 degrees C., the mixture being replenished once or twice a week to make good the inevitable waste. The bars were cooled in the pots, and the surface layer turned off and analyzed. The results follow:

New mixture	0.967 per cent carbon
End of first day	0.909 per cent carbon
End of fourth day	0.981 per cent carbon
End of twenty-ninth day	1.06 per cent carbon

The author considers 0.9 to 1.1 carbon satisfactory, and preferable to less than 0.9 per cent. The cementite does not appear to form laminæ unless the percentage of carbon is greater than 1.05; and for work that has to be ground a slight degree of supersaturation at the surface is considered necessary. Charred leather at 1000 degrees C. imparts about 1.3 per cent carbon; at 925 degrees C. about 1.2 per cent carbon; and Guillet's composition(barium carbonate, 40 per cent; wood charcoal, 60 per cent) at 925 degrees C. about 1.2 per cent.

These analyses disclose the average carbon content of the layer in question, but they do not give any evidence of uniformity. It is quite possible that a composition having large grains may produce local inequalities in the degree of carburization. To test this point, the author has employed the coloring solution, also the scleroscope and sclerometer referred to later. Even when the case on 1-inch bars of "Ubas" steel was not more than 0.012 inch deep, the color developed showed no indication whatever of local paucity of carbon. These bars were carburized in mixture made with grains of charcoal which would not pass through a sieve having five meshes per linear inch, and the bars were uniformly hard all over, even after grinding off the outside layers of the shallow case. On account of the low specific gravity of the composition and its comparative freedom from dust, oil and moisture, the heating-up period is a smaller proportion of the total time, so less judgment is

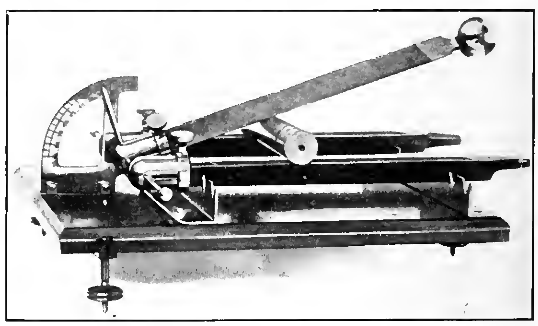

Fig. 8. Quadrant Sclerometer of Adjustable Three-file Form

required in allowing for the size of pots, etc. The productive capacity of the hardening plant and staff is correspondingly increased, and the steel too is all the better for the shorter heating.

An Improvement in Tempering

The use of hot tallow and lead for tempering is, of course, well known; but the application of an electric welder, which, the author believes, was originated by V. A. Holroyd, presents some novel and advantageous features. Fig. 6 shows an electric welder arranged for tempering casehardened articles. It is particularly useful for local softening or tempering, and, unlike tempering in tallow, the core of the article is left softer than the outside. This is especially advantageous for casehardened parts. The operation is a very quick one, and the surface is left quite clean.

Methods of Testing Hardness

So far as the author is aware, very little work has been done to provide commercial means for testing the suitability of casehardened articles. The practice of examining test-pieces carburized, heat-treated and hardened along with each batch is, of course, sound as far as it goes. The Shore scleroscope and Brinell test have their spheres of usefulness, but still the file is the instrument most used, and perhaps rightly, for it does give an idea of the resistance the surface of the article offers to abrasion under pressure, which is what most articles are casehardened to withstand. This and the Brinell test are, we believe, the instruments in commonest use for testing casehardened work and test-pieces.

Fig. 9. (A) Quadrant Sclerometer for testing Flat Surfaces (B) Quadrant Sclerometer for testing Concave Surfaces

For small articles a modified center punch is particularly suitable for rapidly getting a working idea as to whether the case is above the minimum permissible depth. An ordinary six-inch Brown & Sharpe automatic center punch is used. To the end has been fitted a screwed-on container for holding a 1/8-inch bicycle ball. The hard point has been removed and the container screwed on in its place. The ball protrudes just sufficiently to prevent the container from coming into contact with the article under test. This tool is very useful for large as well as small articles, and its readings appear to refer more to the case and less to the core than those obtained with a Brinell testing machine.

An Improved Sclerometer

On account of the variable element in testing resistance to abrasion with a file by hand, the author sought to devise means for measuring the friction under a given load. Small flat articles can be placed on the top of a file, and the hardness gaged by raising one end of the file and observing the angle when the article slides. This led to placing the article under the file so that its weight causes relative motion, which motion ceases (if not too rapid) when the frictional forces are great enough. The instrument shown in Fig. 7 is for testing round surfaces. A soft bar holds the top file up so that it makes an angle of about 70 degrees with the bottom one. A hard bar will not hold the file up until the angle falls to about 15 degrees to 20 degrees. The actual angle is indicated by figures engraved on the slotted quadrant. A hardened and tempered bar gives readings between these angles according to the degree of temper. Another form adapted to take larger articles is made with "three-cornered" files, so that the outer two can be moved further apart at will. This is shown in Fig. 8.

For concave surfaces, such as the ball races of motor-car bearings, a different type (seen at *B*, Fig. 9) is employed. The essential part of this is a short piece of round file which, with its two ends resting on the bearings, slides down one side or is deflected as the bearing is rotated. The angle taken up depends on the hardness and consequent friction, and is measured on a graduated quadrant. For flat surfaces, the instrument shown at *A*, Fig. 9, is used. A short file is mounted in a holder which slides along a smooth bar until friction arrests the motion.

That the quadrant sclerometer is very sensitive is shown by the way it detects slight degrees of tempering. Several are in regular use at both the Rudge-Whitworth Works, where they have to a large extent superseded the cruder hand test with ordinary files. They are handy and capable of dealing with large quantities of work in a short time. Instead of files, carborundum or alundum sticks or pencils may be employed, but files give very good results and last many months without showing any errors due to wear, provided they are properly made and appropriately aged before use. Various standards have been adopted for different articles, and the angle should come between the specified limits.

Production of Colors on Hardened Work

Many articles, such as cups and cones, cannot be conveniently tested with a scleroscope or sclerometer on account of their shape. Realizing the need for some method which would enable articles of all sorts to be tested in bulk, the author turned his attention to the production of colors on hardened surfaces which would afford an indication of the nature of the steel composing such surfaces. The ordinary solutions employed by the metallographer are unsuitable for commercial application; some because of their inflammability, others because they will not flow evenly over a somewhat oily or greasy surface. A suitable solution which has been found to give satisfactory results consists of alcohol, 1 liter; distilled water, 1 liter; nitric acid, pure, 100 cubic centimeters.

Articles ground or polished after hardening and immersed in this for one-quarter to one minute are stained brown or light blue where the structure is martensite; dark blue or dark grey where there is troostite; and hardly stained at all on ferrite or pearlite. By treating hardened articles in this way inequalities are rendered visible and can readily be detected. The fact that the whole of the surface is tested, and not merely the parts touched by the file, sclerometer or scleroscope is an enormous advantage for commercial purposes. The test reveals at once spots that have been splashed before quenching, also superficial tempering due to a glazed surface on the grinding wheel or to excessive pressure. It does not appear to be possible to obtain a colorimetric scale of hardness in this way, but when a number of articles are dipped at the same time, the eye readily detects those that have a different appearance and all that is then necessary is to check the odd ones with a file or sclerometer. This test is also suitable for tools and complicated articles that cannot conveniently be tested with an instrument. It also shows the depth of case if a part is left on and ground away, and should prove useful for ascertaining whether an article has been properly tempered or not.

A PLEA FOR ACCURATE PATTERNMAKING

A DISCUSSION OF THE RELATION BETWEEN THE PATTERN SHOP, FOUNDRY AND MACHINE SHOP

BY HARRY E. HARRIS*

There is probably no factor in machine shop work which causes more uncertainty than the accuracy of the work of the patternmaking department. Where only a few pieces are to be made, a little extra machine work required to correct the result of the patternmaker's lack of foresight or the molder's carelessness does not amount to much. But in the case of interchangeable manufacture on a large scale, where competition makes the price obtained for the work relatively low, it is safe to say that too great refinement in patternmaking is impossible. Proper construction of the pattern, making suitable allowances for coring, shrinkage, rapping and fitting of the core prints, are far more important factors in the cost of production than is generally realized.

The removal of fins frequently left around cored holes is quite an item of expense in the foundry and may be regarded as an indication that the cores were loose in the molds.

Machinery

Consequently, when the metal was poured, the cores shifted sufficiently to throw the cored holes off center. The result is that an excessive amount of metal must be allowed for finish so this error may be compensated for in the machining operation, and the removal of this metal often requires two or more cuts to be taken where a single cut might have sufficed. By keeping cored holes to their largest practicable diameter and as close to the central position as possible, the extra metal required and the consequent amount of work in machining is reduced to a minimum. In cases where the hole is to be used for a bearing, a further advantage is secured, owing to the fact that the metal is of much closer grain than it would be if a heavier chip was taken. This is but one instance of the observance of precautions in patternmaking which makes possible material savings in the cost of subsequent machining operations.

* Consulting Engineer, Greenfield Tap & Die Corporation, Greenfield, Mass.

In addition to the saving in machine work, a considerable economy is effected by the reduction in the amount of metal required for the castings. The writer has a case in mind where a certain lever had to have both hubs accurately finished so that they were exactly parallel to each other. This was originally done by leaving 1/16 inch of metal for finishing on each face of the hubs, the machining operation being performed expeditiously by straddle milling. Multiple fixtures were used in connection with high-speed steel cutters and one operator was able to look after three machines. Each of the machines was equipped with two fixtures which were arranged one on each side of the cutter arbor. Thus all three machines were cutting practically continuously, as it was possible for the finished work to be replaced by rough castings in one of the fixtures while the cutters were working on the four levers held in the fixture at the opposite end of the table.

By changing the pattern so that the amount of material to be removed in machining was greatly reduced, it was found possible to finish the faces of these hubs on a double-head disk grinder, and in six months' time the saving of metal and labor effected by this change was sufficient to pay for the new machine. The cost of manufacturing was not only reduced, but the quality of the work produced was better than that which it had been possible to secure by milling. The operator of the grinding machine could remove the few thousandths left on the faces of the hubs almost as fast as he could put the work between the disks and lay it down again. The laborious clamping, cost of cutter up-keep, and trouble with the cutters due to hard scale on the work was eliminated. It was merely necessary for the operator to put fresh abrasive disks on the wheels of his machine every night before going home; this required about fifteen minutes, while the changing of the disks during the day took approximately twenty minutes. In order to secure these advantages, it was necessary for the pattern to be accurately made with proper allowance for rapping and shrinkage. It was also necessary to insist upon good work from the molders. This was obtained by furnishing the foundry with an inexpensive snap gage for testing the castings. These castings were tested again when they reached the machine shop, and any of them which did not check up to the gage were returned and not paid for.

There are many other instances where the ends of hubs and other small surfaces on castings can be economically finished on the disk or surface grinding machine, if the allowance for finishing is reduced to a minimum. This means the saving of a great deal of time which would otherwise be required for planing, milling or facing such parts. The difficulty which lies in the way of taking advantage of these economies is not physical but rather psychological, owing to the fact that the molder does not know much about the use of gages or accurate work until the necessity for it is explained to him. When he once thoroughly grasps the idea, however, that he is to be supplied with accurate patterns and that he can do good work just as quickly as he formerly did inaccurate work, he will be glad to cooperate, particularly when it is explained to him that it will no longer be necessary to file cores and retouch patterns in order to obtain a good job. On the other hand, the demand for good patternmakers who really understand their business far exceeds the supply.

It is usually the case that half the work of the metal patternmaker in the average shop consists of changing the patterns after a run of castings has been made from them, in order to correct slight defects that the molder has managed to develop in the majority of the castings. After the patternmaker has added a little metal at this spot, removed some at other places and bent the pattern a little at certain points, he and his foreman feel satisfied that it is correct. It is more than likely, however, that the next run of castings will show errors, and if such is the case the patternmaker will undoubtedly get the blame. Although it is quite possible that he is not responsible for the error in the castings, he is to blame for not knowing enough about foundry work to know how these errors were developed in castings made from pat-

terns that he knew were accurate. It is quite possible by proper cooperation between the foundry and machine shop, and between the molder and the patternmaker to secure results in the way of economy that should not be overlooked by the management of any progressive plant. It is not claimed that it is always possible to make a pattern the first time so that the castings will leave nothing to be desired; but any necessary changes and corrections should be accurately and intelligently made after conducting a careful study of the conditions which necessitate such modifications.

The writer has intimate knowledge of conditions in a certain firm engaged in the manufacture of relatively small parts, where all allowances and dimensions are figured out by the engineering department, after it had conducted a careful investigation. For instance, with fine sand for light work it was found that the minimum fillet to be allowed on any inside corner must be at least 0.020 inch. A coarser sand would naturally require a larger fillet and *vice versa.* Sharp corners had to be rounded to a corresponding degree. The observance of these directions was found to aid the molders to produce good clean molds. In order to prevent the formation of fins, it was necessary for the cores to be an accurate fit in the core prints in the mold. A print on the pattern made the same size as the core box would not give this result, as the rapping of the pattern and the shrinkage of the cores would be responsible for a serious inaccuracy. To illustrate, it was found that a core print 1 inch in diameter on the pattern enlarged the print in the mold approximately 0.012 inch, due to rapping; and that when the cores were baked, they shrunk 0.008 inch. Thus it is obvious that the metal core box should be made 0.008 inch larger than the desired size of the cored hole, and that the prints on the patterns should be 0.012 inch smaller. Where the print joins the body of the pattern, a 0.020 inch fillet should be provided. Patterns were made according to these specifications and the molders were very much pleased after they had used them.

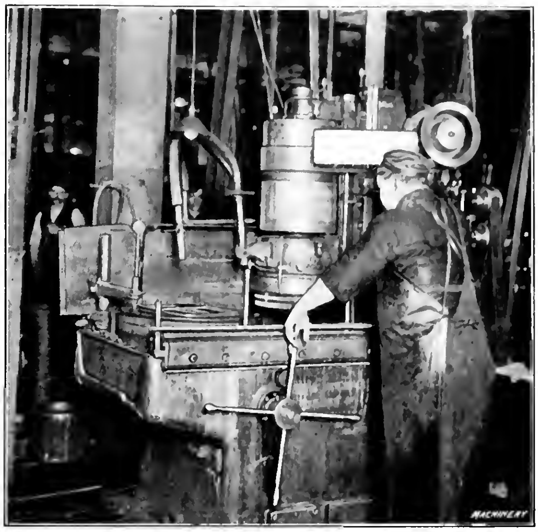
As this method was used on all of the regular manufacturing work done by this company, there was a good deal of calculation to be performed to determine the shrinkage in different cases. To simplify this work, a table of shrinkages was figured out. This table is the means of saving a great deal of mathematical work in determining shrinkage to 0.0001 inch, and it is also the means of avoiding errors in calculation. It is presented herewith in the hope that it may be of value to other readers of MACHINERY. As metal patterns become more generally used, it is possible that micrometers and vernier scales giving readings of over-size dimensions may be developed which are made for use as shrink rules. In this way, dimensions could be taken direct from the work or drawing, instead of requiring to be re-figured to provide for shrinkage.

By way of conclusion, it may not be out of place to say a few words in regard to the composition of metal patterns and core boxes. A long series of experiments in the foundry of the company previously referred to, showed that the cast-iron patterns and core boxes which have rusted on the surface and been subsequently treated with beeswax, were capable of producing the greatest number of castings with the minimum amount of trouble. Brass and white metal patterns and core boxes appeared to get greasy and sticky, and a further disadvantage was due to the fact that they were heavier and more easily bent. Experience has also shown that they are not so easily withdrawn from a sand mold. The chief advantage of brass for use in making metal patterns is the ease with which an error can be corrected or changes made by adding solder patches. White metal is inexpensive and patterns may be quickly made from it for handling "hurry jobs;" but neither of these metals is as durable as iron or steel. They lose their shape and accuracy quite quickly, due to the abrasive action of the sand, and many cases are on record where large quantities of castings have had to be discarded because they were under size, the cause being finally traced to the wear developed in brass or white metal patterns. If properly rusted and waxed, however, cast-iron patterns will last almost forever. They should be re-waxed occasionally, this being done by simply warming them, rubbing the wax over the surface and then rubbing the surface off before the patterns get cold, in order to remove the excess wax.

* * *

HOLDING COPPER ON A MAGNETIC CHUCK

We all know that copper is not magnetic and could not ordinarily be held on a magnetic chuck. Yet in the accompanying illustration is shown the method that the Pierce-Arrow Motor Car Co. of Buffalo, N. Y., employs in holding copper pans on the magnetic chuck of a vertical surface grinder. The grinding operation on the pans consists in facing off the upturned edges to the finished height. The



Grinding Copper Radiator Ends on a Blanchard Grinder

metal of the pans is about 1/16 inch thick, and the flange is turned up for a distance of approximately ½ inch. Therefore, in order to hold these pans to the magnetic chuck, steel plates are placed inside the pan, through which the magnetic chuck acts, pulling the blocks and consequently the pan down to the chuck. This is a good method of holding these pieces and the grinding operation is performed without difficulty. C. L. L.

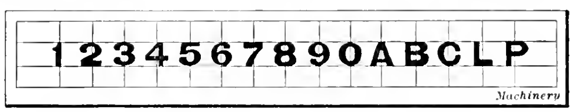
METHOD OF NUMBERING DRAWINGS

The accompanying illustration shows a method for rapidly placing the drawing numbers on drawings. A small slip of tracing cloth is provided with figures and letters as shown. When the drawing number and symbols for a drawing are to



Figures and Letters on Piece of Tracing Cloth used as a Guide in placing Numbers on Drawings

be printed on it, it is only necessary to slip this piece of tracing cloth underneath the tracing, and copy off the required letters and figures free-hand. In the case shown, only five letters were used in addition to figures to designate the drawing numbers. The whole alphabet, of course, could be treated in the same manner. The vertical and horizontal lines drawn help to locate the piece of tracing cloth in the right position beneath the tracing when numbers consisting of several figures are to be printed.

An endowment of $2000 has been received by the American Society of Mechanical Engineers from Henry Hess, one of its members, the income from which is to be used for prizes for technical papers prepared by junior and student members.

LOBDELL CALENDER ROLL GRINDING MACHINE

DETAILS OF AN INGENIOUS FORM GRINDING MECHANISM USED IN CROWNING THE TOP AND BOTTOM ROLLS OF A SET

The manufacture of paper requires some of the most ponderous and costly machinery used in any line of manufacture. A continuous paper-making machine of the Fourdrinier type is perhaps 80 to 90 feet long, beginning at the breast box, from which the pulp is deposited on the endless wire screen belt, and ending with the finished roll of paper. The machine is divided into two parts known as the wet and dry ends, respectively. The wet end includes the stuff box, sand table, strainer, breast box, deckel straps, dandy roll, couch rolls, endless felt belts, first-press rolls and second-press rolls. The dry end, as the name implies, dries the wet paper web by passing it over massive drying cylinders, thence to the nip rolls and over more drying cylinders, and finally to the calender rolls which give it uniform thickness, hardness and surface finish.

The great size and weight of the calender rolls, of which there may be two or three stacks, are astonishing to one unfamiliar with paper making. The illustration Fig. 1 shows a stack composed of twelve rolls, the total weight of which is over 40,000 pounds. This stack is a baby, however, compared to some that have been made. Rolls 200 inches long and 30 inches in diameter have been made for some of the largest paper-making machines. Now, when it is taken into account that these rolls must be as hard as the traditional "hub of Hades" and perfectly round and highly polished, the problem of production seems sufficiently difficult, but when, in addition, it is considered that the bottom and top rolls have to be ground large in the middle, tapering to the ends, in order to compensate for deflection, the problem becomes still more difficult. But like many other tasks which appear very difficult to the layman, it is handled with precision and certainty in several plants in the United States that make a specialty of grinding calender rolls.

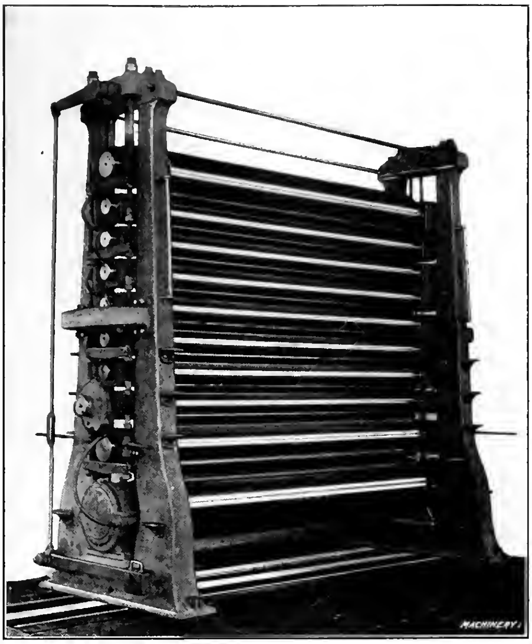

Fig. 1. Stack of Twelve Ground Paper Calender Rolls

The Lobdell roll grinding machine of the electrically-driven type, made by the Lobdell Car Wheel Co., Wilmington, Del., is shown in Fig. 2. This machine is built in three sizes, the smallest having capacity for rolls up to 18 inches diameter, and the largest, for rolls up to 30 inches diameter. The length of calender rolls varies, a not uncommon length being about 100 inches. Some of the rolls are hollow for steam coils, but as many are solid castings it is evident that the machine must be of massive construction to support the great weight of the roll. The largest size machine has a bed 23 feet 6 inches long and weighs 30,000 pounds.

The rolls are supported on their journals by V-blocks which are adjustable on the bed for various lengths. The V-blocks have been found best for this work, inasmuch as the journal automatically centers itself and requires no lateral adjustment. Two grinding wheels are provided, one on each side of the roll. The wheels are each driven by two belts. The spindle bearings are a plain taper and are supported in phosphor-bronze bearings, a construction peculiar to the Lobdell roll grinding machine and the result of many years' experience with this peculiar type of grinding. Calender rolls must be ground with great accuracy and to the utmost smoothness, and the metal is dense chilled cast iron. The grinding wheels are mounted on a carriage, and in the case of the motor-driven machine the carriage also carries the motors overhead. In the case of the belt-driven machines, two overhead drums are provided of a length equal to the longest traverse required.

The grinding wheels are mounted on opposite sides of the roll and the thrusts of the wheels against the roll are bal-

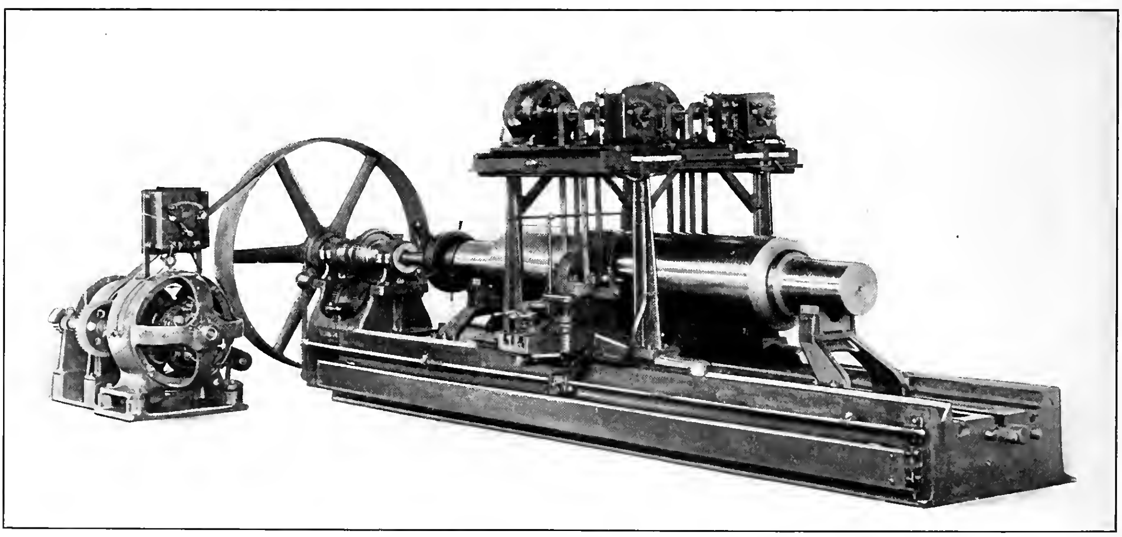

Fig. 2. Lobdell electrically driven Roll Grinding Machine

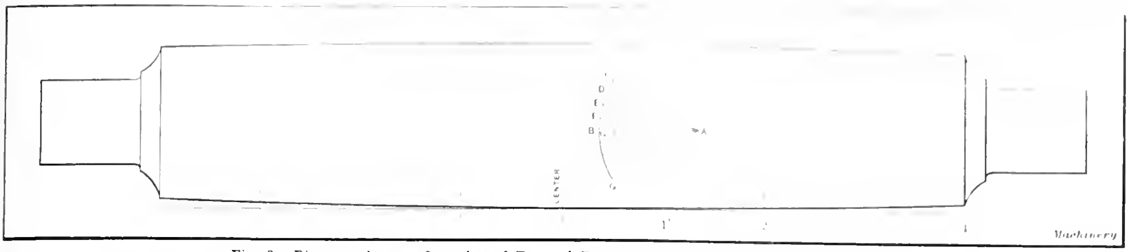

Fig. 3. Diagram showing Crowning of Top and Bottom Rolls to compensate for Deflection

anced. The wheels are comparatively narrow, the usual width being about 1½ inch, and the feed of the carriage is somewhat less than the wheel width, of course, as is usual in all cylindrical grinding operations. The roll is flooded during grinding.

As will be noted in Fig. 1, a stack of calender rolls is erected so that the entire weight is carried on the bottom roll. Besides this, additional load is imposed by weights acting through a system of multiplying levers. The effect of the superimposed load, which may amount to 50,000 pounds, is to deflect both the top and the bottom rolls an appreciable amount. To compensate for this deflection, both the top and the bottom rolls must be ground with a "crown," that is, larger in the center than at the ends. The amount of crown varies with the diameter and length of roll, being 0.010 inch in the case of 16-inch rolls, 116 inches long.

It is evident that an ordinary former or guide for producing the crown is open to several objections. The crown is so small that it would be difficult to make a long guide with the required amount accurately apportioned to each foot of

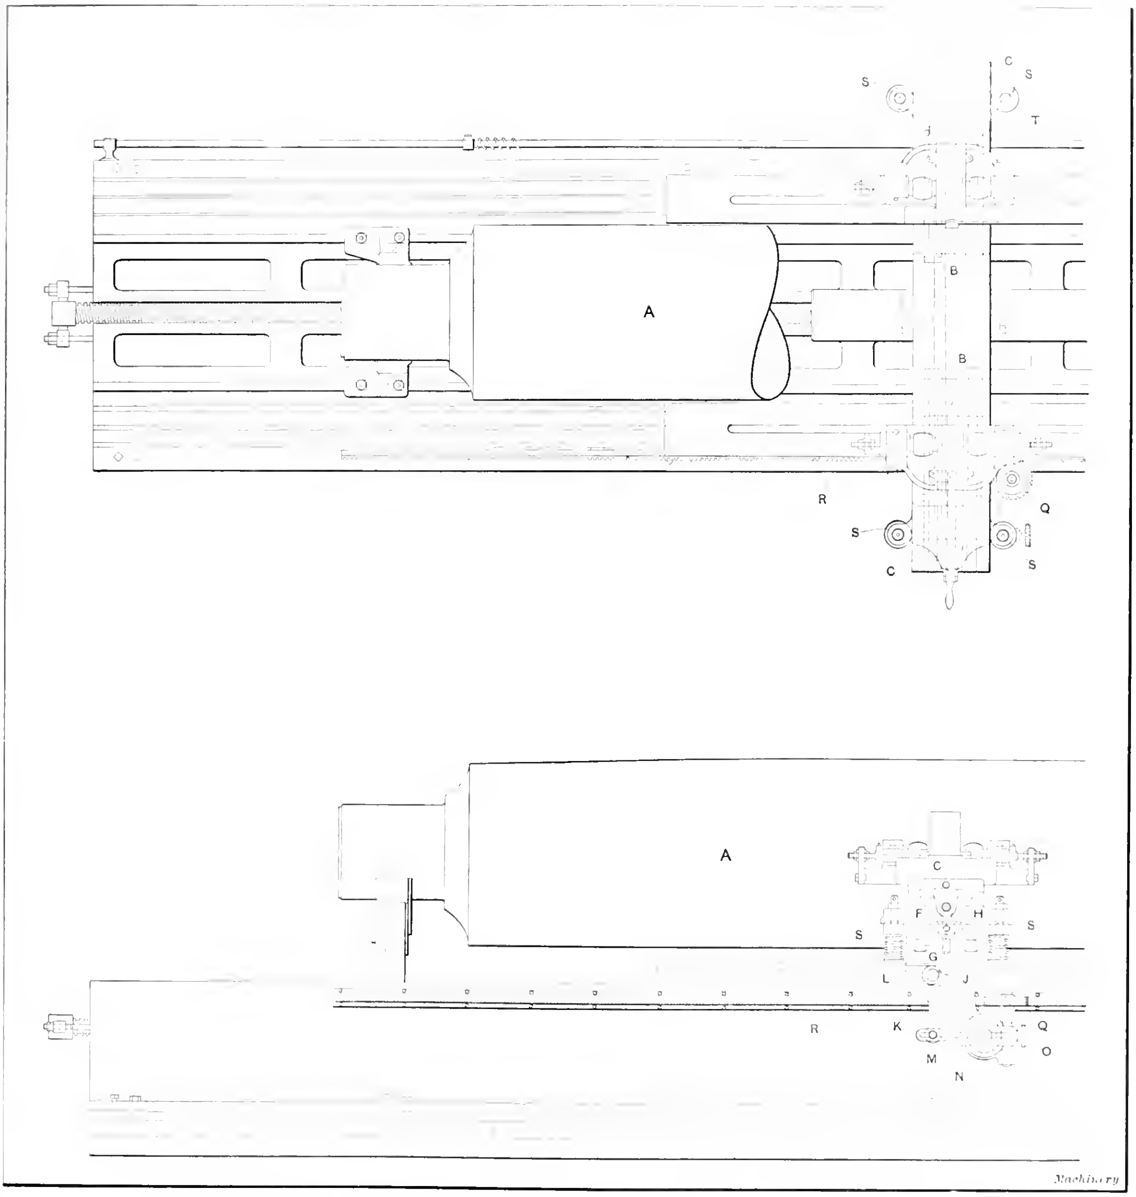

Fig. 4. Plan and Elevation of Lobdell Roll Grinding Machine showing Construction of Carriage and Crowning Device

its length. (See Fig. 3.) The crown being so small, the wear of the guide shoes and deflections would tend to destroy its accuracy. Another objection is that either a large number of formers or guides must be provided or means for changing the shape of the guide by set-screws. The latter are objectionable because of the practical impossibility of making the crown uniform. When these difficulties are understood, the fine points of the Lobdell crowning device will be better appreciated.

The construction of the roll crowning device is shown in Figs. 4 and 5. The roll *A* is mounted by the ends in V-blocks and is ground by the opposite wheels *B*. The wheels are given a slight in-and-out movement which makes the roll of the shape indicated in Fig. 3, the movement being controlled by the mechanism about to be described.

The rack *R* is bolted to the front of the bed, and engages with a pinion *Q*. This pinion carries a worm which drives the worm-wheel *N*. On the worm-wheel is a crankpin whose throw is adjustable by means of a screw *O*. The crankpin is connected to the lever *K* by connecting-rod *M*. The lever *K* is mounted on a transverse shaft *L* extending across the bed under the carriage bridge. At each end are two short horizontal levers mounted on *L* on which rest vertical pins *J*, which, in turn, support a bar *G*.

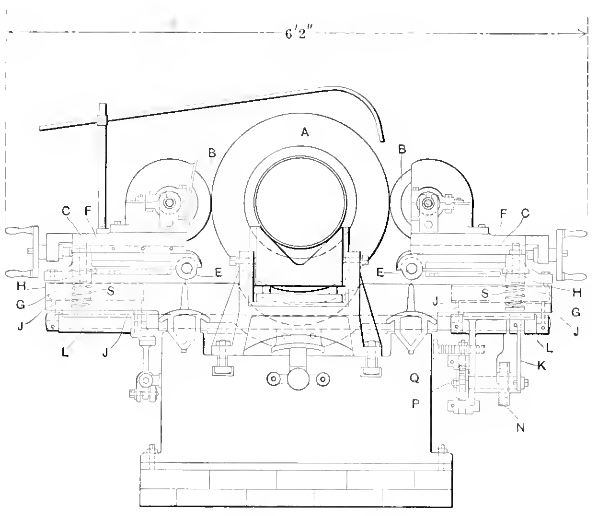

Fig. 5. End View of Lobdell Roll Grinding Machine showing Carriage Construction

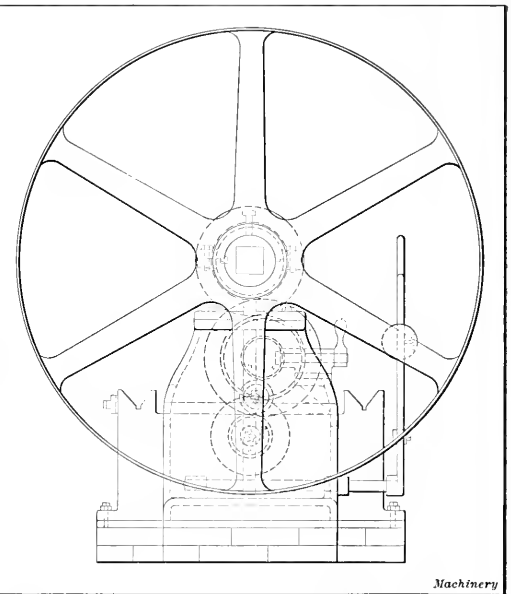

Fig. 6. End View of Lobdell Roll Grinding Machine showing Driving Gear for Roll and Carriage

The function of this train of mechanism is to raise and lower the grinding wheel heads on the pivots *E* and to provide means for making the angular movement the same for a given adjustment for any diameter of roll within the capacity of the machine. The point of contact between the bars *G* and the grinding wheel cross-slide heads is at *H*. It is evident that the rise and fall will be the same for a given adjustment no matter at what point *H* contacts with *G*. The wheel slides have two lateral adjustments, one being by means of the screw and handle which moves the top slide on which the wheel is mounted and a lower slide, the base of which is bolted to the carriage but provided with tee-slots for changing the position laterally. The springs *S* are provided to take up the slack in the mechanism and insure the movement of the wheels in the crowning operation following exactly the curve determined by the design of the mechanism.

The operator is provided with a table of roll lengths, diameters, crowns and crankpin adjustments, from which he can read the adjustment necessary for screw *O* to control the position of the crankpin on worm-wheel *N*. The amount of calender or crown has been carefully determined for all lengths and diameters of calender rolls within commercial limits. For example, 0.010 inch crown is given to a 16-inch roll, 116 inches long. The adjustment required for the crankpin is 0.339 inch eccentricity, that is, it is set to swing in a circle of 0.678 inch diameter. The crown produced is a true arc of a circle in the direction of its length, this fact being indicated by the small diagram within the outline of the roll, Fig. 3.

The carriage is traversed by a square feed-screw which bears throughout its entire length in a groove in the bed. The groove is planed accurately to shape in order to form a solid support throughout the length. A half-nut of phosphor-bronze is engaged with the screw. The screw is reversed at the end of the travel by a feed-rod *T* having adjustable collars which shift the reversing gears into engagement.

BLUEPRINT MARKING FLUID

A very useful and absolutely permanent marking fluid for writing in white on blueprints, may be made by taking a little soda ash and making a saturated water solution. This may be done as follows: Take a small bottle and nearly fill it with water; then add the soda ash, shaking the bottle from time to time, until the water will not dissolve any more of the crystals. Next strain the solution to remove the undissolved crystals and any dirt which may be present, and then pour it back into the bottle ready for use. This may be kept indefinitely.

This solution may be applied to the blueprint with either a drawing pen or ordinary writing pen. It works equally well in either case. Where the liquid is applied it bleaches the blue color of the print and leaves it a clear white. It sometimes happens that if the solution has been made too strong, a white powder forms on the lines when they are dry, but this may be brushed off. In such cases, if a little water is added to the bleaching solution there will not be any difficulty of this kind the next time it is used.

If soda ash is not available, an efficient substitute can be prepared by using common baking soda. In this case, however, the lines are not quite so clear and sharp as those produced with the solution of soda ash. If it is desired to make colored lines, a preparation for this purpose may be made by adding ink to a solution prepared according to the preceding instructions. When this is done, the solution bleaches the blueprints so that the colored ink shows up well.

SCREW MACHINE TOOL EQUIPMENT—2

STANDARD TYPE OF TOOLS USED ON THE CLEVELAND AUTOMATIC SCREW MACHINE

BY DOUGLAS T. HAMILTON*

In the following various types of counterbore, boring tool and reamer holders, together with box-tools for straight and taper turning, will be described.

Standard Adjustable Counterbore, Boring and Recessing Tool-holders

A counterbore holder of the adjustable type is shown at *A* in Fig. 8. The front holder or plate *a* is bolted firmly to the shank *b*, and is adjusted by means of four set-screws *c*, only two of which are shown. This holder is made adjustable in order to set the cutting tool perfectly concentric with the hole in the work.

A somewhat similar type of holder is shown at *B*, but in this case it is used for retaining a boring tool. The front part of this tool is adjustable only by means of two set-screws *d*, which work through the shank of the clamping bolt *e*, and in this way secure the desired adjustment to set the boring tool concentric or to the correct diameter. *C* shows a standard type of recessing tool for use in enlarging a hole back from the end. It comprises a shank *f*, to which is fulcrumed a holder *g* on a stud *h*. This tool is operated by means of a cam *i* held in an arm *j* that is clamped to the cross-slide of the machine. Cam *i* comes in contact with the pin *k* on the holder and operates it after the tool has advanced into the hole in the work. A stud in the sliding part of this holder is spring-controlled and contacts with the screw *k* which acts as a stop for setting the cutting tool in a concentric position to enter the hole in the work.

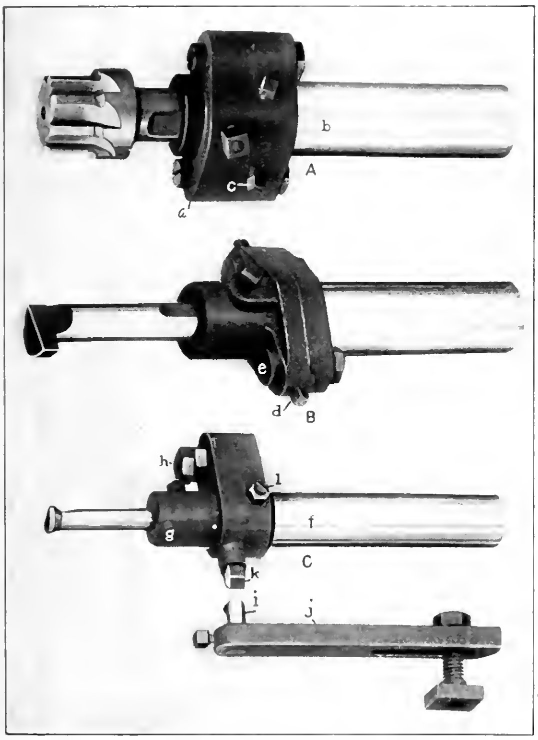

Fig. 8. Standard Adjustable Counterbore Boring and Recessing Tool-holders

High-speed Drill, Boring and Reaming Tool-holders

A high-speed drill-holder that can be used on the larger sizes of machines for increasing the speed of small drills in the turret is shown in Fig. 9. The revolving spindle *a* is mounted in two bronze bearings with the driving gear *b* shown at *B*. The thrust is taken on the ball bearing *c* shown at *C*. The drill chuck *d* is of the spring collet type. The shank *e* is ground to fit the tool hole in the turret and the rear end of this shank is a reservoir for oil which lubricates all the bearings in the holder. Sufficient oil should be put in at the point *f* to completely fill the reservoir. For holding small reamers the spindle *a* is especially constructed to receive a floating type of reamer-holder instead of the drill-holder shown. This holder is driven by a shaft running through the turret shaft and a small pulley belted to the overhead works.

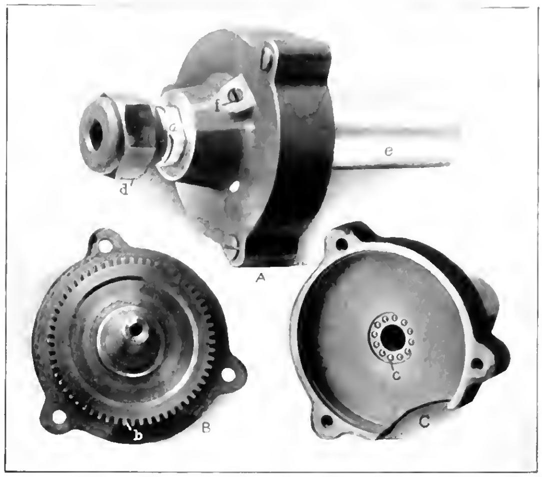

Fig. 9. High-speed Drill-holder

The holder just described is also made up to use with a boring tool and it is shown fitted up in this manner in Fig. 10. In this case the front end of the holder comprises a chuck *a* which is dovetailed to the front part of the holder and is held in position by two studs on which nuts, as illustrated, are fastened. The boring tool is held in this holder by means of a hollow hexagon set-screw. This tool enables boring to be accomplished at a high rate of speed and also gives sufficient adjustment so that the boring tool can be set to bore accurately to size. It is especially adapted for driving small boring tools at a high rate of speed when all the other tools in the turret are larger and require a slow spindle speed for the work.

Roller Steadyrest, Shaving and Roughing Box-tools

A simple steadyrest of the roller support type is shown at *A* in Fig. 11. The roller supports *a* are held in slides *b* which are adjusted by means of screws *c*. The slides are then clamped in the desired position by means of the clamp bolts *d*. A simple type of shaving box-tool is shown at *B* in Fig. 11. This tool is provided with V-supports as illustrated, which are adjusted by the collar-head screw *e* and are clamped in position by means of the clamp bolts *f*. The turning tool *g* is adjusted by a collar-head screw *h* and is held in position by a set-screw *i*. This tool is of very simple construction and is used where only one diameter is to be turned at a time.

C in Fig. 11 shows the standard roughing box-tool. This tool is provided with roller supports which are held and operated in a similar manner to that shown at *A* in Fig. 11, and the turning tool *j* is held in a square hole provided in the stud *k*; this stud clamps the turning tool against the face of the box-tool holder. Adjustment for height is secured by means of the set-screw *l*. Two set-screws, one shown at *m*, act as an adjustment for stud *k*.

The type of box-tool shown at *A* in Fig. 12 accommodates three turning tools, and can also carry a centering tool or drill, which is held in the shank of the holder. The flat arm or member *a* of this box-tool has two splines cut in its face

* Associate Editor of MACHINERY.

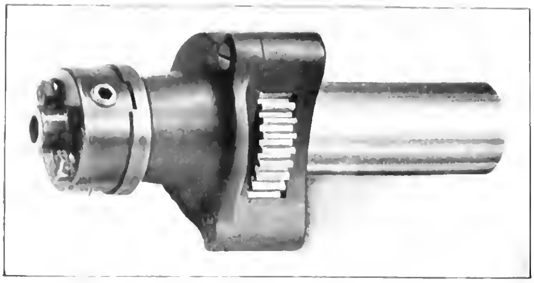

Fig. 10. High-speed Adjustable Boring Tool

the full length, in one of which the three holders *b* for the cutting tools are held, and in the other two the brackets *c* for roller supports. The roller supports are held in the same manner as previously described. This box-tool can be used for turning three different diameters at one setting and is used for roughing or finishing purposes. The roller supports may be adjusted to lead or follow the cutting tools by simply moving them along the slot in the holder. The brackets carrying the supports can be placed in any desired position and the holders for the cutting tools can also be adjusted to suit the various diameters and lengths of shoulders on the work.

An adjustable type of roughing hollow mill is shown at *B* in Fig. 12. This is supplied with four cutters *d* which are

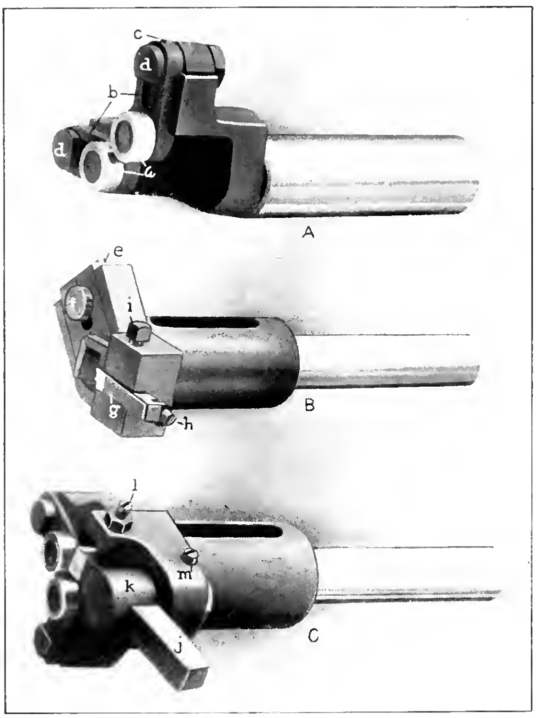

Fig. 11. Roller Steadyrest, Shaving and Roughing Box-tools

adjusted as shown. The flat arm *e* of the box-tool has a spline cut the full length, and also a slot through which the studs enter. The studs are made integral with the cutter-heads and are clamped by nuts as shown. The four cutters in the head are adjusted by removing the head from the arm and placing it on a stand fitted with a plug gage of the same diameter as the work to be turned. This stand holds the cutter-head in the correct relation to the plug gage so that the tools can be brought into contact with the plug gage and then clamped. This tool is also supplied with a hole in the shank for holding a centering tool or drill. The heads for the cutters are adjustable along the body of the holder.

Another type of box-tool is shown at *C* in Fig. 12. This is of open-type construction and is supplied with one turning tool clamped to its face as illustrated, the work being supported at this point by roller supports. The second tool, which is set at an angle and held down by a heel clamp, can be used for turning a second diameter on the work; the work is supported with V-supports held in the projection of the holder as illustrated. This tool-holder is of simple construction and embodies the general principles incorporated in the other holders previously described.

Taper Turning Box-tools

The taper turning box-tool shown in Fig. 13 is held by a shank in the turret of the machine and is supplied with a bushing on the front end which guides the work. The

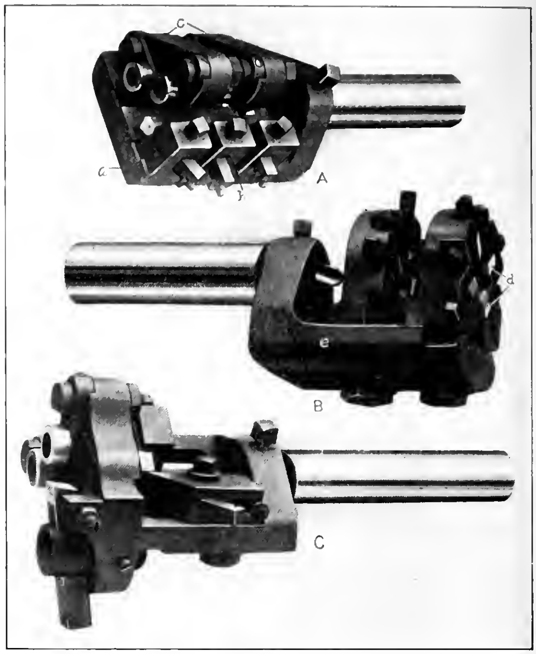

Fig. 12. Multiple Turning Tool, Adjustable Hollow Mill and Standard Three-tool Box-mill

circular slide *A* carries the turning tool *B* and is fitted with a pin *C* which comes in contact with the adjustable guide *D* held on the cross-slide. When the turning operation is completed, the cross-slide recedes, allowing a spring located inside the holder to move the slide *A* back to its original position. The guide *D* held on the holder *E* which is attached to the cross-slide can be made of any shape so that any irregular form as well as tapered work can be secured. This guide is fulcrumed on a pin in the bracket and is supported and adjusted by two set-screws as illustrated.

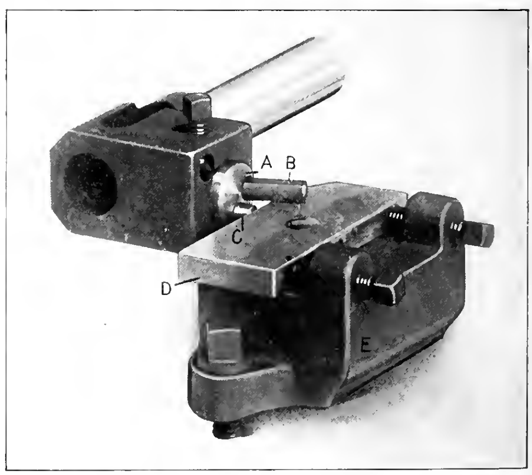

Fig. 13. Turning Tool for Taper or Irregular Shapes

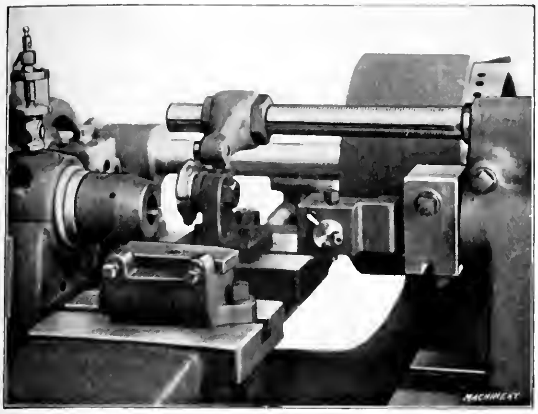

Fig. 14. Illustration showing Application of Taper Turning Tool presented in Fig. 13

Fig. 14 shows how this taper turning box-tool is operated. Here it can be seen that the guide is fastened to the cross-slide of the machine. The taper turning tool in this case, however, is held in the spindle of the plain type of machine, not the turret type.

The peripheral speeds in feet per minute recommended for box-tools and external cutting tools, in general, when provided with high-speed cutters, are as follows:

Brass	180—250
Cold-rolled Steel	120—150
Tool Steel	50— 60

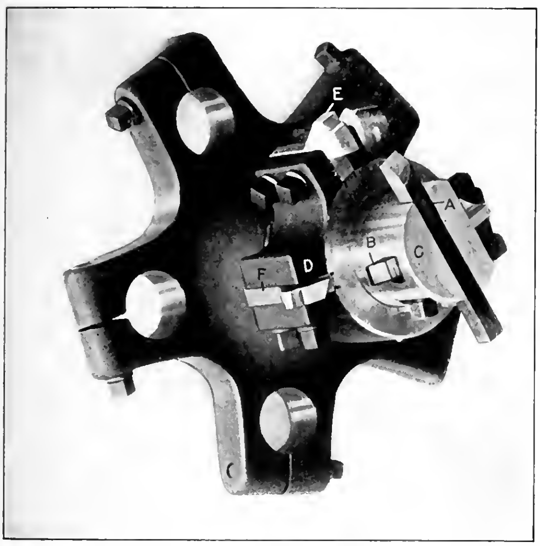

Fig. 15. Overhanging Turning Attachment with Extra Cutter-head

Overhanging Turning Attachment

The turning attachment shown in Fig. 15 is attached to the face of the turret by a clamp which surrounds the shanks of the turret tools. This attachment is put in position before any of the other tools in the turret so that the shanks of the other tools can pass through the holes in the five arms of the holder. The various arms, which are split, are then clamped by the set-screws shown. This type of tool can be used for performing a multiplicity of operations. In this particular case it is set up with roughing and finishing tools. The roughing tool *A* and the finishing tool *B* are mounted in the stem *C*. Also an extra cutter-head *D* is supplied with cutters *E* and *F* for rough- and finish-counterboring. The cutter-head can be adjusted longitudinally so that any desired relation can be obtained between the cutter *A* and the cutters in the cutter-head *D*. Attachments of this type are particularly adapted for over turning in connection with flat forming tools, and for this work it is sometimes necessary to have the shank much longer than is shown in the illustration. This part is therefore made according to the requirements

Die- and Tap-holders

The types of die- and tap-holders used in the Cleveland automatics do not differ from those on any other type of automatic screw machine; two representative types are shown in Fig. 17. That at *A* is a releasing button die-holder, while that shown at *B* is a releasing tap- or die-holder. The tap-holder, of course, is provided with bushings for holding taps having shanks of different diameters. As a rule, automatic opening dies are used on Cleveland automatics, but spring or button dies of the type shown at *C* and *D* can be used to good advantage, especially on brass work.

Adjustable Knurling Tool-holders

At *C* in Fig. 2 is shown a knurling tool-holder that can be used on the cross-slide for knurling thumb-screws or for straight knurling. It cannot, however, be used for longitudinal knurling. This knurling tool-holder consists simply of a base carrying an arm fulcrumed on a pin. Adjustment for height is secured by the set-screw *c* and the knurl is held

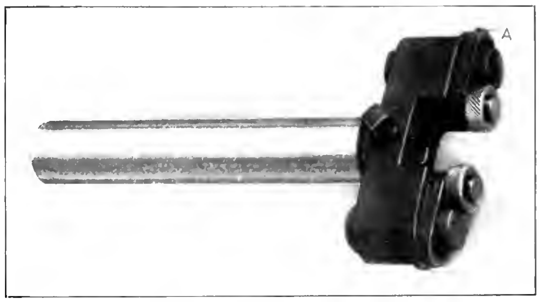

Fig. 16. Adjustable Knurling Tool used in the Turret for Spiral or Diamond Knurling

on a stud by a nut, the stud passing through the arm as illustrated.

A knurling tool-holder which can be used for diamond or straight knurling is shown in Fig. 16. This holder is carried in the turret and is provided with two adjustable knurling holders that are held in a groove in the face of the shank by a stud and nut as shown. Adjustment is secured by means of the headless screws *A*. The knurls are held on plain studs which are driven into the adjusting members and held from turning by the small set-screws shown. This type of holder is used exclusively for knurling longitudinally.

* * *

It may be a surprise to many to know that there are in the United States not less than 37,000 electric vehicles in use. Of these nearly 3000 are registered in Chicago, 2000 in New York, and 1800 in Cleveland.

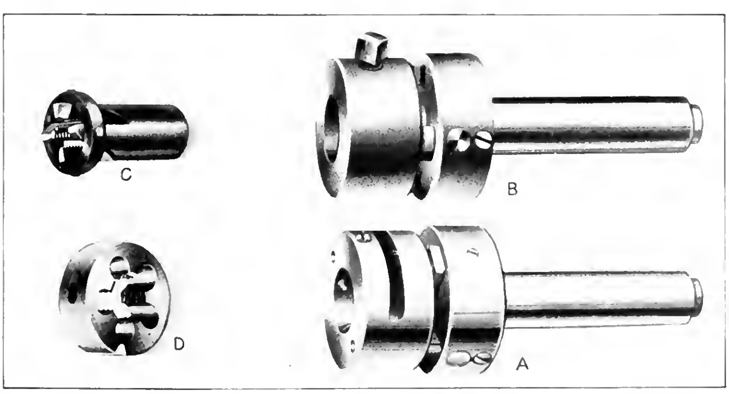

Fig. 17. Releasing Tap- and Die-holders

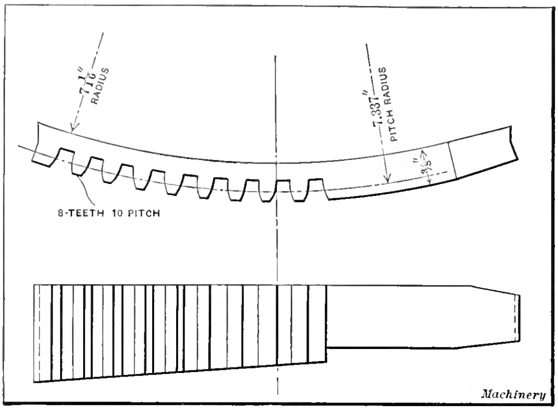
INDEXING MOVEMENTS FOR SMALL ANGLES ON MILLING MACHINE

BY P. J. RYAN*

Ordinarily, it is assumed that the only method for exactly indexing small angles is by moving the indexing pin one hole in the 27-hole circle, which gives an indexing movement of 20 minutes, or one hole in the 18-hole circle, which gives an indexing movement of 30 minutes. However, the writer has used a very simple method for a number of years which makes it possible to index angles accurately to 1 minute. This consists of using the rear pin which is a part of every dividing head, and which is used for holding the index plate in a fixed position while indexing in the usual way. This pin may also be used to index in an opposite direction to that of the regular indexing-arm pin, in a different circle, or to index in the same direction, thus adding to or subtracting from the movement made by the indexing-arm pin.

The method is very simple. For instance, if we use the plate with the 20-hole circle on the outside, the back pin will be in the 20-hole circle and the regular indexing pin may be



Circular Rack on which Method No. 3 is used for spacing the Teeth

placed in the 18-hole circle; by simply withdrawing the rear pin from the 20-hole circle and turning the plate backward or counter-clockwise one hole, and again inserting the pin, and then withdrawing the regular indexing pin from the 18-hole circle and moving it one hole in the 18-hole circle clockwise, we will have moved the work through an arc of exactly three minutes, and can, therefore, index any angle within a maximum error of 1½ minute. In this way, any part of an angle greater than 30 minutes may be indexed by first moving one hole in the 18-hole circle for each 30 minutes and then indexing the remainder within 1½ minute by moving one hole backward in the 20-hole circle and one hole forward in the 18-hole circle for every three minutes.

A still more accurate result may be obtained by placing the plate having the 27-hole circle on the outside of the 20-hole plate and pinning the two together through any two holes which happen to come opposite each other. This is equivalent to having a plate with both a 20- and a 27-hole circle. With this arrangement an exact movement of 1 minute may be had by moving the pins three holes in the 20-hole circle in a clockwise direction and then the regular index-arm pin four holes in the 27-hole circle in a counter-clockwise direction. This gives a movement to the dividing head of 1 minute in a clockwise direction, so that all angles may be thus indexed with an error which cannot exceed 30 seconds.

Table I shows the two methods outlined above for angles less than 30 or 20 minutes, respectively. It is not necessary

Machinery

*Clockwise movements in these cases

to show figures for any greater angle than 30 minutes by method No. 1 or 20 minutes by method No. 2, as any angle greater than these may be indexed directly either in the 18-hole or 27-hole circles by well-known methods. (These methods are explained in MACHINERY'S Reference Book No. 18, "Shop Arithmetic for the Machinist," and in MACHINERY'S HANDBOOK, pages 935 to 937, inclusive.)

When it is possible to use the No. 1 method, it should be employed because of its simplicity, provided a degree of accuracy within 1½ minute is sufficient. For all ordinary work, this is the case. If a greater degree of accuracy is desired, the No. 2 method should be employed. As an example of the No. 2 method, assume that it is required to index for an angle of 39 degrees 56 minutes. First index by the usual methods, as referred to above, 39 degrees and 40 minutes by direct indexing in the 27-hole circle; the movement in this case would be four complete turns, and then 11 holes in the 27-hole circle. Next index for 16 minutes by moving the back pin 8 holes in the 20-hole circle in a clockwise direction, and then moving the indexing-arm pin 10 holes in the 27-hole circle in a counter-clockwise direction. This will give a total movement of the work of 39 degrees 56 minutes.

Table II gives the movements necessary for method No. 3, which enables smaller angles to be indexed than are obtained by either of the preceding methods. While this table is arranged for indexing angles, it can also be used to obtain any number of divisions or fractions of a division by simply dividing the number of seconds in a circle, *i. e.*, 1,296,000, by the required number of divisions, the quotient being the required angle to index for expressed in seconds. The maximum error of the result obtained in this way never exceeds 7½ seconds.

This method consists of using two index plates as in the case of method No. 2, but an additional movement is obtained by moving the outside plate in its relation with the inside plate, by means of the small plug in the 16-hole circle, which is employed in method No. 2 to lock the plates together. The illustration shows a piece of work which we recently handled by this method. It was necessary to cut 10-pitch teeth on a circular rack or segment which was to operate in a slot 14.875 inches outside diameter. On this diameter we would have had to index for 146.75 teeth if the teeth had been accurately cut. Converting this result to an angular movement, it is found that it would be necessary to index through an angle of $1,296,000 \div 146.75 = 8835.8$ seconds $= 2$ degrees, 27 minutes, 15.8 seconds for each tooth.

The larger part of this angle, *i. e.*, 2 degrees 20 minutes, was first indexed directly in the 27-hole circle, by moving through seven holes in a clockwise direction. This leaves an angle of 7 minutes 15.8 seconds to be indexed. The necessary movement can be obtained from Table II and a result secured which is within 0.8 second of accurate. The necessary movement for this angle of 7 minutes 15 seconds is first, 7 holes counter-clockwise in the 20-hole circle; second, 2 holes counter-clockwise in the 27-hole circle; third, 7 holes clockwise in the 16-hole circle. Canceling the opposite movements in the 27-hole circle we find that the resulting movement necessary to obtain an angle of 2 degrees 27 minutes and 15 seconds is first, 7 holes counter-clockwise in the 20-hole circle; second, 5 holes clockwise in the 27-hole circle; third, 7 holes clockwise in the 16-hole circle. The error should never exceed 7½ seconds, as when this error occurs it is only necessary to index for 15 seconds and wait for the error to accumulate again. This method may appear complicated, but in reality it is quite simple when it has once been thoroughly mastered.

ANNEALING STEEL CASTINGS

The following method of annealing steel castings was adopted by the American Society for Testing Materials, and referred to the members for letter ballot at the Atlantic City meeting.

1. The castings should preferably be sufficiently cleaned of adhering sand before annealing to insure thorough and uniform heating.

2. The castings should be heated slowly and uniformly to temperatures (in degrees C.) varying with the carbon content of the steel, and approximately as follows:

Up to 0.16	925
0.16 to 0.34	875
0.35 to 0.54	850
0.55 to 0.79	830

Nothing in these recommendations shall operate against the temperatures aimed at being 50 and, in special cases, 100 degrees C. higher than those given in the table, when necessary to attain the desired result.

3. The castings should be kept at the maximum temperature a sufficient length of time to insure the refining of the grain. In general, the heavier the sections of the casting, the longer must be the time of exposure to the maximum temperature.

4. (*a*) The castings should be cooled slowly and uniformly in the furnace, when it is desired that the steel shall possess the maximum softness.

(*b*) The castings may be cooled at an accelerated rate, when it is desired that the steel possess rather higher tensile strength and elastic limit than can be procured by very slow cooling. This cooling must be so conducted as to leave the steel reasonably free from cooling stresses.

The manner of carrying out this accelerated cooling should be such as will attain the desired result. For instance, the castings may be withdrawn from the furnace and buried in a bed of material that is a poor conductor of heat; or the annealing furnace may be so thrown open that it will cool more rapidly than if left closed. Should the castings be of such uneven section that they cool at unequal rates at various points when the furnace is opened, especially if the carbon of the steel is high, the furnace should be closed after the castings have become black, and their further cooling so retarded that the stresses set up by the unequal rates of cooling are relieved.

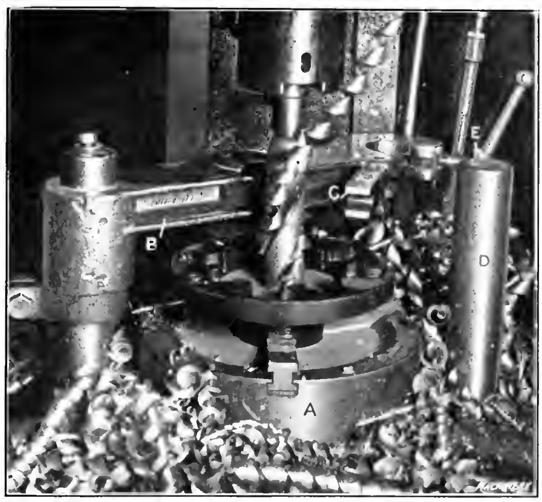
A SPOTTING JIG

In the drilling department of the Pierce-Arrow Motor Car Co., Buffalo, N. Y., a spotting or centering jig for drilling heavy work is employed. This is shown in the illustration and its purpose is to locate the drill while it is spotting the work, after which it may be swung aside to allow the chips to emerge freely. In the illustration the work has been spotted and the arm swung clear to permit the chips to leave



Spotting Jig with Arm clear of the Work

the drill freely. On the job in question the work is circular, and is held in the universal chuck *A*. After locating the work, the arm of the jig *B* that has a bushing at the center is swung into position and latch *C* is thrown around the post *D* and held there by lock *E*. After the hole has been spotted, the lock is loosened, the latch opened and arm *B* is swung out of the way, thus allowing plenty of chip room. C. L. L.

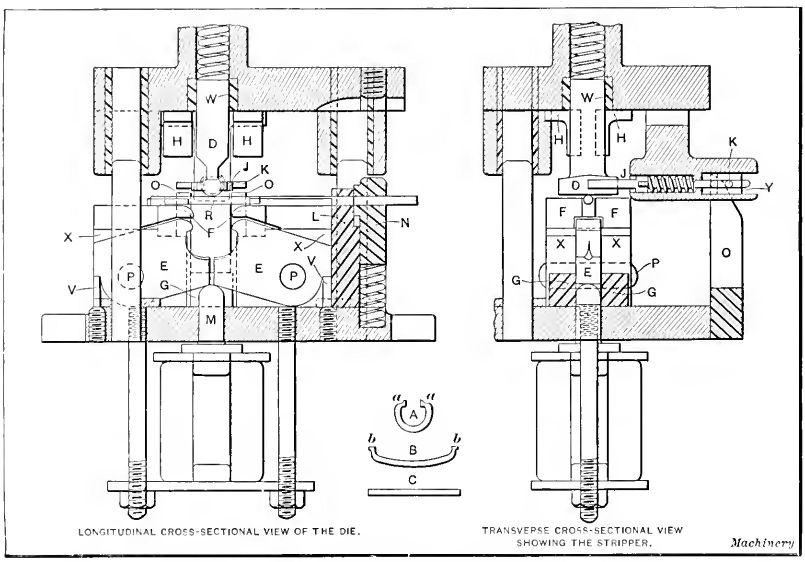
A CUTTING AND BENDING DIE

BY SPRING CRAIG*

The part shown at A in the accompanying illustration is used to support an electric light fixture. These parts are sold in lots of from 10,000 to 100,000; they are made of 7/32-inch polished brass rod, and a particularly interesting punch and die is employed for cutting off the blanks and bending them to the required shape.

It frequently happens that difficult problems in die work find their way to jobbing shops which are the headquarters of traveling tool- and die-makers. These men seldom stay in one place for any great length of time; they keep moving from place to place, and I have known those who have worked in upward of one hundred different shops. Likewise, some of the traveling mechanics whom I have met have been across the continent and back; and in at least one case I came across a man who had worked his way around the world and was familiar with more languages than English and profanity.

At that time I was somewhat of a nomad myself and the job of making the punch and die for producing these parts was turned over to me after several men had failed to produce a satisfactory tool. The only requirement was that the work should be produced in not more than three operations. The idea was to cut off blanks of the form shown at C, and then bend them to shape in two operations, as shown at B and A. Difficulty was experienced in bending the ends a and after some experimenting we came to the conclusion that in performing the second operation the ends b would have to be bent in to more than a right angle. To accomplish this, a very expensive punch and die would have been necessary, even if the desired result could have been obtained under any circumstances.



Combination Cutting and Bending Die for making the Piece shown at A

After working on the problem for eight or nine days, I decided to discard this method. The proprietor of the shop had put the job up to me and given me a free hand to work my own way. The result was that I finally managed to develop the punch and die which form the subject of the present article. This tool finishes the work complete in one operation and has a capacity for producing 10,000 pieces a day.

The design will be readily understood from the accompanying illustration which shows longitudinal and transverse cross-sectional views through the punch and die. The bed is made of cast iron and has four upright members X cast integral with it. The two upright pieces at the right-hand end of the die have slots milled in them at an angle of 60 degrees, these slots being employed to control the movement of the cut-off slide N. The two parts E are fitted between the uprights X and are machined to the form of the work which it is required to produce. These members E are carried by two hardened and ground pivots P about which they swing to bend the work around the punch. The two screws V are adjusted to hold the dies E, so that they cannot swing open too far. The plunger M is actuated by a rubber bumper which holds the dies E open except when the punch comes down; this bumper also opens the dies after the punch has completed its working stroke.

The cut-off mechanism consists of two members L and N which are made of tool steel and have a hole drilled through them a little larger than the stock which is to be cut off. The member L is held stationary while the slide N is free to move up and down, its movement being controlled by the 60-degree slots in the pieces X, which were referred to in a previous paragraph. When the ram of the press descends, a screw in the punch-holder is adjusted so that it pushes the slide N through a sufficient distance to cut off the blank. After the shearing operation has been completed, the spring under the slide N returns it to the starting point, where the holes in the members N and L are in line ready to have the stock for the next piece fed through.

The two pieces F are made of tool steel. They are mounted on top of the uprights X, above the dies E. These pieces have a groove on their upper face of the required size to receive the stock that is to be bent in the die. It will be seen from the illustration that the ends of the pieces F are machined in such a way that the work will be bent smoothly over them when the punch D comes down. The same ends are cut away on the sides a short distance back to allow the blocks H to straddle the pieces F. As the ram descends, the punch carries the work down between the dies E, and continued movement of the ram causes the blocks H to come in contact with the dies E. This causes the dies E to be forced inward with the result that the ends a of the work are bent to the required form around the core on the punch D. The punch works in a steel bushing W and is backed up by a heavy compression spring. The downward travel of the punch is limited by having its ends come in contact with the blocks G which are clearly shown in the transverse sectional view. The press continues its travel for another 1/16 inch, and it is this 1/16 inch of over travel which causes the blocks H to engage the dies E and set the ends of the work a to the required form.

On the up-stroke of the press the stripper J is released and pushes the work off the punch. This stripper is made in the form of a fork, its design being clearly shown in the transverse sectional view. It is placed at the back of the die because it would be in the operator's way if it were located at the front. The stripper J straddles the punch, and the piece Y is threaded at the small end to screw into the boss connecting the two prongs. A hole is drilled in the opposite end of the stripper and a hardened piece of drill rod K is driven into it. This piece of drill rod comes in contact with the forked cam O. When the punch-holder comes down, the cam O engages the pin K and pulls the stripper out of the way, causing the spring behind it to be compressed. This spring is released on the up-stroke of the press, thereby moving the stripper forward and knocking the piece of work off the punch. This tool has given most satisfactory results. It requires very little care to maintain it in operating condition and, as previously stated, has a capacity for producing 10,000 pieces per day.

* Address: 301 Church St., Toronto, Canada.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

UNIFICATION OF WEIGHTS AND MEASURES —FOR AND AGAINST

We notice with a great deal of pleasure in the July number of MACHINERY your editorial, "Unification of Weights and Measures," and wish to thank you for the very sensible stand you are taking in the matter, and without, as you say, going into the merits of the controversy "Metric vs. English System."

We here have adopted the metric system and apply it to such things and operations as we can conveniently, though it is still necessary to purchase many materials and to do many things with the English system, but we shall welcome the day that will surely come when the metric system is universal.

It is only too true, as you say, that the longer the change is put off the more difficult it will be, and so we hope the changing will not be put off much longer.

THE DELAVAL SEPARATOR CO.,
Poughkeepsie, N. Y. T. H. Miller, Supt.

To put it mildly, I was surprised to see the editorial favoring the metric system in the July number. You should have known better than to express an opinion favorable to the system, and assuming that your words were intended to mean what they appear to mean, you should have known better than to repeat the stale untruth "It is already used by three-fourths of the civilized world." Have you forgotten the official "confession" of the French minister of Commerce, Industry and Labor, published in the transactions of the American Society of Mechanical Engineers, Vol. XXVIII, page 877? Let me remind you that this official is charged with the enforcement of the law for the suppression of old units of measurements in France, and that in this confession he acknowledges himself powerless to do it, and plaintively appeals to local chambers of commerce to use their influence to persuade where the law is unable to compel. This official confession confirms all that has been said regarding the continued use of old units in France after more than a century of effort to suppress them. Explain if you can in any way creditable to the system this continued preference for old units by the French people.

This state of things exists, although the metric system was introduced in France before the large development of organized industry and when the change was, comparatively speaking, easy. Among the few organized industries in existence there at that time was the manufacture of silk fabrics, and this is precisely the industry which adheres most tenaciously to its old units and which illustrates most forcibly the impossibility of changing units of measurement in organized industry. Another and wider illustration is the lumber industry, for throughout metric Europe lumber is sawn to the inch and to nothing else; and similar illustrations can be repeated indefinitely.

Wherever the adoption of the system has been attempted, the result has been a partial adoption—adoption in fields of use in which the change is easy, and failure to adopt in other fields. Now the entire metric case is based on the tacit assumption that the old units are to disappear, but this they have not done in any metric country on earth. If the old units are to continue, every metric argument is annulled and inverted. Instead of uniformity the result is confusion; instead of ratios between units being simpler and more uniform, they become more complex and diverse; instead of calculations being simplified they become more complex by reason of the repeated conversions required between old and new units. Witness the extended conversion tables of English and metric units with which reference books are burdened and which are made necessary by the use of two systems side by side. You should read Mr. Dale's exposition of the effect of the superposition of metric commercial units on the old factory units of the textile industry of all metric Europe. The result is a state of chaos that defies description, and it is precisely to this state that the "adoption" of the metric system in our mechanical industries would lead. So far as "academic discussion" is concerned it is the metric party that is made up of academicians. It is the metric party that chases rainbows while the anti-metric party studies facts. The metric party presents the system as imagination conceives it to be, while the anti-metric party presents the case as it is.

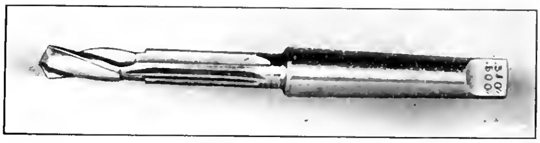
I have, however, no intention of presenting an extended argument here. My forthcoming book, "Methods of Machine Shop Work," contains a discussion of this subject as releated to the machine shop, and I refer you and your readers to it in lieu of a repetition of the same facts here. Let me add, however, that no candid man can study the metric system, not as it is conceived to be, but as it is, and fail to decide against it, for there never was a case in which the theory and the facts are so opposed. F. A. HALSEY

New York City Editor Emeritus, *American Machinist*

COMBINATION DRILL AND REAMER

In modern machine shop practice, one of the most fruitful methods of increasing efficiency consists of the elimination of unnecessary handling of the parts to be machined. If it is possible to combine two tools so that their work is done in a single operation, the handling and time required to set up the work is reduced in direct proportion, and there is also a reduction in the machining time. It was to secure these advantages that the combination drill and reamer shown in the accompanying illustration was designed.

This tool consists primarily of an ordinary reamer with a standard taper shank and tang to fit in the spindle of an



Tool for drilling and reaming a Hole in One Operation

upright drill press. The cutting end of the reamer has been lengthened and formed into a regular two-lipped twist drill, this drill first entering a cored hole in the casting, cutting away the metal and enlarging the hole to such a size that the reamer may easily follow it. In this way the hole is finished to the standard size in a single operation. It has been found in practice that by combining the two operations in this way, they can be done almost as quickly as either of the individual operations was formerly performed, with the result that a great saving of time has been effected.

A. C. NELLA

COLLEGE OF THE MIDNIGHT LAMP

In these summer months, when schools and colleges are sending out their thousands of graduates, one's thoughts turn naturally to the army of men who do not celebrate commencement nor join the friendly reunions and revels of "class day"—men who perhaps left school at an early age to take their places in the workaday world. Yet many of these men must be classed among the educated, because they have trained minds as well as skilled hands, and are students in one of the largest and best of colleges—the one that grants no degrees, issues no diplomas, and has no alumni, for no man worth his salt who has once enrolled as a student in the College of the Midnight Lamp, ever graduates.

In many other points this college differs from its sister educational institutions. It publishes no list of its faculty, yet on its teaching staff are many honored names, for it includes every man who publishes, in trade papers or elsewhere,

information of value and interest to any of its students. This college has no students entered in obedience to paternal mandate and supported by paternal checks. Its tuition fees are small and are paid from the students' daily earnings. Its pupils, at entrance, are often of mature age, with very definite ideas of what they wish to learn. They are men accustomed to daily labor, who have found that mere labor brings small returns of pleasure or profits, while the work of the skilled hand, directed by the trained mind, yields not only a fatter pay envelope, but the keen and lasting satisfaction of mental growth and accomplishment.

Some there are, as in all schools, who start bravely but soon fall out of the ranks, but there remain those in whom are the insatiable thirst for knowledge and the firm and steadfast resolution that will hold them unflinchingly to the arduous program of nightly study after daily toil. What are they studying? Most of those I have met have begun with some subject directly related to their daily work, but they do not stop when the first topic is mastered. The curriculum is wide, and as all courses are elective every student is free to follow his own tastes and inclinations.

One man, who hesitatingly took up geometry and trigonometry soon after completing his apprenticeship in the machine shop, followed on through higher mathematics, then, wishing to know more of the materials on which he worked, studied deeply the chemistry of steel, meanwhile "as a diversion," he says, acquiring a reading knowledge of three languages, and learning shorthand "to save time in keeping notebooks." It can hardly be charged that his devotion to study has seriously interfered with his regular work, for he has risen step by step to the head of the mechanical department of the corporation by which he has been employed for thirty years, and has lately received a year's leave of absence, that he may give to a similar concern in another country the benefit of his expert knowledge. This, of course, is an exceptional instance. What does the ordinary student gain? To what end does he employ in study the hours which others spend in amusement or in sleep?

While these questions can be only partially answered in terms of dollars and cents, the consciousness of increased knowledge and broader outlook being a large part of the compensation, still the effect on the pay envelope is of prime importance to all of us who earn our living by our trade. One often reads tales of men who have gained large increases of wages after taking a course in a correspondence school, and sometimes hears these ridiculed as extravagant, but I have yet to see one which I cannot duplicate from my own observation. The machinist who doubles his earning power in two short years is no figment of an ad. writer's vivid imagination. I've seen it done. Does what he learns lead to his advancement? Not that alone, but study added to the unrelaxing bulldog strain in his make-up that led him to begin the study and kept him at it, and if his case seems unusual, it is only because most of us lack just that quality.

We often hear pessimistic talk of the decadence of our trade—that it is poorly paid, offers no future for a young man, etc., but it seems to me that it depends, mainly, on the young man himself. He may look enviously at those who are able to secure the well-rounded, symmetrical training which he thinks a properly equipped technical school bestows; he may regret his inability to spare even the moderate fees for a correspondence school course, but *if he has it in him* he can obtain all the education he wants, all the mental training he desires, almost without money cost, from the institution that has given us so many of our best men—the College of the Midnight Lamp.

New London, N. H. GUY H. GARDNER

POWER PRESS PUSH GUARDS

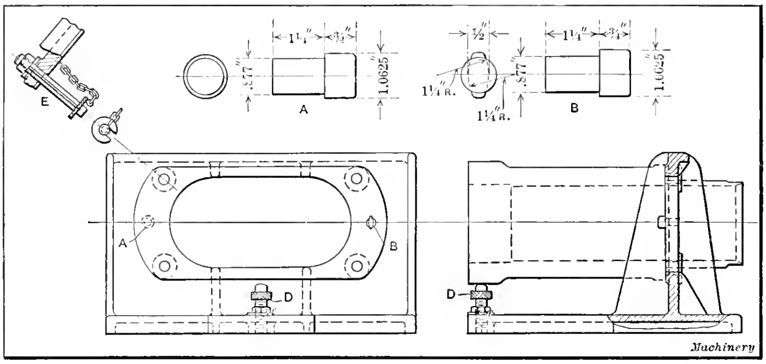
We noticed in the July number of MACHINERY, engineering edition, that credit was not given where credit is due. The so-called Hemphill push guard device for safeguarding a power punching press was exhibited by the Stiles & Parker Press Co. at the Centennial Exposition in Philadelphia in 1876. The E. W. Bliss Co., since buying the Stiles & Parker press business, has put a number of these devices on presses. Mr. Hemphill simply copied the Bliss device on a press fitted up for the Travelers' Insurance Co. by us in 1908.

We enclose a photograph showing this identical press from which he made his copy; also a photograph showing a cutting press made by us over twenty years ago for a Baltimore concern, on which the same device was applied.

Brooklyn, N. Y. E. W. BLISS CO.

GRINDING FIXTURE FOR HOLDING TWIN CYLINDERS

A grinding fixture for holding gasoline engine cylinders that are cast in pairs is illustrated herewith. This fixture was designed for a large internal grinder having a table equipped with an indexing cross-slide. As the movement of this cross-slide was sufficient for indexing from one cylinder bore to the other, it was possible to design a comparatively simple fixture, but owing to the size of the cylinders the fixture had to be very strong and rigid as well as easy to operate. The cylinder casting is shown in outline in the side view.



Grinding Fixture for Twin Cylinders

The cylinders are first bored and all other necessary machine work is done before grinding. The holes in the base are also drilled and reamed by a jig located from the two bores. The fixture is provided with two dowel pins *A* and *B*, one of which is round and the other oval. These pins fit into the reamed holes and accurately locate the cylinder in relation to the bores. Pin *B* is made oval (see also enlarged view) to avoid the binding which might occur in case both pins were round. In other words, with the oval pin the distance between the drilled holes can vary slightly, whereas if both pins were round and fitted the holes closely there might be trouble from center-to-center variations.

The jack-screw *D* which supports the outer ends of the cylinders is adjustable. The four bolts engaging the four holes in the base hold the cylinder firmly in position. These bolts, one of which is shown in detail at *E*, have keyways which engage tongues or keys on washers that are screwed to the back of the fixture. This arrangement prevents the bolts from turning when being tightened or released. The slip washers which form the heads are attached to the fixture by chains which prevents their being lost. When these washers are removed the bolts can, of course, be passed through the holes when inserting or removing work. M. W. W.

A DIAL COMPAROMETER

We recently came to the conclusion that the usual form of commercial indicators were not accurate enough for measuring such work as size blocks, plug gages, type and a variety

of other parts where great accuracy is essential, and to meet the requirements of such cases the indicator shown in Fig. 1 was designed. The case of this instrument measures about 2.75 inches in diameter, and the dial indicates 0.010 inch for one complete revolution of the pointer. The arrangement of the working parts is as follows: Lever *A* is 2 inches long from the fulcrum screw *B* to the pin *C*, and is 1/8 inch long from the screw *B* to the flange on the plunger *D*. This means that when plunger *D* is moved through 0.010 inch, the end of lever *A* in contact with the pin *C* moves through a distance of 0.160 inch, as the length of the lever from *B* to *C* is sixteen times the length from *B* to the flange on the plunger *D*. The segment gear *E* measures 1.125 inch from the pivot *F* to the pitch line, and the pinion *G* is 1/4-inch pitch diameter or 0.7854 inch in circumference. As it is desired to have one complete revolution of the pointer over the dial represent a movement of 0.010 inch of the plunger in contact with the work, the pin *C* must be located on the segment gear at such a distance from the pivot *F* that this movement of 0.010 inch of the contact point will produce a movement of 0.7854 inch at the pitch line of the segment gear *E*. This, in turn, will cause the pinion *G* to make one complete revolution.

Fig. 2 shows the method of arriving at the result. We know from geometry that corresponding sides of similar triangles

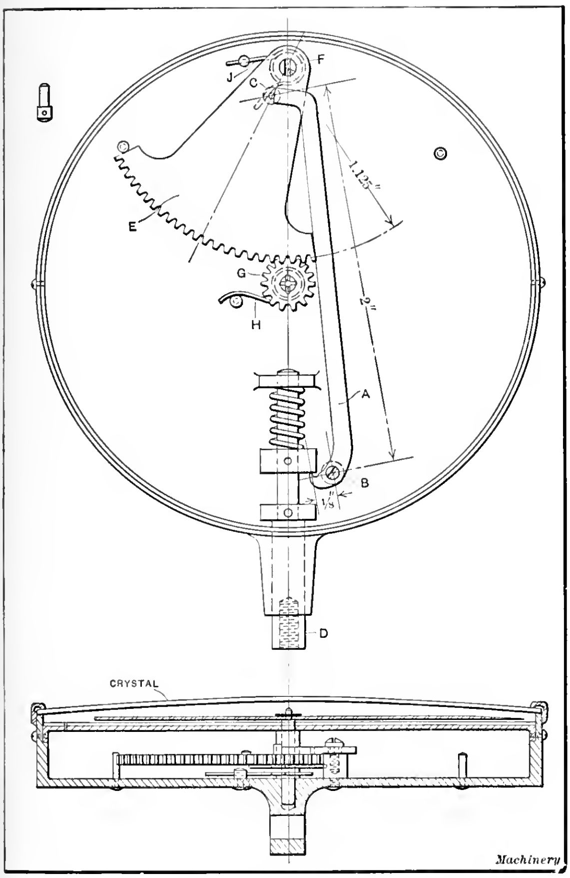


Fig. 1. Dial Comparometer for measuring Size Blocks and Other very Accurate Work

are proportional to each other, and applying this principle to the present case, we have:

$$\frac{FC}{0.160} = \frac{1.125}{0.7854}$$

$$FC = \frac{0.160 \times 1.125}{0.7854} = 0.229 \text{ inch.}$$

In Fig. 2, *F* and *C* represent the pivot on which the segment gear is carried, and the contact point of the lever *A*, respectively. The value 0.229 inch represents the distance at which the pin *C* must be located on the pivot *F*. The dial of the instrument is graduated to 100 equal parts, each of which represents 0.0001 inch. The spaces between consecutive graduations are sufficiently large so that half and quarter spaces may be readily estimated. This instrument is very sensitive and is practically "fool proof" as far as breaking the mechanism by forcing in the plunger *D* is concerned. It will be seen that two small pins are provided to limit the movement of the segment gear *E* in either direction. The pinion is always in mesh with one side of the teeth on the segment gear owing to the action of the hair spring *H*.

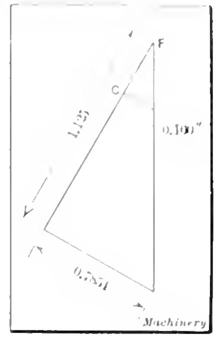

Fig. 2. Method of computing Required Leverage

The operation of the comparometer may be briefly described as follows: A movement of the contact point on the work moves the plunger *D*, and the flange on this plunger moves the short end of the lever *A* with which it is kept in contact by the action of a spring *J* on the segment gear and the spiral spring on the plunger. In this way a uniform contact is maintained between the long end of the lever *A* and the pin *C*, and also between the flange on the plunger and the short end of the lever *A*. The movement of the lever *A* in contact with the pin *C* causes the required movement of the segment gear which turns the pinion and the pointer that is carried on its shaft. The operation of this indicator is absolutely smooth, there being no tendency for the pointer to "hesitate" or "jump."

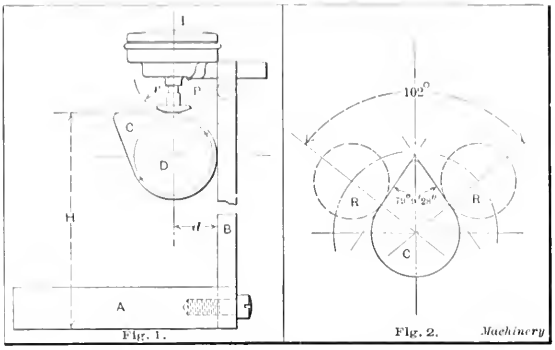
New Britain, Conn. W. C. Betz

CHECKING A CAMSHAFT WITH THE DIAL INDICATOR

Whether or not a camshaft, made from a carefully planned design, will perform just what it is intended to do may remain a matter of uncertainty until it is tried out. Of this much, however, we are assured: if after a careful checking it meets all predetermined conditions every one interested is relieved. With a new design it is not always possible or convenient to make an actual test on a motor, and any method that makes it possible to accurately check up the vital points of the camshaft will be welcome. As the measurements for length, diameter, etc., are easily made with regular tools, this article will be confined to a method of measuring the relation of the opening and closing points of the cams, with reference to some starting point as, for instance, the keyway for the camshaft gear.

Fig. 1 shows a stand of simple construction, which was made to carry a Starrett dial indicator. Its design could have been elaborated by providing vertical and lateral adjustments, but these were unnecessary. The base *A* is made sufficiently heavy to stand firmly, and the vertical support *B* is notched into the base and secured by screws. The upper end of the support is drilled and reamed to receive the shank of the indicator *I*, and also split and provided with a screw to clamp the shank. The indicator contact point *P* is a spherical segment whose radius *r* is one-half the diameter of the cam roll. The center line of the indicator must stand in the same relation with the camshaft, as the roll would occupy in the motor, which in this case is on the center line of the camshaft. The distance *d* is then one-half of *D*, and the height *H* is such as to give a good contact between the point *P* and the cam *C* and allow the full limit of the indicator movement.

With the camshaft suitably dogged and mounted between the index centers, the first move would be to find the center of the keyway for the camshaft gear, as the probabilities are that the centers of the cams are laid out with reference to that center. Let us assume that we have our inlet cam shaped as shown in Figs. 1 and 2, and that the center of this cam coincides with the center line of the keyway; also that the opening and closing points are at the positions occupied by the cam rolls represented by the dotted circles *R* in Fig. 2. The actual opening and closing points are then one-half of 102 degrees, or 51 degrees in advance and 51 de-



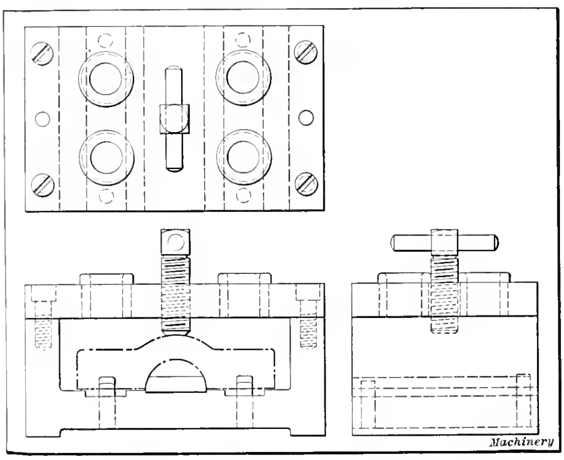
Figs. 1 and 2. Stand for the Dial Indicator and Diagram showing Method of Procedure

grees back of the starting point. With the indicator set on the dwell of the cam, allowing for a rise of 0.003 inch (the clearance under the valve stem) before zero, and with the indicator in the position shown, we index the camshaft around to the correct angle. If the work has been accurately done, the indicator needle should just begin to rise at that 51-degree angle; if not, it will rise either too soon or too late and the amount of error is read from the index circle. The relation of all the other cams to the keyway is checked in similar manner, taking all inlet points in their firing order and then all closing points. The amount of error found, in spite of very careful workmanship, is sometimes surprising, even when measurements with micrometers and a protractor show up well; but, thanks to that highly useful instrument, the indicator, many things in our line are being reduced to a degree of accuracy approaching perfection.

Hartford, Conn. ERNEST A. RUNGE

DESIGNING JIGS AND FIXTURES

The simple form of drill jig shown in the accompanying illustration, which is for a small bearing cap, illustrates a very good method of designing jigs and special fixtures. The part for which a jig is required is first laid out, and thus the



Drill Jig used to illustrate Method of designing Jigs and Fixtures

jig is designed by working around this lay-out. The part should preferably be drawn in red, green or some other light colored ink, and one or more views should be shown, as this will give a clearer idea of its shape and size and will be a help in determining the best and most accurate method of handling work. This method is particularly helpful in designing jigs for complicated parts. By drawing the work on the tracing with some light colored ink, then drawing the jig and dimension lines with black ink, the blueprint will show the distinction between the work and jig very plainly. The jig and dimension lines show on the print in bold, white lines while the work is in light, pale lines. This method is a great help to the patternmaker in working out the pattern for the jig or fixture because he can more readily understand the jig drawing. When the drawing is arranged in this way, it is also helpful to the toolmaker because he can not only understand the drawing better but also has a clearer idea of the parts which require the most accuracy. M. W. W.

[In the illustration, the work is indicated by dot-and-dash lines in the usual manner, as the pale lines on the original blueprint cannot be reproduced.—EDITOR.]

IDEAL DRAWER BOTTOM

Some time ago we had occasion to build several cabinets for filing tracings and pencil sketches. The drawers were 26½ by 38½ inches in size and were used without partitions for storing our largest size drawings which were 24 by 36 inches. Some of the drawers were divided up with partitions as shown in Fig. 2 to accommodate drawings 18 by 24, 12 by 18, 9 by 12 and 6 by 9 inches in size. The partitions were made of ½-inch stock. Upson wall board was found to constitute an ideal bottom for the drawers. This material is about 3/16 inch thick and can be bought in sheets large enough to make the entire bottom of the drawer from a single piece, thus eliminating cracks or joints. A further advantage is that the material has no tendency to shrink or warp out of shape. It is flat and stiff enough to require little reinforcement, and is considerably lighter than wood. In making the drawers, a groove was cut in each of the four sides to receive the edges of the wall board, and a small wood strip, ½ by 1 inch in size, was fastened across the center of the drawer on the under side of the wall board to act as a reinforcement. These cabinets have now been in use for nearly a year and are still in perfect condition.

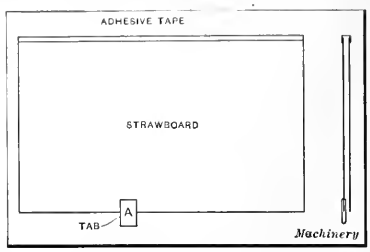


Fig. 1. Type of Binder used for filing Drawings

Pencil sketches are filed in these cabinets in alphabetical order, and owing to an insufficient number of drawers it was necessary to file the sketches coming under several index letters in the same drawer. In order to keep the drawings of different index letters separate, binders were made for each letter in all of the different sizes. These binders were made of two pieces of No. 50 strawboard, fastened together on the side which is placed toward the back of the drawer. Adhesive cloth tape is used for this purpose, the method being clearly shown in Fig. 1. It will also be seen from this illustration that a tab of this cloth tape is fastened to the front

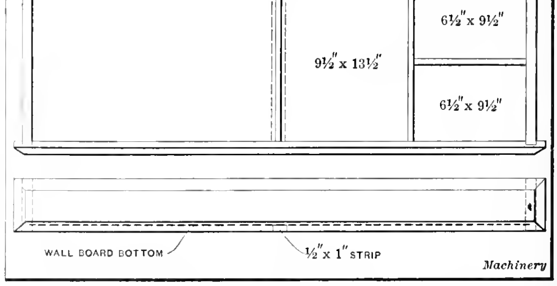

Fig. 2. Design of Drawer equipped with Upson Wall Board Bottom

of the top sheet of the binder, the proper index letter being marked on this tab. This arrangement makes it possible to locate any required binder promptly and the tab can also be used to lift the cover. These binders not only separate the drawings of different classes, but also prevent sketches from working out at the back of the drawers.

Aurora, Ill. E. J. G. PHILLIPS

SPRING STRIPPER PUNCH AND DIE

The punch and die illustrated in Fig. 2 was designed for punching five holes in the piece shown in Fig. 1. Owing to somewhat unusual conditions in gaging the work in this die, a spring stripper was found most satisfactory. Referring to the illustration, the stripper will be seen at *A*. It is operated by springs supported by the bolster *B*.

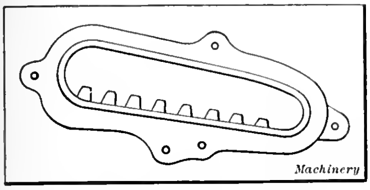

Fig. 1. The Work to be punched

The first step in designing the die was to determine the number of springs required to operate the stripper. The holes to be punched are ½ inch in diameter and the thickness of the work ⅜ inch, the material being malleable iron. A test was conducted by forcing a ½-inch punch through a ⅜-inch malleable iron plate, stopping the press at the bottom of the stroke and releasing the punch so that it could be removed with the plate. The plate and punch were then taken to a Riehle testing machine and it was found that a force of 1200 pounds was necessary to pull the punch out. It was obvious, then, that a force of 6000 pounds was necessary to strip the work off five punches.

It was decided to use springs coiled from wire 5/16 inch in diameter, the diameter of the coils being 1¼ inch. Referring to the table in MACHINERY'S Handbook, giving the maximum load in pounds which different sizes of helical springs will carry, it is found that the load that can be supported by springs of this size is 1220 pounds. Allowing a factor of safety of 1½—as the springs are not subjected to severe vibration—the total load used in calculating is $1.5 \times 6000 = 9000$ pounds. The number of springs required is then found to be $9000 \div 1220 = 7.35$. Using the next higher number, we find that eight springs are necessary. Four of the springs are held between the stripper *A* and bolster *B* by means of bolts *C* and the other four springs are secured by pins entering into the ends of the springs. One of these pins is shown at *D* in Fig. 2. Two 1¼-inch guide pins line up the die.

Each coil of a spring of the size used for the stripper may be compressed 0.138 inch. Allowing 5 inches between the stripper and the bolster, there will be sufficient room for springs with eight coils. The total allowable compression of these springs will be $8 \times 0.138 = 1.104$ inch. The stroke of the press is 2 inches and allowing the stripper to act through the last 1 1/16 inch of the stroke, the required pressure will be secured to strip the work from the punches.

Hamilton, Canada J. M. HARRISON

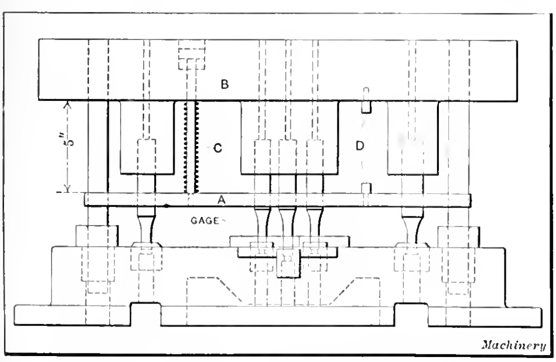

Fig. 2. Punch and Die for which the Spring Stripper was designed

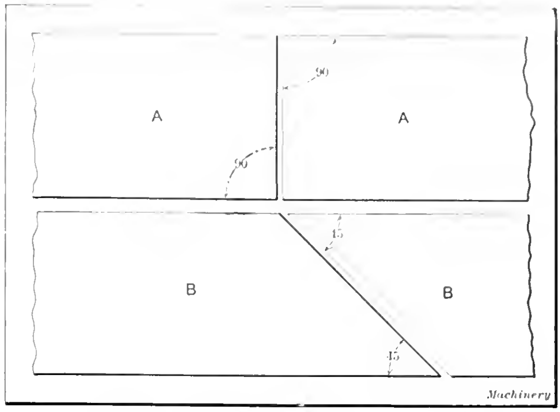


Leather Belts laced at Angles of 45 and 90 Degrees

LACING LEATHER BELTING

It is a time-honored custom in splicing leather belting to cut the ends of the belt which are to be laced together so that the splice makes an angle of 90 degrees with the edge of the belt. This method is shown at *A* in the accompanying illustration. Anyone who has had much to do with the maintenance of belting knows that the rawhide laces wear and pull out long before the belt is worn out. The use of steel lacing does not eliminate the difficulty, because the holes in the belt finally become so large that the splice pulls apart.

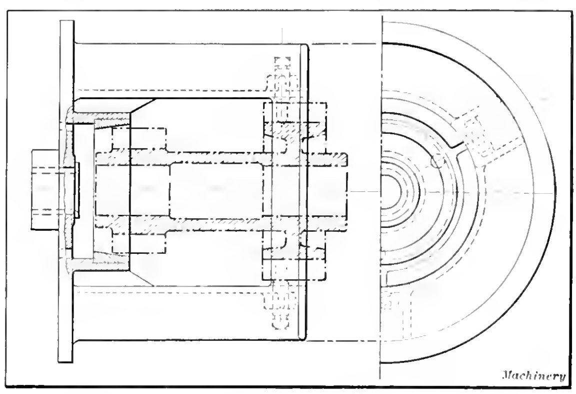
If the belt is spliced at an angle of 45 degrees, as shown at *B*, and laced in the usual manner, it will be found that the lacing will last fully as long as the belt. This is due to the fact that with the belt cut at a 45-degree angle, there are more strands of the lacing for a given width of belt, and the strain of the lacing in the holes is distributed over a greater distance than when the belt is cut in the usual manner.

East Orange, N. J. GEORGE GARRISON

[Mr. Garrison has used this method of splicing belts in certain classes of work, and finds the results entirely satisfactory. We have never seen this method used before and it appears that the practice of making the splice on an angle might have a tendency to cause the belt to run off the pulley. If other readers of MACHINERY have used this method, we should be pleased to hear of their experience.—EDITOR.]

CHUCK FOR TWIN SPUR GEARS

The chuck illustrated herewith was designed to produce more gears on a large turret lathe than were being produced



Special Chuck for holding Twin Spur Gears while boring Hub

on the same lathe equipped with a regular chuck having special jaws and clamps. This new chuck was also designed to insure greater accuracy. The dot-and-dash lines show the twin spur gears in place in the chuck. These gears are of cast steel and have one long hub, the bore of which must be accurate in relation to the teeth. The chuck has a finished boss that fits into the faceplate of the lathe and this boss is provided with a bushing for guiding the pilot of the turret

boring-bars, thus making the chuck and bars accurate in relation to each other.

The back of the chuck contains a taper ring of casehardened steel, which forms an accurate centering device for the smallest of the two gears, the gear being centered by the outside of the teeth. The larger gear, which has a number of teeth divisible by 3, is set centrally in the chuck by adjusting three screws that engage the bottoms of the teeth. These screws provide a means for locating the gears centrally, and also act as drivers. The chuck is of light construction and is well ribbed. The projecting ring and ribs not only strengthen the chuck but serve as guards to prevent the screw heads from injuring the lathe operator. As the guard ring is only a trifle larger than the gear, it is of value to the operator in judging the position of the gear when centering it.

M. W. W.

DESIGN OF SHEAR FOR CUTTING ANGLE IRONS

I was particularly interested in reading the answers to J. D. Y.'s inquiry in regard to the design of shear blades for cutting angle irons, which have been published in MACHINERY. I have had quite a little experience along this line and would like to add a suggestion in regard to the best method of handling this class of work. Three or four years ago I received orders to make a shear for cutting angle irons, the chief requirement being that it would be capable of cutting the pieces off square and free from burrs. I made a shear

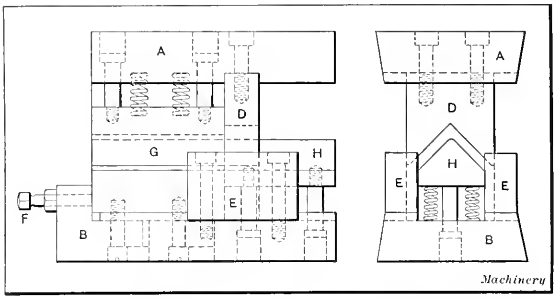


Fig. 1. Side and End Views of Shear for cutting Angle Irons

somewhat similar to the one described by J. M. Henry and tried it out. The first lot of angle irons was cut fairly well and I thought that the problem had been solved very satisfactorily, but the next lot of stock that came in was much softer and when we started to cut it up our troubles began. I tried all sorts of remedies but found it impossible to get satisfactory results until I finally hit upon the scheme of making a pair of shear blades equipped with spring pads. An equipment of this kind is illustrated in Figs. 1 and 2, from which the design will be readily understood.

Referring to Fig. 1, the upper and lower blocks upon which the shear blades are mounted are shown at *A* and *B*, respectively. The lower blade *C* is made of tool steel and formed to the shape of the inside of the angle iron. The upper blade *D* which is also made of tool steel is machined to the same angle as the outside of the angle iron. The lower block *B*, which is shown in Fig. 2, has a longitudinal slot cut in it to receive the blade *C* and a transverse slot to receive the backing up pieces *E* which support the upper blade. The block *B* also has holes machined in it to receive the screws for holding the shear blade in place, these holes being elongated so that the blade may be adjusted by means of the screw *F* to compensate for the effect of grinding.

The backing up pieces *E* fit snugly against the upper blade and are fastened to the block *B* by two fillister-head screws and a dowel pin. The spring pad for the upper blade is marked *G*, and *H* is the spring pad carried by the lower blade. These pads are held by two shoulder screws and each pad has four springs under it. The function of the pads is to hold the stock so that it cannot move lengthwise while being cut. The pad *G* extends 1/4 inch below the edge of the upper blade so that when the ram descends, the pad grips the angle iron before the blade comes into action. As the ram continues its downward stroke, the blade slides into the grooves in the side blocks *E* which makes it impossible for the upper and lower blades to separate.

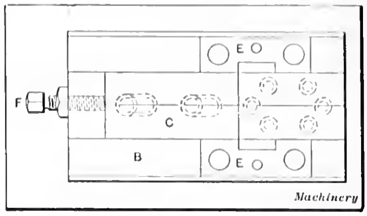

Fig. 2. Plan View of the Lower Shear

A shear of this kind may be made to cut all sizes of angle iron from 1/2 up to 2 inches. This shear is used in a punch press and has been in operation for about three years. Aside from replacing the blades when they become worn out, it has given practically no trouble. Of course the first cost of this shear will be higher than that of an ordinary shear of the type described in previous contributions, but where it is absolutely necessary to cut angle irons without leaving any burrs, it will soon pay for itself.

Chicago, Ill. A. H. WILSON

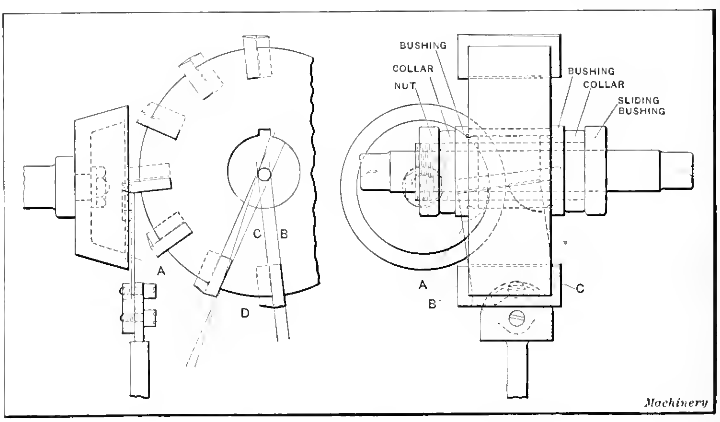
METHOD OF CUTTING PLATE GLASS

Among the numerous odd jobs met with in the general machine shop, there are few so "ticklish" as that of cutting plate glass where it is required to have the edges perfectly smooth and straight. If this work is attempted with the aid of a diamond glass cutter and rule, the glass will break with a ragged edge. The best method of overcoming this difficulty is described in the following: I have used it in cutting plate glass as thick as 1/2 inch and obtained excellent results. First obtain a good diamond glass cutter, and with this tool scratch the glass along the line on which it is to be cut, using any good straightedge to guide the diamond. In this connection it may be mentioned that the deeper the cut the more uniform the surfaces of the cut edge will be. After laying the glass on a cold surface with the cut side up, for which purpose the surface plate is very satisfactory, an iron or steel rod about 1/4 inch in diameter is heated to a dull red. This rod is then laid along the line scratched by the diamond point and pressed lightly against the glass. When held in position for from one to four minutes—depending on the thickness of the glass—it will be found that the glass will crack along the line, leaving a perfectly uniform surface.

JULIUS R. HANSEN

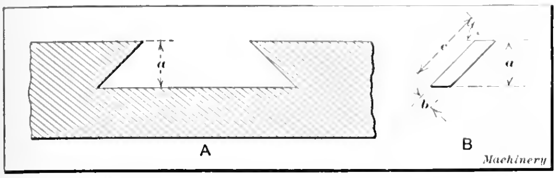
FIXTURE FOR GRINDING INSERTED-TOOTH CUTTERS

The accompanying illustration shows a fixture that has proved itself a great time-saver in grinding milling cutters



Tool Grinder Fixture for sharpening Angular Inserted-tooth Cutters

with inserted angular blades. The cutter to be ground is held on a sliding bushing which is carried on a straight mandrel mounted between centers on the grinding machine. This arrangement has been used for years in grinding spiral and straight milling cutters, but it is not suitable for grinding cutters with angular inserted blades without the use of the rest *A*. This rest holds the cutting edge of the blade at exactly the same height at both ends and gives excellent results on both angular and straight inserted-blade cutters.



Dimensions of Slide and Gib that should be given

The rest may be set to the desired angle for holding different cutters.

It will be noticed that the line *B* of the face of the blade has "drag" because it points ahead of the center, and that line *C* at the opposite side of the cutter has "rake" because it points back of the center. If it were attempted to grind an angular cutter with the blade supported on an ordinary rest at *D*, it will be seen that the blade would be at different heights on the emery wheel as it slides across the rest.

Franklin, Pa. FRED R. IRWIN

PROPER DIMENSIONS FOR A GIB

In the April number of MACHINERY, W. Butz invites a discussion in regard to the proper method of dimensioning a gib. As it seems to be a question of the necessary dimensions for both the required size of the stock and the gib to be machined from it, the writer believes that none of the three methods shown by Mr. Butz is entirely satisfactory. In dimensioning the slide *A*, one would naturally give the dimension *a*. The same dimension *a* should be given on the gib *B*. This dimension *a*, together with the proportions *b* and *c* and the angle *a*, should be given. Where the gib is proportioned in this way, and the required length of the gib is specified, the machinist has complete information and can proceed with the machining operations.

Whitinsville, Mass. S. H. HELLAND

DRILLED AND PUNCHED HOLES FOR A. S. M. E. STANDARD SCREWS

The accompanying table is taken from my note-book and gives the sizes of tap drills which have been found to give satisfactory results when drilling for A. S. M. E. standard tapped holes in various metals. In cases when it is desired to punch the hole, either for tapping size or for the body size—as in the case of sheet metal work—this table also gives the diameter to which it has been found the punches should be made in order to give satisfactory results. Designers who may have jigs to lay out or punch press tools to design where these sizes are called into play will find that the data presented in this table gives excellent results without involving much expenditure for the replacement of taps which break if too much stock is left for tapping.

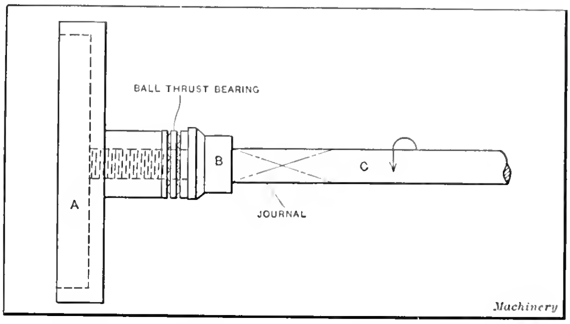
Machinery

A BALL BEARING APPLICATION

Part of a certain special machine is shown in the accompanying illustration. The mandrel shaft *C* carries the collar *B*, which is shrunk on against a shoulder. A left-hand threaded stem extends beyond the collar, and on this threaded stem there is a cast-iron flange *A*. Formerly this flange screwed up to the collar, and the nature of the work tightened the flange against the collar, which, in addition to the close fit of the long thread, made removal difficult. Sometimes the flange had to be removed after running two hours, and sometimes it was left on for a week; but it was always difficult to unscrew. The mandrel would have to be blocked and a pipe wrench applied to the hub of the flange in order to unscrew it; this usually required two men.

The writer was asked to remedy the trouble. An entirely different construction seemed to be the best remedy, but this was not feasible at the time. Naturally, knock-off arbors were thought of, but were rejected as being too complicated and too delicate for the rough unskilled labor which operated the machine. We had in our stock-room different sizes of standard ball thrust collar bearings. One of these was secured between the flange hub and the collar on the mandrel, as the illustration shows. With this bearing in place, the flange unscrewed as easily as it went on, and twirling it on with a "bang," made no difference; neither would a week's service, as it always came off readily. And curious to relate, there was no tendency for the flange to unscrew of itself, even though it was screwed on lightly and the machine run "light."



Flange screwed against Ball Thrust Bearing to facilitate Removal

Middletown, N. Y. DONALD A. HAMPSON

RELIEVING TAPS BY HAND

Having had an experience of some forty years in making and using taps, it seems to me that a tap relieved by hand with a file will work easier and last longer than a machine-relieved tap. A tap must be beveled at the end for several threads so that it will start into a hole, and, of course, it must be relieved on top of the beveled part. The first tooth to cut in starting cuts the whole width of the bottom of a V-thread; the next following tooth a little deeper, the next still deeper and so on until the full depth is attained, and all the cutting is done by the beveled or leading part of the tap.

My way of relieving a tap is to use a three-cornered file, the teeth of which are ground off on one side so they will not cut at all. I file the front side of the thread or tooth so it will be thinner at the back or away from the cutting side of the tooth. The front side is filed nearly up to the cutting edge, the smooth side of the file being held against the back of the tooth. When a tap is relieved in this way the front side of the thread will do all the cutting and the back will be smooth, just as the lathe tool left it, and the tap will cut freely and easily.

Of course I am aware that nearly all shops buy their taps now, but I have seldom seen taps that would work so freely and last so long as those relieved as described in the foregoing. Relieving both sides of the thread or tooth is not only unnecessary, but harmful, as the tap is more likely to chatter and cut a poor thread. It would probably be difficult to machine-relieve the thread on only one side, but I am convinced that taps relieved in that way are much more satisfactory.

Cleveland, Ohio S. S. Jennison

MAKING TUBING FROM HEAVY STOCK

The illustrations presented in this connection show two dies used for making a tube out of heavy stock. The method of using these dies is as follows: A ¼-inch plate of cold-rolled steel is placed in position on the die shown in Fig. 1, and

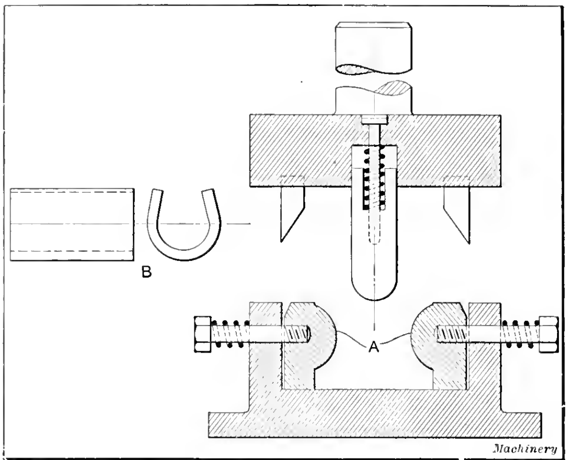


Fig. 1. Novel Punch and Die for performing the First Operation

when the punch descends it forces this plate to the bottom of the die, bending it between the surfaces *A*. The punch-holder and cams continue their downward movement, and the cams force the two surfaces *A* in, thus bending the work to the form shown at *B*. The work is next transferred to the die shown in Fig. 2, which closes it up to form a tube.

Milwaukee, Wis. W. Butzlaff

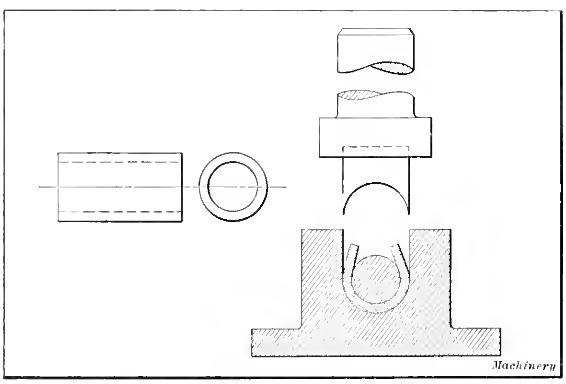

Fig. 2. Punch and Die for closing up the Tube

TWO LATHE TOOLS

Two useful forms of lathe tools are shown in the accompanying illustrations. The tool illustrated in Fig. 1 is either used in the tailstock of the lathe or placed in position against the work and supported by the tail-center at *A*. When using a lathe with badly worn spindle bearings, the use of this tool does away with the tendency toward vibration and at the same time takes up end play. For the purpose of description, let us suppose that a large casting or forging is held in the chuck of such a lathe in order to be turned and faced. The face *B* is brought up against the work, upon which it secures

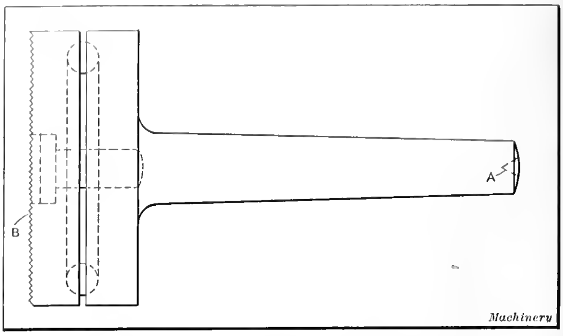

Fig. 1. Auxiliary Tailstock for supporting Work in a Lathe with Worn Spindle Bearings

a firm grip by means of the knurled surface. The support provided in this way prevents the lathe tool from digging into the work and thus produces a much better finish than would otherwise be obtained. It will be seen that the tool consists of two revolving disks which have races machined in them to carry ball bearings. The right-hand disk has a taper shank which fits the tailstock. The knurled disk which engages with the work is hardened and held in position by means of a fillister head screw.

The tool shown in Fig. 2 is a micrometer stop that is used to eliminate all guesswork when boring a recess in a piece held in the lathe chuck. For instance, suppose it is desired to bore out a hole three inches deep. After roughing out the hole to approximately the required depth, the stop is placed in position on the lathe bed near the headstock and the carriage brought up to it. The stop is clamped to the lathe bed by means of a C-clamp. The next step is to take a light cut on the bottom of the hole or recess in the work, after which an accurate measurement of the depth is made. By subtracting

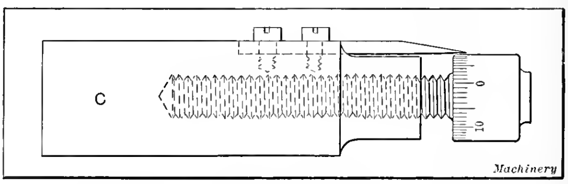

Fig. 2. Micrometer Stop for regulating Depth of Final Cut

this measurement from the required depth, the number of thousandths of an inch that must still be bored out is determined. The micrometer screw is then used to set the stop for the required depth, after which the tool can be fed into the work until the carriage engages the stop. This does away with all cut-and-try methods and increases the accuracy and rapidity with which the operation can be performed.

Brooklyn, N. Y. Edward Rantsch

* * *

The imports of machinery to Germany during 1913 exceeded the imports during 1912 by 10 per cent. The exports during 1913 also exceeded the exports during 1912 by about 10 per cent. The total imports during 1913 amounted to 87,902 tons and the total exports to 593,969 tons. Of the imports, 40 per cent came from the United States, and 34 per cent from Great Britain. The exports were mainly to Russia, Austria-Hungary, France and Great Britain.

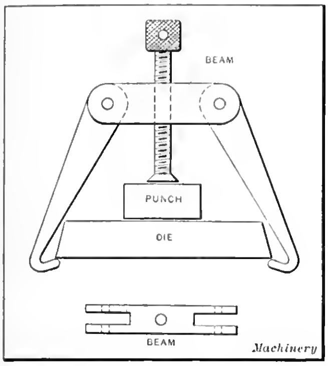
DIEMAKERS' CLAMP



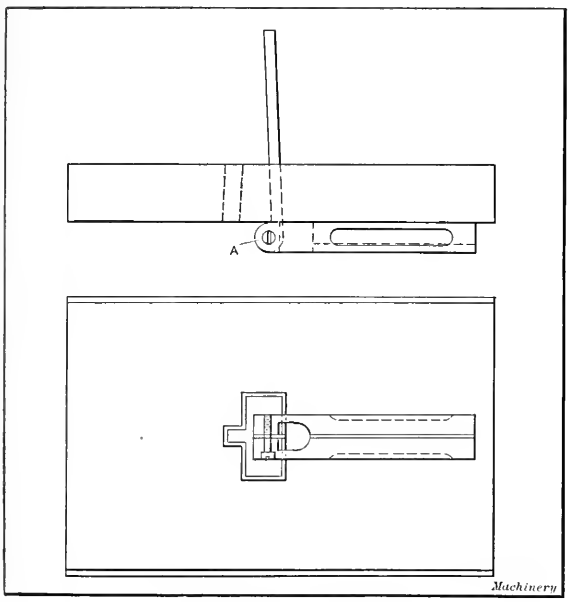
A Useful Form of Clamp for the Diemaker

The accompanying illustration shows a convenient form of diemaker's clamp. This tool is especially useful in transferring the shape of the hole in a blanking die onto the piece of steel from which the punch is to be made. The use of this device practically eliminates the chance of the punch slipping, when scribing its outline on the die, which would result in an inaccurate layout.

Upper Hamilton, Ontario, Canada. H. GROVES

ADJUSTABLE ANGLE GAGE

The accompanying illustration shows a useful form of adjustable angle gage which has several advantages over any other design that I have seen. The only drawback is that this form of tool takes longer to make than other types which are in general use. It will be seen from the illustration that the stock has a slot machined in it which is deep enough to enable the blade to lie flush with the upper surface when the tool is folded up. The hole in the stock must be made large enough and the sides thin enough to enable the screw to



Toolmaker's Adjustable Angle Gage

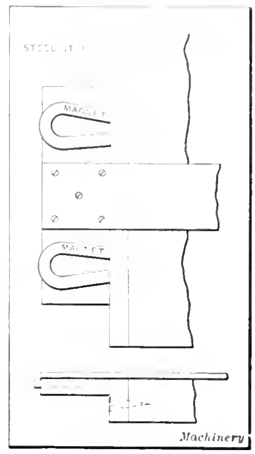
tighten up the blade in any required position. The blade is made of spring steel. After the stock had been hardened and tempered, the blade was put in place and folded into the slot. The stock was then ground on all sides, a magnetic chuck being used for this purpose.

It will be found convenient to have the end of the stock graduated at *A* and to have an index mark on the blade so that any required angular setting may be obtained. The chief features of the design are that the gage is adjustable and that the hole through the stock enables a toolmaker to see right along the blade when he is using the gage in small holes. The blade is also held square with the stock so that the gage may be used with the blade edgewise in narrow holes. The making of this gage will naturally depend upon the ability of the toolmaker and the appliances which are at his disposal.

Meriden, Conn. JAMES GALLIMORE

MAKING THE T-SQUARE STICK

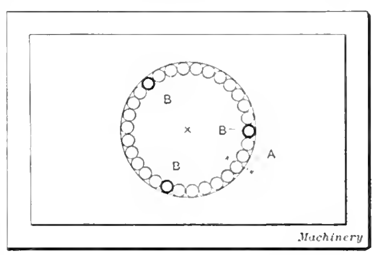
The article "Adjustable Clamps for T-square" by Murray Fahnestock, in the March number of MACHINERY, brings to mind an arrangement used in the drafting-room of the Stockbridge Machine Co., Worcester, Mass. The illustration explains the device, which is a magnetic arrangement for keeping the T-square in place against the edge of the drawing-board. This is especially to be desired when the T-square is to be used in one position for a considerable length of time. The head is mortised so that two ordinary horseshoe magnets can be securely held in it. On the edge of the drawing-board is screwed a steel strip against which the T-square bears. Thus the magnets, and consequently the T-square members, always have an attraction for the end of the drawing-board. While this device is very simple, it has worked out effectively. C. L. L.



A Magnetic T-square

LOCATING A HOLE TO BE BORED

It is sometimes more convenient to drill out the core of a large hole in a die or other piece of work than it is to drill and bore the hole in a lathe. When the core is removed by drilling, it may be conveniently relocated in the hole prior to setting up the work for finish-machining the hole. When this method is to be followed, a center punch mark is made at the center of the core, and a "witness line" *A* is scribed on the work, as shown in the accompanying illustration. After the core has been separated from the block, three drill rod pins of the same size as the drill used for making the holes are driven between the block and the core, as shown at *B*. The block is next mounted on parallels a little higher than the thickness of the block and fastened to the lathe faceplate, where it is accurately located with a center test indicator. The core is then driven out of the block from the front—the space between the work and the faceplate provided by the parallels making this possible—or when a lathe with a hollow spindle is used, the work can be fastened directly to the faceplate and the core driven out from the back. The same method can be used to advantage on pieces with irregular shaped holes that can be finished in a lathe, provided, of course, that the hole is large enough to enable the tool to clear all surfaces except the curve being bored.



Use of Core in locating a Hole to be bored

New Britain, Conn. W. C. BETZ

* * *

The Westinghouse strike at East Pittsburg, Pa., was called off by the workmen July 9, and the day set for return to work was July 13, but a large number of the men reported on the Friday and Saturday preceding. The works are now running full time.

TAPER BORING ATTACHMENT FOR THE TURRET LATHE

The cream separator bowl is full of headaches—for the producer. On account of the weight and thickness of the stock it is very hard to draw up, and as it must run very truly, it must be machined all over carefully.

At the plant of the King Sewing Machine Co., Buffalo, N. Y., which makes cream separators, as well as sewing machines, the bowls are finished very carefully, so that they will run at high speed and still be in balance. This requires that the inside of the bowl be machined perfectly concentric with the outside at all points, and for the purpose of finishing the inside of the tapered part of the bowl, as well as the straight part, the Warner & Swasey turret lathe is used, as shown

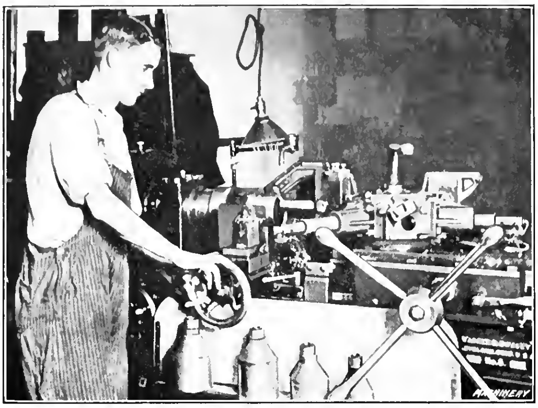


Fig. 1. Taper-boring Operation on Cream Separator Bowls

in the illustration Fig. 1. Fig. 2 shows the details of the taper-turning attachment, and Fig. 3 shows the cream separator bowl itself; in this illustration the surfaces that this taper-turning attachment machines on the inside of the bowl are indicated. It will be seen that the work done by this attachment consists of boring the straight section and then dropping to do the taper section with the same tool.

Referring now to the detail photograph, Fig. 2, the operation of the device may be seen. The tool itself is shown at *A*, being held on toolpost *B* that is made fast in the vertical tool-slide *C*. The tool-slide is fitted into a vertical bracket which is held on the face of the turret in the same manner as the other turret tools. At the upper part of vertical slide *C* is a roller mounted on stud *D*. This roller travels in a groove in the fixed bracket *E* at the rear of the machine. This groove is parallel with the line of turret travel for a short distance and then deflects downward on a taper of 36 degrees, to produce the required taper of the cream separator bowl. When the turret is brought forward for this operation, the cut continues parallel with the ways until the deflection in the slot on bracket *E* is reached. At this point the roll on stud *D* is

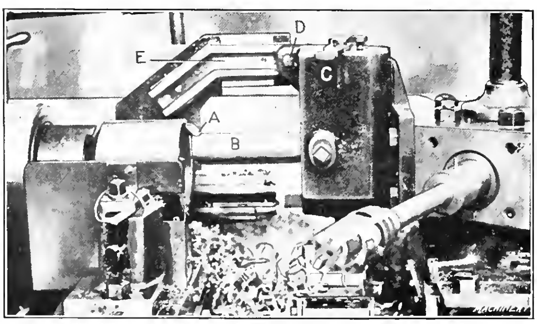

Fig. 2. Taper-boring Attachment

caused to travel downward as well as forward and carries with it the vertically moving slide *C* and also the toolpost *B* and the tool *A*. It should be noticed that tool *A* is sharpened at an angle which will be correct for cutting on the straight section as well as the inclined section. C. L. L.

HEAT-TREATING CASEHARDENED CARBON STEEL

The following practice for heat-treating casehardened carbon steel was recommended and adopted at the Atlantic City meeting of the American Society for Testing Materials, and referred to the members for letter ballot.

1. When hardness of case only is desired and lack of toughness or even brittleness is unimportant, the carburized objects may be quenched from the carburizing temperature, as for instance, by emptying the contents of the boxes into cold water or oil. Both the core and the case are then coarsely crystalline.

2. In order to reduce the hardening stresses and to decrease the danger of distortion and cracking in the quenching bath, the objects may be removed from the box and allowed to cool before quenching to a temperature slightly exceeding the critical range of the case, namely, 800 to 825 degrees C. Both the core and case remain coarsely crystalline.

3. To refine the case and increase its toughness, the carburized objects should be allowed to cool slowly in the carburizing box within the furnace or outside to 650 degrees C., or below, and should then be reheated to a temperature slightly exceeding the lower critical point of the case (in the majority of instances a temperature varying in accordance with the carbon content and thickness of the case between 775 and 825 degrees C., will be suitable), and quenched in water, or, for greater toughness but less hardness, in oil. The objects should be removed from the quenching bath before their temperature has fallen below 100 degrees C. This treatment is more especially to be recommended when the carburizing temperature has not exceeded 900 degrees C. It refines the case but not the core.

4. To refine both the core and the case and to increase their toughness, the objects should be allowed to cool slowly from the carburizing temperature to 650 degrees C. or below and should then be (*a*) reheated to a temperature exceeding the critical point of the core, which will generally be from 900 to 950 degrees C., followed by quenching in water or in oil; and (*b*) before they have cooled below 100 degrees C., they should be reheated to a temperature slightly exceeding

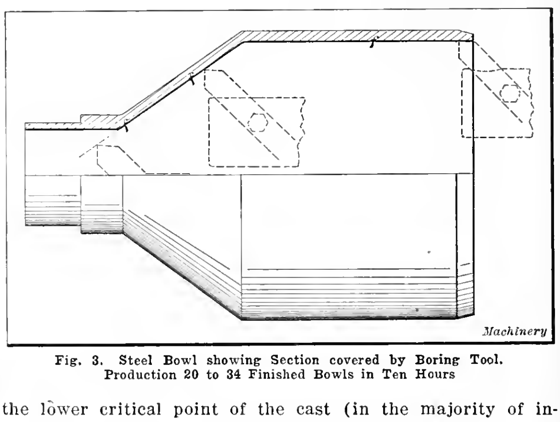

Fig. 3. Steel Bowl showing Section covered by Boring Tool. Production 20 to 34 Finished Bowls in Ten Hours

the lower critical point of the cast (in the majority of instances a temperature varying in accordance with the carbon content and thickness of the case between 775 and 825 degrees C. will be suitable), and again quenched in water or oil.

The objects should be removed from the quenching bath before they have cooled below 100 degrees C., in order to lessen the danger of cracking, and they should be placed in the reheating furnace while still at a temperature of at least 100 degrees C., likewise to lessen the danger of cracking, it being inadvisable (*a*) to allow steel to cool completely in the quenching bath and (*b*) to place hardened steel in a hot furnace. Obviously, if the furnace is cold the hardened steel may likewise be cold when placed in it for reheating.

5. In order to reduce the hardening stresses created by quenching, the objects, as a final treatment, may be tempered by re-heating them to a temperature not exceeding 200 degrees C.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

VAN NORMAN AUTOMATIC RADIAL GRINDER

The Van Norman Machine Tool Co., Waltham Ave., Springfield, Mass., is now building a No. 3½ automatic radial grinder for grinding raceways in cups, cones, or end-thrust rings for ball bearings. After the machine has been properly adjusted and the work set up in the work holder, the wheel is brought in cutting contact with the raceway, after which the operation is entirely automatic. Two important advantages are obtained in this way: first, one operator is able to look after a group of machines, so that the production cost is materially reduced; second, the precision of the machine rather than the skill of the operator is responsible for the accuracy of the work, so that it is possible to employ less highly trained help for grinding the raceways of the highest grades of ball bearings. This, of course, means a further reduction of production costs. Where a considerable amount of stock is to be removed, it has been found desirable to rough- and finish-grind in two operations. One machine or group of machines is arranged for the roughing cut, using a coarse wheel and operating with a fast feed. The finishing cut is done with a fine wheel and slower feed. These machines are built in two styles. Fig. 1 illustrates the machine for grinding single-row ball-bearing races, while the machine for grinding double-row races is shown in Fig. 2. The general design of these machines is the same and the description applies to both except that a detailed description is given of the means for shifting the work-head in grinding double-row bearings on the machine shown in Fig. 2.

Fig. 1. Van Norman No. 3½ Automatic Radial Grinder for grinding Single-row Ball Bearings

The most obvious features of these machines are their compact and rigid construction, and the provision of handy appliances which facilitate setting up the work and operating the machine. The extreme nicety which is required in the making of high-grade ball bearings to insure accuracy and interchangeability of parts is so well known that it requires no comment. This high degree of accuracy makes it necessary for grinders used in finishing ball bearing parts to be so constructed that there is practically no vibration. Particular attention has been paid to this point in designing these new Van Norman grinders. Referring to the illustrations, it will be seen that the slides upon which the work-head and wheel-head are mounted are located directly over the main frame of the machine. The slides are of unusually massive construction, which, together with the way in which they are supported, reduces vibration to a minimum. The work which different manufacturers grind on these machines varies considerably in shape and size. For this reason no standard style of work-holding equipment is sent out with the machines. The work-holding head oscillates about a vertical pivotal center, in order to obtain the required curvature of the race, and the necessary depth is obtained by the cross-feed of the wheel-head.

In preparing one of these machines for operation, there are three settings to be made: First, the work-head must be positioned by adjusting the upper head slide so that a line through the center of the path of the raceway to be ground will be exactly over the vertical pivotal center. Second, the work-head is positioned by means of the cross-slide of the head so that the radial center of the raceway is exactly over the vertical pivotal center. Third, the grinding wheel must be brought to the correct grinding position over the pivotal center. These settings of the work-head and grinding wheel are accomplished by means of a series of stops used in conjunction with plugs or distance gages of the required lengths which are placed between the stops. This will be better understood by the following description, which explains the method of procedure for each case.

Fig. 2. Van Norman No. 3½ Automatic Radial Grinder for grinding Double-row Ball Bearings

As a typical example of making the transverse setting, suppose it is required to grind a race in which the diameter of the ball center circle is 1.5 inch. It will be necessary to locate the head 0.750 inch off center, and this is done by means of a plug or gage, the length of which is exactly 0.750 inch. When in contact, the stops shown at *A* in Figs. 1 and 2 locate the central axial line of the work-holding spindle exactly over the vertical pivotal center of the oscillating head, while the stops shown at *B* in Fig. 3 locate the shoulder on the spindle exactly over the pivotal center when these stops are in contact. The 0.750-inch plug or gage is placed between the stops shown at *A* in Figs. 1 and 2, and the slide brought up so that both stops engage the ends of the plug. The cross-slide of the work-head is then locked in this position. The next step is to move the work-head back the required distance so that the radial center of the race held in the work-holder is exactly over the axis about which the head swings. For this purpose the shoulder near the front end of the spindle is made the reference point, and this shoulder is exactly over the axis about which the work-head swings when the stops *B* are in contact. Suppose that a work-holding fixture of the form shown in Fig. 4 is used, in which the distance from the reference point on the spindle to the face of the work-holding fixture against which the race is held is 1.250 inch. Further, assume that the race is 0.750 inch wide. Under these conditions it will obviously be necessary to have the reference point on the spindle 1.625 inch from the axis about which the work-head oscillates. This is done by means of a second plug or gage 1.625 inch in length placed between the stops *B* on the longitudinal slide of the work-head, which is shown in Fig. 3.

The next step is to locate the grinding wheel over the center line of the work, as indicated at the left-hand side of Fig. 4. The wheel-head is mounted on a slide which is moved back and forth by means of a hand-operated rack and pinion. When the wheel is in the working position, the adjustable stop shown at *C* in Figs. 1 and 2 is in contact with its bearing on the frame of the machine. In order to true the wheel, the work-head is moved around to its central position, where a plunger *D* enters a hole in the swivel slide support and holds the truing device securely in place. In this position the post *E* upon which the diamond holder is mounted is properly located. The distance between the axis about which the work-head oscillates and the center of the stud upon which the truing device is mounted is approxi-

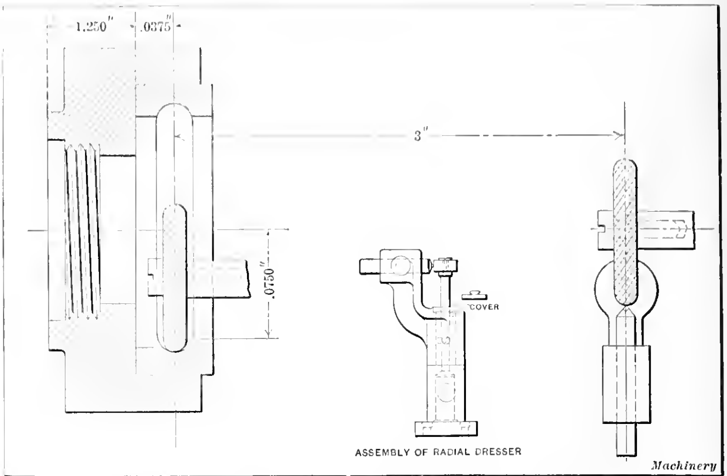

Fig. 4. Diagram showing Method of setting up the Work and truing the Wheel

mately 3 inches. In order to true the wheel, it is obviously necessary to move it back to the diamond point, and this is accomplished by means of the distance plug shown at *F* in Figs. 1 and 2, the length of this plug corresponding to the distance between the vertical pivotal center and the center of the stud *E*. In starting to true the wheel, the wheel-slide is released and moved back rather more than 3 inches; after which the 3-inch distance plug is swung into place and the slide moved forward to bring the stop *C* into contact with it. This locates the wheel in the correct position for truing.

With this preliminary statement, the method of procedure in setting up a new wheel in correct relation to the work may be explained. With the stop *C* in contact with the distance plug *F*, the wheel is brought into contact with the diamond point, which may be swung back and forth about its stud. The first step is to locate the wheel in such a position that the diamond point is centrally located in regard to the wheel. If it is found that the wheel is not located centrally on the diamond point, the adjustable stop *C* is regulated until the wheel is brought into the required position. This also locates the wheel in the correct relation to the work, because when the wheel has been trued, the distance plug *F* is removed and the wheel-slide brought forward to bring the stop *C* up against its bearing on the frame of the machine, causing the slide to be advanced exactly 3 inches. This brings the wheel central in regard to the work. After the wheel has been used for such a length of time that it requires truing, it is merely necessary to move the wheel-slide back and engage the stop *C* with the distance plug *F*, as previously described, and then swing the diamond point back and forth across the periphery of the wheel.

Fig. 4 also shows a detailed view of the device for truing the wheel. The stud upon which the wheel-truing device is mounted is secured to the base of the oscillating head; and the method by which the wheel truing device is located in line with the spindle of the wheel-head has already been described. Referring to the assembly view shown in Fig. 4, it will be seen that the bracket in which the diamond holder is mounted is slipped over the stud and held in place by a binding screw. It is obviously necessary to have the diamond holder located in different positions in the bracket when tru-

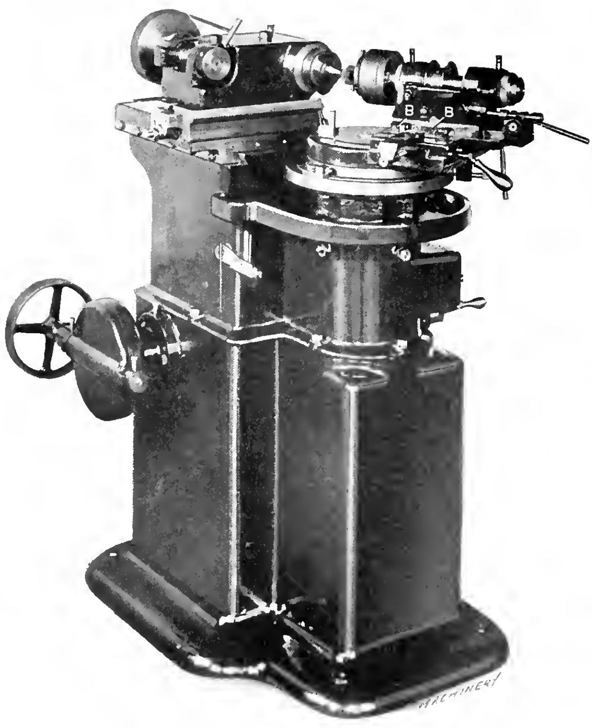

Fig. 3. Rear View of the Van Norman No. $3\frac{1}{2}$ Automatic Radial Grinder

ing wheels for grinding races of different radii. This is conveniently accomplished by having a small disk, the diameter of which is the same as the radius of the raceway to be ground, set up on a pin which slips into a hole in the bracket, as shown in the illustration. With the proper sized disk in place, the diamond point is brought into contact with the disk, after which the binding screw is tightened to secure the diamond holder in place. With this device any operator is competent to adjust the diamond point for truing the wheel to the correct radius, provided he has been given a disk of the proper diameter. The bracket and diamond holder which it carries are swung back and forth on the stud to true the wheel.

The wheel-head is arranged for both automatic and hand cross-feed. Power for the automatic feed is provided by the lower pulley shown at the right-hand side of the machine in Figs. 1 and 2, the power being transmitted through gearing to a vertical shaft inside the column of the machine, which is shown at *H* in Fig. 5. At the top of this shaft there is an edge cam *I*, on the upper side of which the face cam *J* is located. Each revolution of the shaft *H* brings the face cam *J* into contact with the plunger *K*, causing this plunger to be raised. The motion is transmitted by the plate *G* to the plunger *L* which actuates the pawl *M*, this pawl being adjustably set to pick the required number of teeth on the feed ratchet wheel. Each tooth of the ratchet wheel gives a cross-feed of 0.000025 inch to the wheel-head. The ratchet wheel is provided with a shoe which may be set to disengage the automatic feed at any point. When the pawl has moved the ratchet wheel around to the limit of the required motion, the shoe comes under the pawl, disengaging the feed. When so desired, the pawl *M* may be swung back out of engagement with the ratchet wheel and the small lever *N* used to feed the wheel-head by hand. Pushing down this lever causes the ratchet wheel to be turned by the second pawl shown in the illustration. Manufacturers using this grinding machine have found that the amount of wear developed in the grinding wheel in grinding each race can be accurately determined. For instance, one manufacturer has found that for the wheels and stock which he uses, the wheel is worn 0.00025 inch for each race. This wear is easily compensated for by setting the shoe on the feed ratchet after grinding each race, so that the wheel-head is fed in the necessary additional distance to compensate for the wear of the wheel.

Power for oscillating the work-head is also taken from the shaft *H*. The edge cam *I* mounted at the top of this shaft engages with a roller carried by the lever *O*. As the cam *I* rotates, the lever *O* moves to the left and transmits motion through the connecting-rod *P*. This rod is secured to the double disk *Q* which is loosely mounted on a pivot that rotates the work-head. It will be seen that the disk *Q* is made in two parts, which are secured together by two bolts, the heads of which fit in T-slots in the lower disk. By loosening these bolts, the two sections of the disk *Q* may be adjusted in relation to each other in order to regulate the field of oscillation of the work-head. The angle through which the work-head oscillates may also be adjusted by regulating the position of the crankpin which secures the connecting-rod *P* to the lever *O*. Below the double disk *Q* there is a block splined to the pivot that rotates the work-head. This block carries a tapered pin which enters a hole in the disk *Q* when it is desired to have the work-head oscillated by power.

When it is required to have the work-head free so that it may be oscillated by hand, the lever *S* is swung over to the left. This draws the tapered plunger down out of the disk *Q*, leaving the disk free to oscillate about the pivot without causing the work-head to move. The head may then be swung back and forth by hand. When it is again desired to

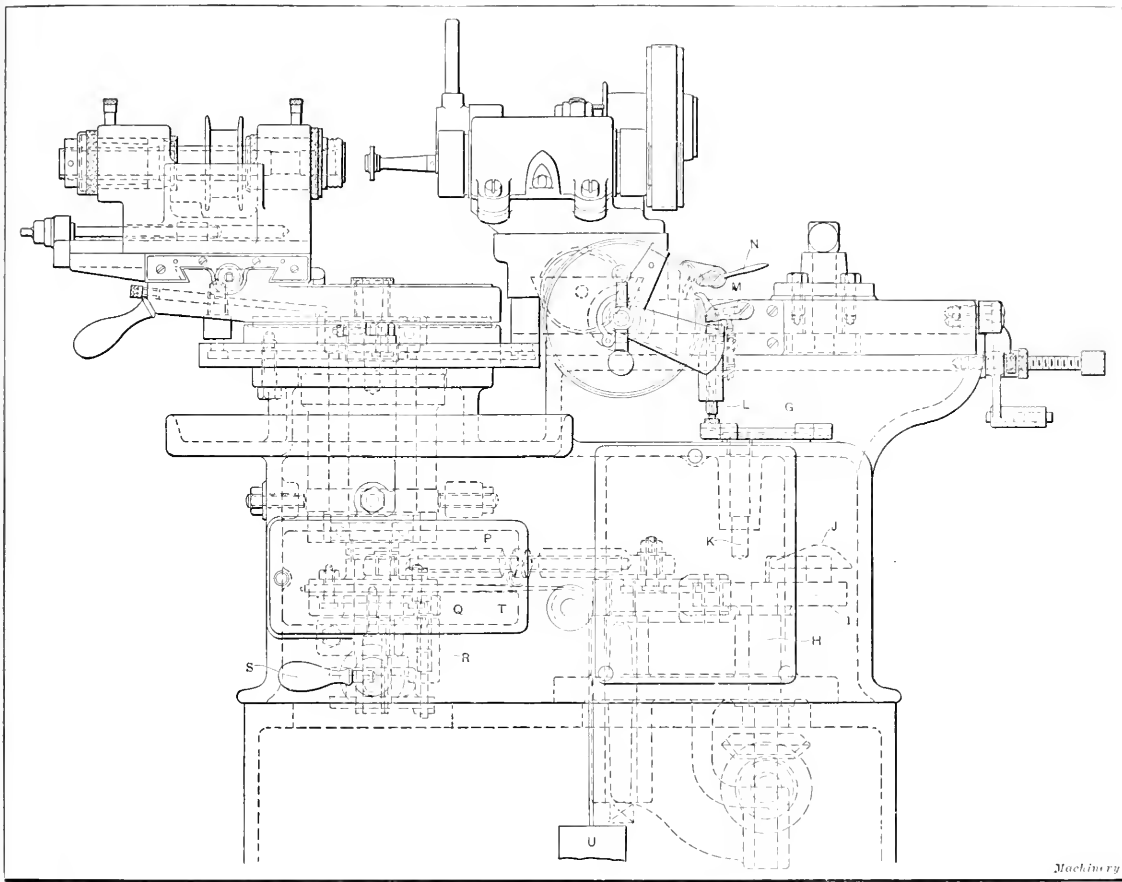

Fig. 5. Front Elevation of the Van Norman No. 3½ Automatic Radial Grinder

bring the power oscillation into action, the handle S is moved to the right. This releases the plunger which is pushed up against the bottom of the disk Q by a compression spring, and when the hole in this disk comes over the plunger, the latter is pushed up, thus connecting the disk with the pivot and bringing the power oscillation into action. The forward oscillation of the work-head is controlled by the cam I, as previously described, and when the high point of this cam has been passed, the work-head is returned through the action of the chain T and counterweight U, the movement being controlled by the contour of the cam. A very smooth motion is secured in this way, as the cam and roller which govern the oscillation of the head are always held in contact with each other and there is no lost motion.

Fig. 1 shows the machine for grinding the races of single-row ball bearings, while a machine for grinding the races of double-row bearings is illustrated in Fig. 2. These two machines are identical except that the one shown in Fig. 2 is provided with means for shifting the work after the first race has been ground, to bring it into position for grinding the second race. Referring to the illustration, it will be seen that there are two straight levers at the extreme left. In shifting the work, the operator swings the first of these levers over with his right hand. The lever turns a pinion which meshes with a rack on the cross-slide in the work-head, and by turning the handle the work is moved back away from the wheel. He then takes the second lever in his left hand and swings it over. This lever turns a second pinion meshing with a rack which actuates a longitudinal slide in the work-head. This slide causes the work to be moved over to bring it into the proper position for grinding the second race. An adjustable stop is provided on the longitudinal slide which can be set to enable the work-head to be brought into position for grinding the second race. The first lever is then swung back to return the work-head into position to start grinding.

Machines of this type are built either with or without a pump and water equipment for wet grinding. The regular equipment does not include chucking devices, as the great variety of work handled by different manufacturers makes it desirable for each to make his own work-holding fixtures. The radial diamond holder for truing the wheel is part of the regular equipment but the diamond is not supplied with the holder. The work-holding head swings 9 inches, and although this machine is especially adapted for grinding raceways from the smallest diameters up to 4 inches, larger sizes can easily be ground. The vital features of these grinders are protected by patents issued and pending. The net weight of the machine is 1600 pounds.

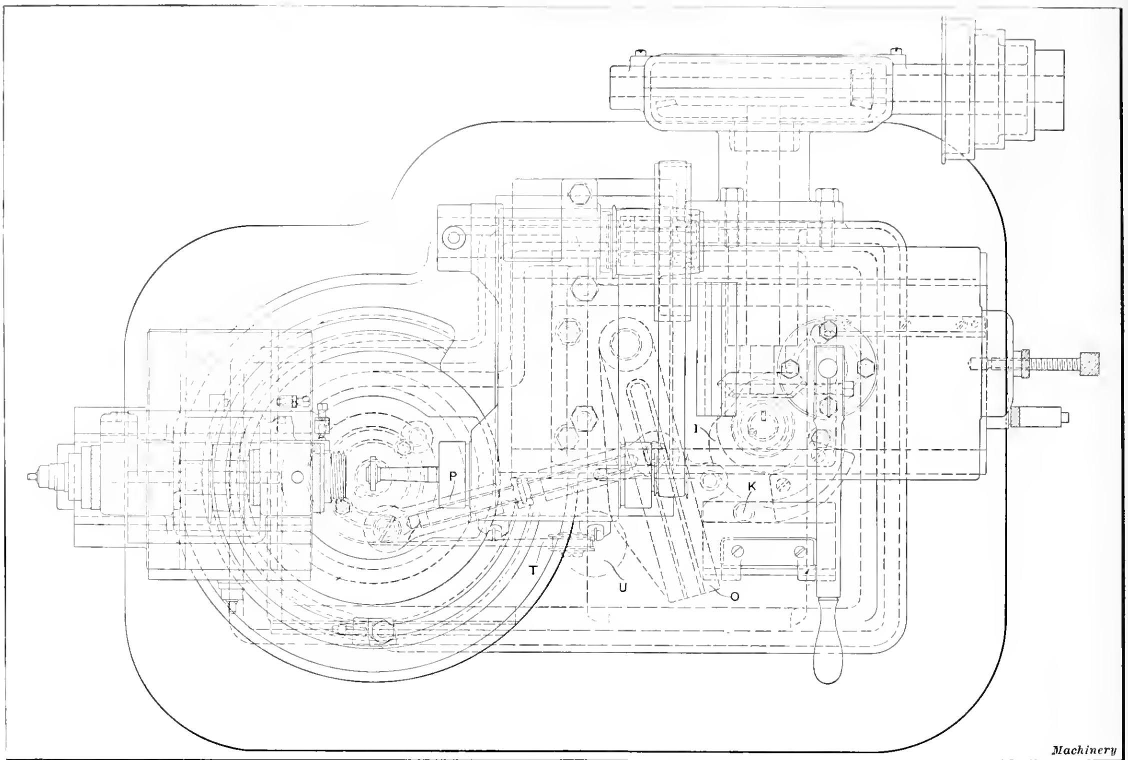

Fig. 6. Plan View of the Van Norman No. 3½ Radial Grinder

"UNIDRAFT" DRAFTING FABRIC

The Universal Drafting Machine Co., Cleveland, Ohio, is about to place a new drafting fabric upon the market which provides for making drawings and blueprints by an entirely new process. This fabric is somewhat similar to ordinary tracing cloth but it is covered with an opaque surface. In making a drawing on this material, the draftsman works with a pointed steel tool instead of a pencil; this tool is used exactly as a pencil would be and scrapes away the opaque surface along the lines which make up the drawing. This exposes the transparent fabric to permit the passage of light. In making blueprints from such drawings, the method of procedure is exactly the same as where ordinary tracings are used, but as the lines are transparent and the remainder of the drawing opaque, it will be evident that the resulting blueprint has blue lines on a white background instead of white lines on a blue background.

The use of this material eliminates the necessity of making a tracing either for the purpose of producing blueprints or for providing a clear and durable drawing for future reference. The lines are clean cut and drawings may be made on this material just as rapidly as it is possible to make them on paper with an ordinary drawing pencil. The surface of the "Unidraft" fabric is a dull brown which reflects very little light into the draftsman's eyes, thus reducing eye-strain and troubles resulting from this cause. The elimination of the necessity of making tracings is the means of effecting a considerable saving on each drawing, and where there are a great many drawings to be made on a single job, there is also a great reduction of the time required to get out

a complete set of drawings. Another advantage is that all errors due to tracing are eliminated and the checking and correcting of drawings is materially simplified, because the lines stand out far more distinctly than the lines of an ordinary pencil drawing.

It will be evident from the preceding description that it is possible to make a blueprint at any time before the drawing is completed and this is often a very valuable feature in the case of drawings showing general layouts. As the surface of "Unidraft" is a dull brown, it does not show dirt, which is another point that will be appreciated by those who have had experience in the making of drawings which are worked on for a considerable length of time, or with drawings which are allowed to lie about in places where there is

Fig. 3. Enlarged View of Tool used to Draw on "Unidraft"

covered with an opaque brown surface which is cut through by a steel pointed instrument. This exposes a white line which stands out in strong contrast to the dark background. An idea of how strongly the drawing stands out will be

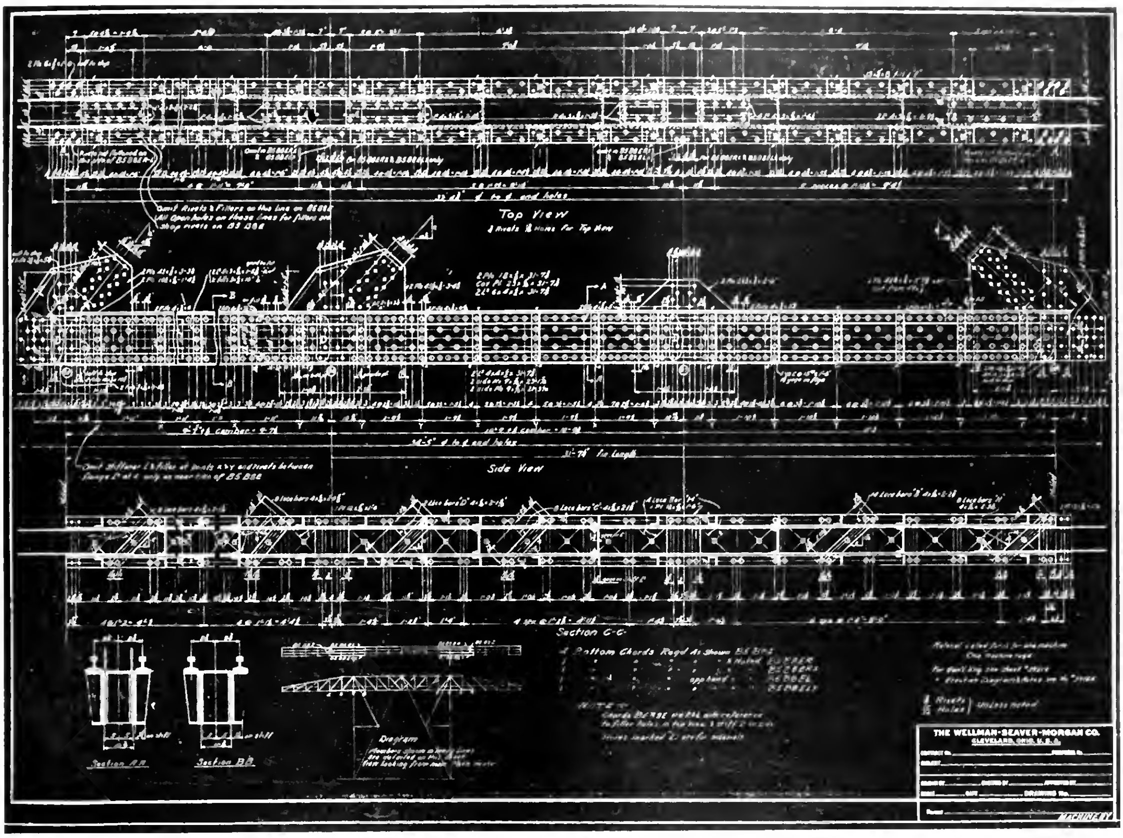

Fig. 1. Example of a Complicated Structural Drawing made on "Unidraft"

a lot of dust and dirt. Another point in favor of "Unidraft" is that the necessity for sharpening pencils is eliminated because the draftsman works with a steel tool which does not change its shape.

It has already been mentioned that "Unidraft" fabric is gathered from the illustrations which show reproductions of several drawings made on this material. Fig. 1 shows quite a complex structural drawing, while Fig. 2 illustrates a relatively simple design. It must be clearly understood that this material is applicable for use in making the most complicated mechanical and structural drawings and for all other classes of drawings which can be made with pencil and then traced. It is just as easy to erase a mistake made on "Unidraft" as it is to erase a line from a pencil drawing, and considerably easier than it is to erase an ink line. The erasing is done with an ordinary writing pen which inks in the line that it is desired to erase; erasing on "Unidraft" is merely a matter of replacing the opaque surface where it has been taken off by mistake. Either straight or curved lines can be erased in this way and after the erasure has been made, it is possible to redraw any part of the line with the steel tool. In the event of it being desired to change a full line into a dotted line, this is very easily done by simply dotting in the spaces with ink.

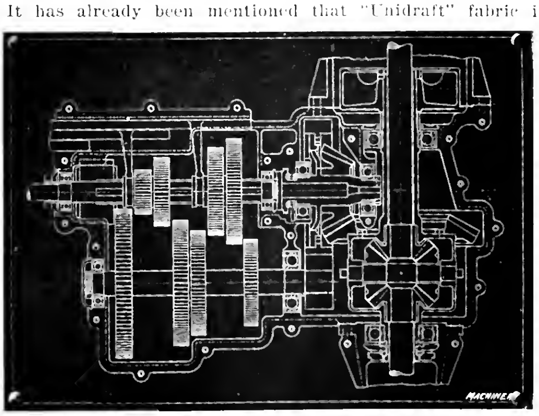

Fig. 2. Simpler Drawing—Note how the Lines stand out

It has already been stated that the blueprints of these drawings have blue lines on a white background, but where so desired, the blueprints may be reversed. The width of the line may be varied by varying the pressure on the point

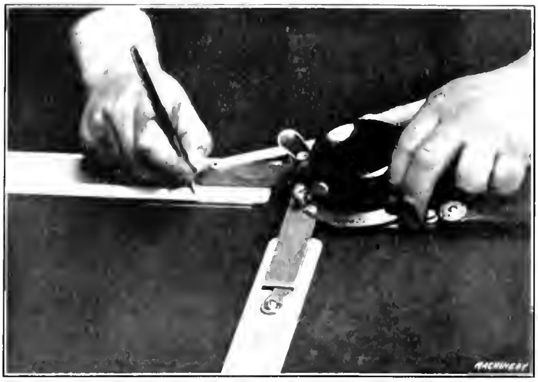

Fig. 4. Method of drawing Straight Lines on "Unidraft"

of the tool in the same way that the width of a pencil line can be varied by varying the pressure. The fabric may be worked on with a drafting machine and with the usual drafting instruments without scratching its surface except at those points where it is desired to draw the lines. Blueprints of drawings on "Unidraft" are made at about the same speed as blueprints of ordinary tracings.

Fig. 5. How Free-hand Lettering is done

It is stated that it is easier to learn to draw on "Unidraft" fabric than to learn to make a good tracing. The cost of making drawings is reduced because the original drawing can be used to make blueprints without requiring a tracing to be made. This saves the cost of tracing cloth, pencils and ink, and also the expense of a tracer's time. The elimination

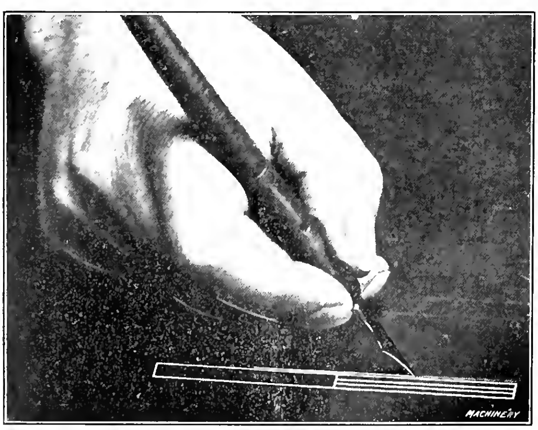

Fig. 6. The Use of an Ordinary Pen to erase a Line

of errors produced in tracing is an important feature, and as the drawing stands out exceptionally clear on the dark background, it is easier to check than it is to check a pencil drawing which often becomes somewhat indistinct before it is completed.

Figs. 1 and 2 show reproductions of drawings made on "Unidraft," and these illustrations give a good idea of the clearness with which the lines stand out. Fig. 3 is an enlarged view of the instrument used for drawing the lines. It will be seen that the point of this instrument is rounded and fine limit lines for lettering may be made by using the tool

Fig. 7. A Bow-pencil provided with a Steel Drawing Point

edgewise. Fig. 4 shows the method of procedure in drawing straight lines and emphasizes the point that the lines come up clearly and distinctly as they are drawn. In Fig. 5, free-hand lettering on "Unidraft" is being done and Fig. 7 shows the use of a bow-pencil provided with a steel point for drawing circles and arcs on this material. In Fig. 6 the drafts-

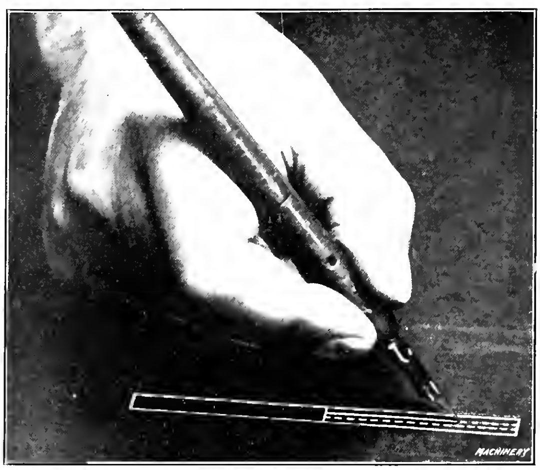

Fig. 8. A Full Line is easily converted into a Dotted Line

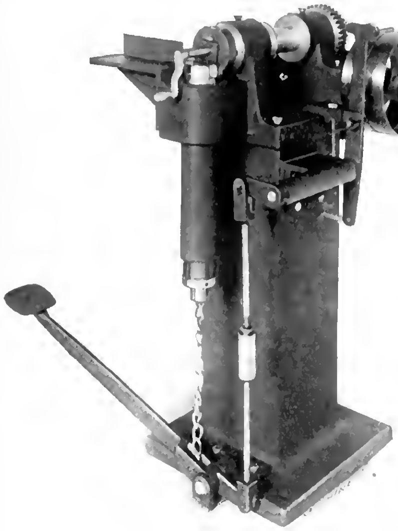
man is using an ordinary pen and ink to erase a line and it will be seen that the portion of the line already erased is to the right of the pen-point. Fig. 8 shows how a full line is easily converted into a dotted line by simply inking in intermediate spaces.

GARVIN COPPER COIL FORMING MACHINE

The machine shown in this illustration was designed to coil copper field coils for automobile lighting systems, taking the copper in strips and coiling it together with a strip of insulation on a rectangular arbor. The copper strip is not only cut to length, but has a right-angle bend at one end, which is used for dogging purposes. A powerful spring keeps the work against the arbor and is controlled by a foot treadle. The machine trips automatically on the completion of three revolutions of the spindle. The coils are stripped off the arbor by turning the crank handle shown in the



Garvin Copper Coil Forming Machine

center of the spindle. The next strip is put in place and the machine will start immediately on removing the foot from the treadle. Other metals can be used in place of copper, and the number of coils and their shape can be changed to suit the work. The machine is manufactured by the Garvin Machine Co., Spring and Varick Sts., New York City, and weighs 665 pounds.

CRESCENT WOOD SURFACER

To meet the requirements of shops that have work which is too heavy for the 24-inch Crescent planer, the Crescent Machine Co., 56 Main St., Leetonia, Ohio, has recently placed on the market a 26-inch machine, two views of which are shown in Figs. 1 and 2. The design is heavy and compact, requiring little floor space, but providing a capacity for handling lumber of large dimensions. There are four feed rolls, all of which are driven by flanged pulleys on each end of the machine. The feed is of the Crescent variable friction

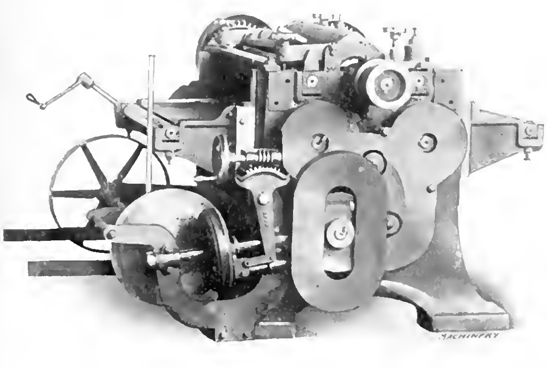


Fig. 1. Crescent 26 by 8-inch Wood Surfacer

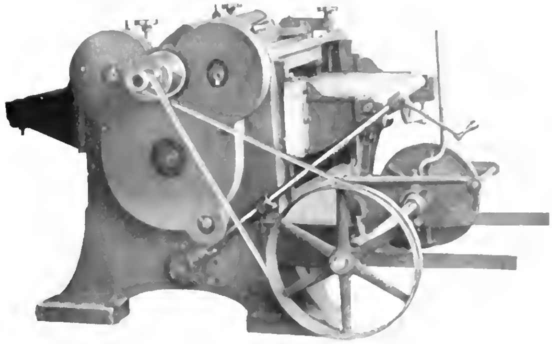

Fig. 2. Opposite Side of Crescent Surfacer shown in Fig. 1

type which has found successful application on other styles of planers built by this company. The range of feed is from 15 to 60 feet per minute, and a pointer and scale are provided for setting the machine for the proper feed.

The pressure of the upper feed rolls is obtained by springs, which some shops have found to be undesirable owing to the fact that the springs are not easily adjusted for different pressures, and because a foot treadle cannot be used to provide additional pressure when it is necessary. These difficulties have been overcome by providing a small handwheel at the top of the machine which may be turned until the desired amount of pressure is obtained. The pressure is quickly adjusted in this way and any pressure up to 600 pounds may be readily obtained. Additional pressure may be secured by operating either of a pair of foot levers. The springs which control the pressure of the rolls are flexible, and they act quickly and uniformly so that the machine is not subjected to uneven strains. The head is usually furnished with two knives, but a four-sided head may be obtained on special order. The countershaft for driving the machine is ordinarily mounted on the ceiling or it may be set on the floor back of the machine where such an arrangement is found more convenient.

"LITTLE DAVID" RIVET SET RETAINER

To provide for the safety of the operators of the "Little David" riveter of its manufacture, the Ingersoll-Rand Co., 11 Broadway, New York City, has recently provided a rivet set retainer for use on this tool. This attachment consists of but a single piece of heavy spring steel, closely wound into a spiral form. One end of this spring fits over the outside of

"Little David" Riveter equipped with an Improved Rivet Set Retainer

the hammer nozzle and hooks over a projection integral with the nozzle. The other end is wound to a smaller diameter. Sets for rivets over 7/8 inch diameter are formed with a coarse thread and are simply screwed into place. Sets for rivets 7/8 inch diameter and smaller are formed with a shoulder and are slipped into the retainer while it is detached from the hammer, the shoulder holding it in place. The device positively prevents the rivet set or piston from being driven out, even when the hammer is run free.

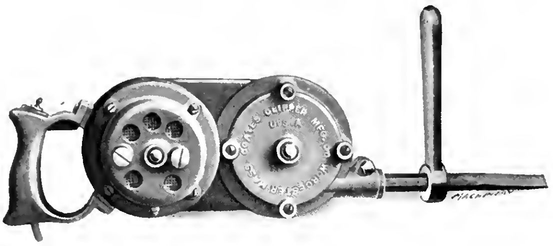
Other important improvements have been embodied in the "Little David" riveter. There is but a single ground joint between handle and barrel, and these parts are securely held together by two bolts, one on each side of the barrel. This construction eliminates the need of a vise in taking the tool apart for inspection, a feature of value to the structural worker, as well as to others who are not usually equipped with

special facilities for repair work. There are no threaded joints on the barrel. The valve chamber is placed beside and parallel to, instead of in line with the cylinder, obviating any possibility of injury to the valve by the piston. This construction gives a very much shorter tool, adding to its usefulness, as it can be used in closer quarters.

"Little David" riveters are made with either outside or inside types of triggers, in five regular sizes adapted for all kinds of riveting work. In addition, there are two sizes of jam riveters which have an exceptionally short over-all length, making them peculiarly well adapted for riveting in very cramped quarters.

COATES CENTRIFUGAL CHIPPING HAMMER

One of the recent products of the Coates Clipper Mfg. Co., Worcester, Mass., is an electrically driven centrifugal chipping hammer. This tool has found successful application in chipping castings, cleaning the bottoms of ships while in drydock, making bolt holes in concrete and a variety of similar classes of work. Power is supplied by a 1/5 horsepower electric motor which is connected to the centrifugal hammer by spur gears. There is a spur gear on the armature spindle and



Coates electrically driven Centrifugal Chipping Hammer

a spur gear on the spindle of the centrifugal hammer, these gears being connected by an intermediate gear. The "ducking" or centrifugal hammer consists of a disk which has the hammers pivoted at its periphery. The disk rotates at high speed, and centrifugal force causes the hammers to fly out and strike the end of the chipping tool, after which they "duck" back to permit the disk to continue its rotation. The hammer delivers two thousand blows per minute on the chipping tool.

STANDARD ROLL GRINDING MACHINE

The Standard Engineering Co., Ellwood City, Pa., is now building a roll grinding machine equipped with two heads, both of which are located on the same side of the roll and arranged for grinding both the necks and bodies. The whole machine is of very massive construction so that a large amount of work can be produced without sacrificing quality. The roll is carried on dead centers and driven by a 10 horsepower variable speed motor mounted on the headstock. The motion is transmitted to the roll by two sets of worm gears entirely enclosed in an oil-tight case, and provided with ball thrust bearings. The headstock is fixed at one end of the machine while the tailstock is movable longitudinally by means of a rack and pinion. In addition to the longitudinal movement, the tailstock has also a transverse adjustment for lining up and grinding tapers. Each of the grinding heads is provided with a 26-inch wheel driven by a 15 horsepower motor mounted on the grinding wheel carriage. This motor is of the variable speed type in order that the peripheral speed of the wheel may be kept uniform as the diameter is reduced through wear. Each wheel is protected by a heavy steel guard, that can be easily removed when changing wheels.

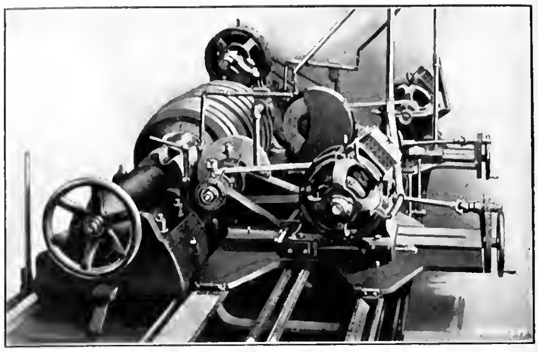


Fig. 2. Partial Plan View of Standard Roll Grinder

The longitudinal travel of each head is obtained by a screw driven by gearing and a belt from the headstock motor. This gearing has clutches for controlling the motion of the grinding head, operated by a handle which may be set at any convenient position on the front of the bed. In addition to the handle, the clutches may be operated by a stop on the carriage so as to obtain a continuous motion in both directions. This motion of the carriage may also be obtained by means of a handwheel which revolves the screw when the clutches are disconnected. The transverse travel of each grinding head is accomplished by means of a screw having a handwheel mounted on its end. In addition, another handwheel is provided which is geared to the screw for the adjustments. This last handwheel and the one for operating the carriage longitudinally are placed in positions which are convenient for the operator while watching his work. The machine is provided with devices for truing the grinding wheels, so arranged that the wheels may have their edges rounded to suit fillets in the roll necks. In addition to carrying the roll on centers, the machine is provided with housings for carrying the roll by its necks in case this method is desired when grinding bodies. These housings are adjustable so that rolls may be "crossed" or various kinds of tapered work accomplished. The machine swings 50 inches and when provided with a bed 30 feet in length, which is the size required to accommodate rolls having a length of 21 feet, it has a weight of about 80,000 pounds.

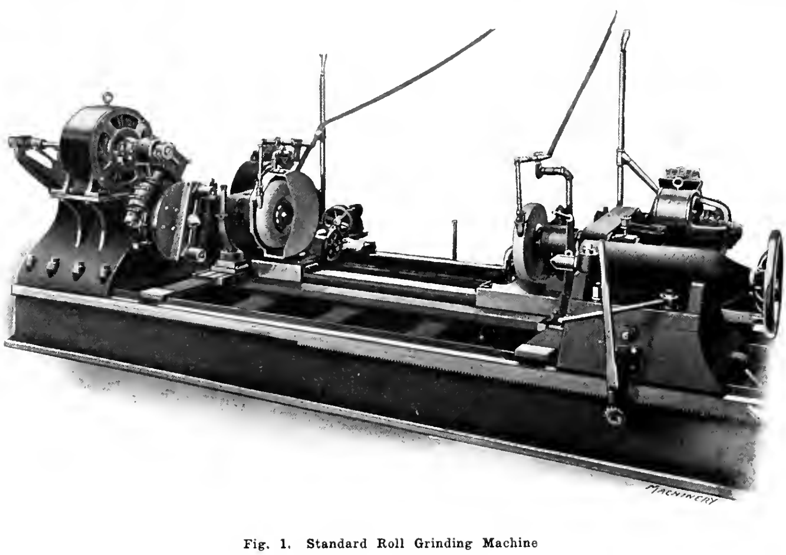

Fig. 1. Standard Roll Grinding Machine

MONARCH GEARED HEAD LATHES

To meet the demand for a lathe equipped with individual motor drive or single pulley drive, the Monarch Machine Co., Sidney, Ohio, has added to its line the 16-inch by 6-foot and the 14-inch by 6-foot machines which are illustrated in Figs. 1 and 2. Fig. 1 shows the application of motor drive, and Fig. 2 shows a machine equipped with the single pulley for taking power direct from the line-shaft. It must be understood, however, that either machine may be provided with single pulley drive or motor drive according to the requirements of the shop in which it is to be installed. The geared headstock provides eight mechanical changes of spindle speed, any of which may be instantly obtained by operating two levers at the front of the headstock. With the driving shaft running at 300 revolutions per minute, spindle speeds of 25, 40, 58, 83, 116, 182, 262 and 375 revolutions per minute are obtainable. This is a wide enough range for most classes of work, but for exceptional cases a two-speed countershaft or a variable-speed motor may be employed to extend the range.

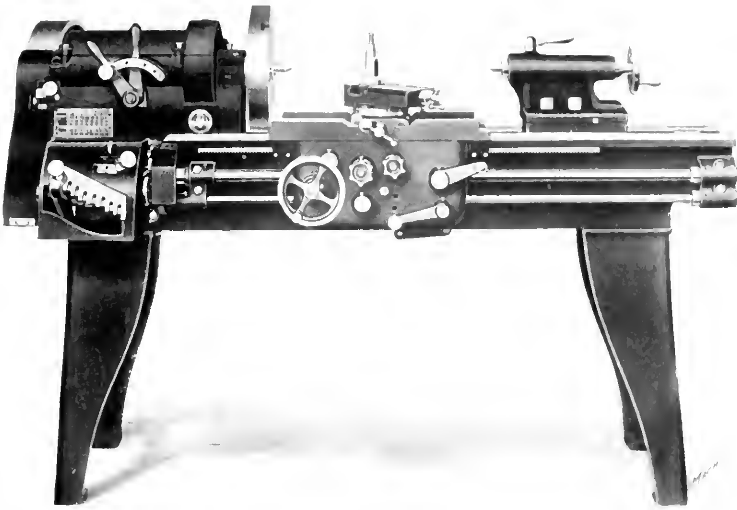

Fig. 2. Monarch 14-inch Lathe equipped with Single Pulley Drive

The geared headstock applied on these lathes is the automobile sliding gear type of transmission with positive clutches. There are twelve gears, eight of which are constantly in mesh. All of the gears have cut teeth; they are 8 pitch and $1\frac{1}{4}$ or $1\frac{1}{2}$ inch face width. All bearings are bushed with phosphor-bronze and the changes are obtained by two levers operating over segments on the front of the headstock. The gears run in oil and the bearings are thoroughly lubricated by the splash system. The headstock is oil-tight and a drain is provided so that the oil may be run out for cleaning. Provision is made for instantly stopping

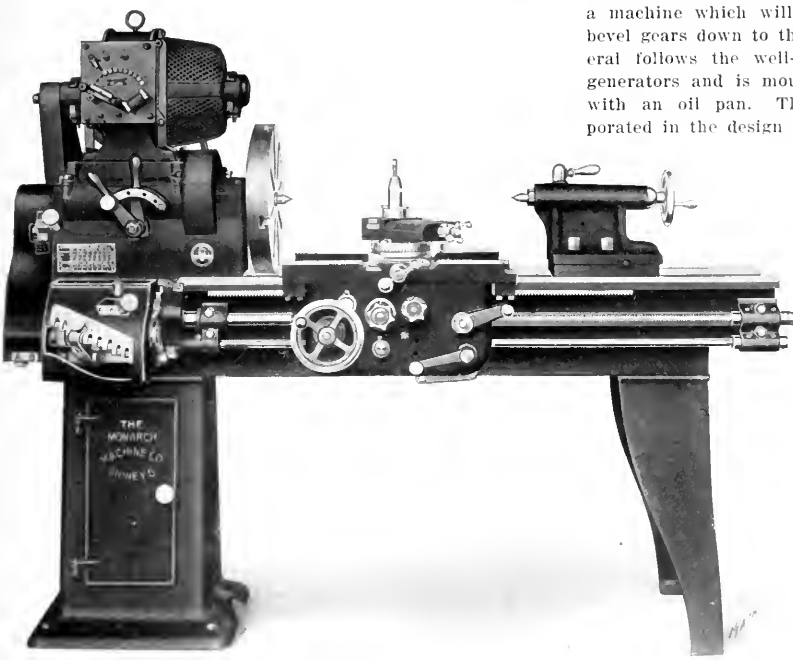

Fig. 1. Monarch 16-inch Lathe equipped with Electric Motor Drive

the spindle and then starting it again at the same speed. This is a particularly useful feature when it is required to stop the work for measuring.

For machines equipped with single pulley drive, the pulley is provided with a friction clutch which is operated by a shipper rod at the back of the lathe. Where individual motor drive is employed, a $1\frac{1}{2}$ or 2 horsepower motor is used. The motor should run at from 1000 to 1100 revolutions per minute. Where the motor is mounted on the headstock, the drive is through a silent chain, which is completely enclosed to provide for the safety of the operator. An ordinary starter such as a manufacturer would recommend for use with a constant-speed motor can be used. This starter is usually mounted as shown in Fig. 1.

GLEASON THREE-INCH BEVEL GEAR GENERATOR

The accompanying illustrations, Figs. 1 and 2, show a small size, generating bevel gear planer developed by the Gleason Works, Rochester, New York, to meet the demand for a machine which will accurately and rapidly handle small bevel gears down to the finest pitches. The machine in general follows the well-known lines of the Gleason two-tool generators and is mounted on a pedestal which is integral with an oil pan. There are several new features incorporated in the design which facilitate rapid changing of the work. Shifting the head is accomplished by means of a rack and pinion operated by a lever, and a micrometer stop is supplied for readily setting the head to any desired distance from the cone center of the machine. The distance from the apex of a gear to the back of the hub being known, to set the head in position all that is necessary is to set the micrometer stop to this distance and then bring the head up to the stop. The locking of the head is effected by means of a single locking lever.

The use of the tool gages is also simplified by supplying a limit gage 0.0005 inch over and under for length, with a separate gage for the pressure angle. The machine can be arranged for either belt or individual motor drive, and Fig. 2 shows the method of attaching the motor. This generator will handle any bevel gear not over $2\frac{1}{8}$ inches cone distance and $\frac{3}{4}$ inch face. The largest pitch recommended is 8 diametral pitch and the smallest pitch for which tools are made as standard is 32 diametral pitch. Smaller pitches can be cut, but this is limited by the tool, which must be of sufficient thickness at the point to stand up to the cut.

Fig. 1. The New Gleason 3-inch Bevel Gear Generator

The machine will generate a tooth in four seconds as the fastest, and forty seconds as the slowest speed. The extremes of tool speed are 400 strokes per minute and 120 per minute, and a slip gear arrangement is provided for throwing the tools out of gear while making changes. The indexing mechanism is positive and runs in an oil bath; and the feed mechanism is similarly provided for. All the wearing surfaces on the machine are square gibbed and the shaft bearings are bronze lined. All gears are pack-hardened, and an oil pump is part of the regular equipment. The machine weighs 1250 pounds and takes 44 by 32 inches floor space.

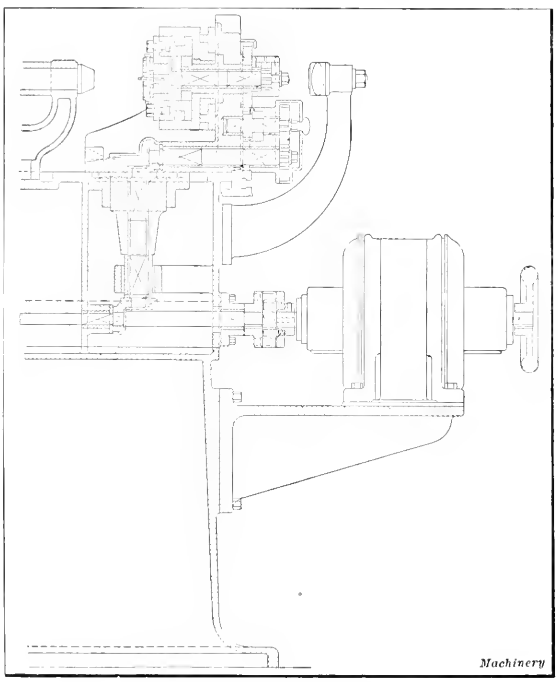

Fig. 2. Partial Cross-sectional View showing Application of Electric Motor Drive

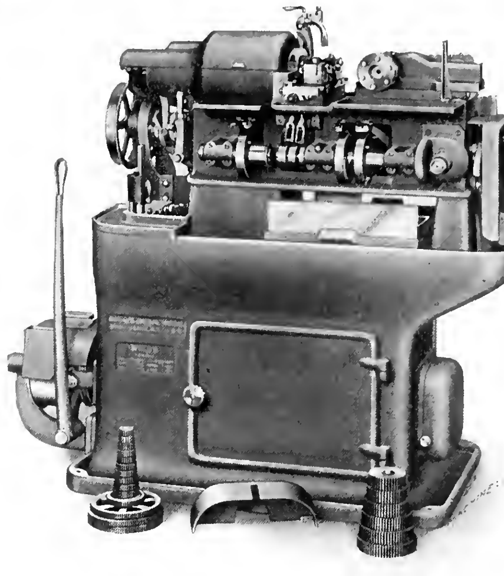
BROWN & SHARPE NO. OG AUTOMATIC SCREW MACHINE

A recent addition to the line of automatic screw machines manufactured by the Brown & Sharpe Mfg. Co., Providence, R. I., is shown in the accompanying illustration. A notable feature of this machine is the method of driving it, only one belt being used. The main driving pulley runs in one direction at a constant speed and is equipped with a friction clutch for starting and stopping, allowing the machine to be belted directly to the lineshaft, with all overhead works eliminated. Not only does this permit the belt-driven machines to be placed to much better advantage on the shop floor, but it makes the arrangement for individual motor drive comparatively simple. A constant-speed motor is employed, it being attached to the rear of the cabinet base. The main driving shaft runs through the base of the machine. Power is transmitted from this shaft to the spindle by a pair of belts, one for driving forward and one backward, an automatically operated friction clutch controlling the change.



Brown & Sharpe No. 0G Automatic Screw Machine

Speed changes are made by means of a pair of change gears located outside of the base at the right-hand end, under the hinged cover. An automatic speed change is incorporated in the driving mechanism and operated by the machine feed shaft. This serves to slow down the spindle in the ratio of 1 to 2¼ for threading and similar operations. This machine handles bar stock up to ½ inch in diameter and turns work to 1¾ inch in length. It is known as the No. OG automatic screw machine. The details of construction and operation of the driving mechanism on this machine are similar in general to those on the No. OOG automatic screw machine, which was fully illustrated and described in the April, 1913, number of MACHINERY.

"CAPITAL" GRINDER

A small rapid production internal grinder has recently been placed on the market by the Lansing Stamping & Tool Co., Lansing, Mich. This machine is rigidly built and is an accurate and economical producer. The grinding spindle is rigidly mounted and driven by two belts, which overcomes vibration or any tendency for the spindle to run out of truth. The machine is designed to finish holes from ⅝ inch to 2 inches in diameter and up to 2 inches in length. Power feed for the table is not provided, because it has been found that for a short hole more satisfactory results are obtained by using hand feed. The feed is accomplished by means of a handwheel which operates a rack and pinion. The table is of heavy construction and the ways are automatically oiled

with rolls set in the bed; this gives a particularly smooth action and makes it possible to produce work with a very high finish. Chatter marks are also entirely eliminated by this construction.

One of the principal features of this machine is the means provided for stopping the work chuck in order to gage the hole. This is accomplished by the mechanism shown in Fig. 2 which consists of a roll carried by a bracket at the back of the table which, through a tripping device, operates a clutch on the countershaft when the table is moved to the extreme of its travel. This clutch is of the conical type and furnished with cork inserts. A spring on the countershaft throws the clutch back into engagement when it is desired to start the machine. The clutch is operated by a fork at the end of a bellcrank lever which receives its motion from a tie-rod operated by a tripping dog. This dog is engaged by the roll carried on a bracket fastened to the table of the machine. As the table is thrown back out of the operating position, this roll comes into contact with the tripping dog, throws the clutch out of engagement and operates the brake, thus stopping the rotation of the work instantly. The clutch can also be thrown out by a foot lever shown in Fig. 2. The provision of this means for stopping work is of such importance that one automobile manufacturer who is using these machines for certain grinding operations has found it possible to increase his rate of production 50 per cent. Also, many parts which were formerly finished by lapping are now ground on this machine.

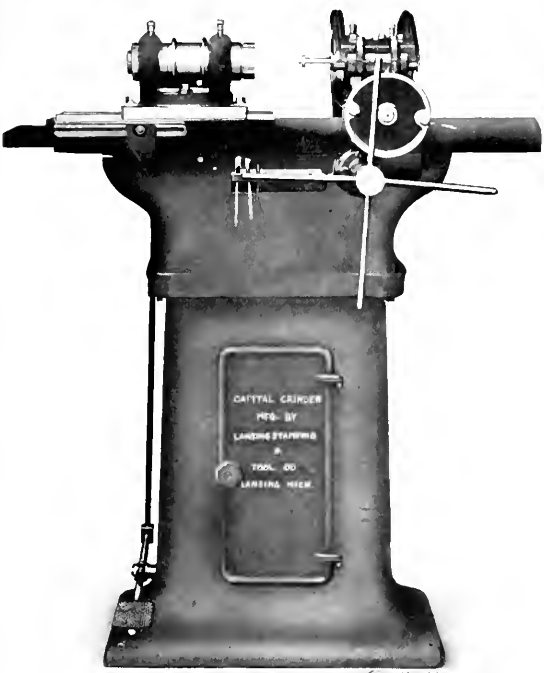


Fig. 1. "Capital" Internal Grinder

Fig. 3 shows a cross-sectional view of the headstock which is very rigid in design and provided with phosphor-bronze tapered bearings that enable adjustment to be made to compensate for wear. The spindle is fitted for carrying spring chucks but jaw chucks can also be used. The spindle is made from 50 point carbon crucible steel; it has a $1\frac{1}{4}$-inch hole through its center to provide for handling collet work and is large enough to accommodate a dust collecting pipe used in connection with the machine when dry grinding operations are being performed. The table upon which the headstock is mounted is made of cast iron; it is 36 inches long with wide V and flat ways and has oiling rollers set in the bed.

The internal grinding spindle is made of hardened and ground tool steel and runs in Hess-Bright ball bearings

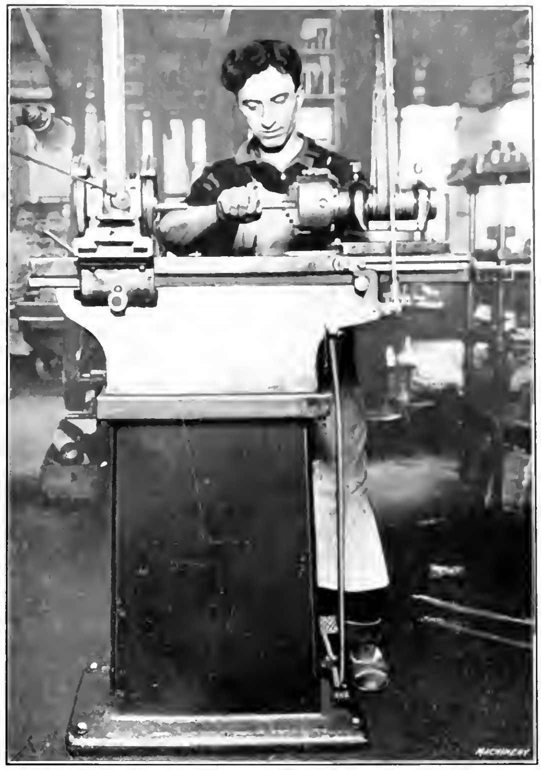

Fig. 2. Rear View of "Capital" Internal Grinder, showing how the Work Chuck is stopped automatically

which have a four-point bearing at the front and a three-point bearing at the rear. This spindle is provided with felt washers to prevent dust getting into the bearings and is capable of running at a speed of 22,000 revolutions per minute. It is driven by two belts which not only afford a steady drive but also eliminate any binding of the spindle in its bearing. This tends to equalize the belt pull and insures a true running spindle. The grinding head is set by a handwheel and dial which has two hundred graduations and can be set to 0.001 inch.

The following will give an idea of the productive capacity of this machine. On cams for automobile cam-shafts the holes in which are $\frac{7}{8}$ inch in diameter by $\frac{7}{8}$ inch long, and from which 0.008 inch has to be removed from the inside diameter, a production of 60 cams per hour is secured. The cams are heat-treated steel. Another job handled on this machine consists of grinding a hole $\frac{3}{4}$ inch in diameter by $1\frac{3}{4}$ inch long in spindle bushings, and this work is produced at the rate of sixty pieces per hour, the same amount of metal being removed from this hole as in the preceding case.

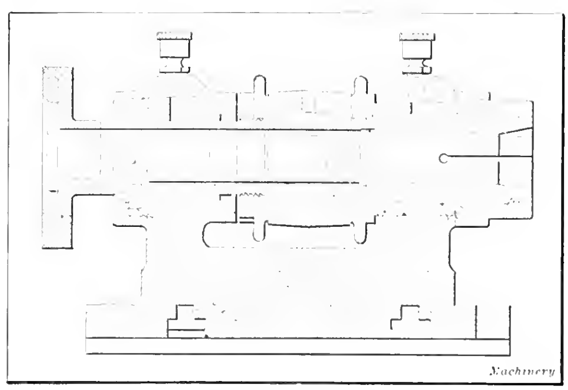

Fig. 3. Cross-sectional View of Headstock of "Capital" Internal Grinder

Bushings for roller bearings which are 1¼ inch in diameter by 2 inches long, and which are required to have an extremely high finish and to be perfectly accurate as regards the concentricity of the bore from end to end, are finished on this machine in a very satisfactory way.

As previously mentioned, the feature of this machine which makes possible such high rates of production is the fact that the work chuck can be instantly stopped for gaging the work. The machine has only one belt shifter which is operated by moving the table back. The workman can caliper the work very rapidly, and in addition to allowing him to turn out work more quickly, the machine is also capable of the highest possible accuracy. The following gives the principal dimensions of these grinders: traverse of table, 10 inches; greatest distance from wheel spindle to work spindle,

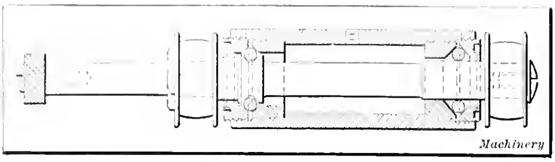

Fig. 4. Special Head for Use in grinding Valve Seats

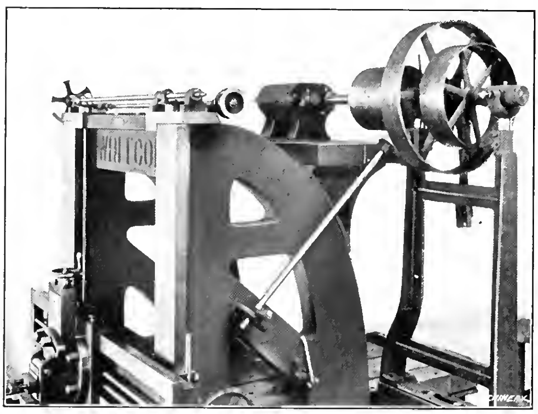
12 inches; swing of work-head over table, 8 inches; swivel of work-head, 60 degrees; size of nose on work spindle, 2 inches in diameter with eight left-hand threads per inch; and length of cross-slide, 15 inches.

WHITCOMB-BLAISDELL PLANER WITH GEARED SPEED BOX

The accompanying illustration shows a planer recently built by the Whitcomb-Blaisdell Machine Tool Co., 134 Gold St., Worcester, Mass., which is equipped with a geared speed-box. This is nothing more than the sliding gear automobile transmission applied to a planer.

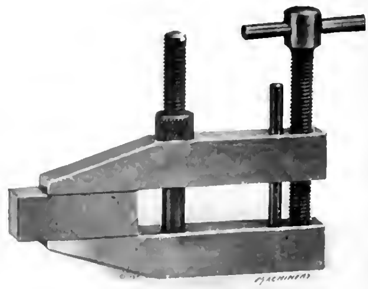
It will be seen from the illustration that the gear-box is mounted on a bracket secured to the housings of the planer. At the side of the machine there is a dial with four stations in which a spring plunger can be entered by operating a suitable hand lever. By locating the plunger in any of these holes, the corresponding pair of gears in the change gear box are engaged to give the required forward speed. The forward speed shaft telescopes inside the return speed shaft. Four cutting speeds of 25, 35, 45 and 60 feet per minute are available, and the return speed is constant at 100 feet. The illustration shows the machine equipped for belt drive, but it is a very easy matter to mount a motor on the bracket and provide the necessary gearing for individual motor drive.



Sliding Gear Speed Box for Whitcomb-Blaisdell Planer

M. B. HILL CLAMP

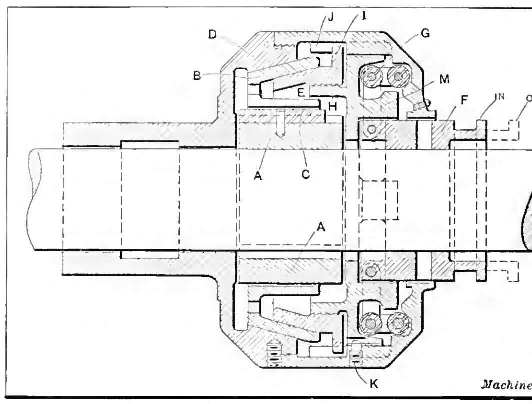
The accompanying illustration shows a clamp made by the M. B. Hill Mfg. Co., Worcester, Mass., which is so designed that one side is prevented from dropping down by means of a pin placed in front of the rear screw. This clamp can be operated with one hand, leaving the other hand free to handle the work. It is claimed that the work can be held more securely and with less strain on the screws than is possible with the old style of clamp, as the pin causes the jaws to have a more even contact on the work. These clamps are made in three sizes to meet the requirements of different classes of work.



M. B. Hill Clamp

AKRON MULTI-CONE CLUTCH

The accompanying illustration shows a cross-sectional view of the "Ideal" multi-cone clutch which is a recent product of the Akron Gear & Engineering Co., Akron, Ohio. This is what might be called a multiple-disk cone clutch and its design represents a departure from the usual types of friction clutches. In order to avoid too sudden engagement of the cones, the face angles are greater than those of the ordinary two-cone clutch, and the clutching force and pulling power lost in this way is compensated for by the addition of a third cone which practically doubles the pulling power. The cones run in oil and have oil films between them which permit the clutch to slip before the films are broken down by the contact pressure. In this way the too sudden engagement of the clutch is avoided.



Cross-sectional View of Akron Multi-cone Clutch

The design of the cones, together with the application of the oil bath, permits immediate disengagement of the clutch when it is thrown out. Very little force is required to throw in the clutch and the movement of the shifter is relatively small so that the clutch is suitable for foot control or for use in places where long levers cannot be employed. The horizontal pressure exerted by the throw-in mechanism is equally distributed over the complete surface so that there is no tendency to distort the cones. When the clutch is thrown out of engagement, the throw-in mechanism is at rest and there is no danger of centrifugal force engaging the clutch.

Referring to the illustration, the driving ring *A* is keyed to the shaft and the middle or driving cone *B* is driven from the ring *A* by means of two feather keys. Both friction surfaces of the cone *B* are provided with oil grooves. The driven cones *D* and *E* are brought into contact with the middle cone *B* when the shifter sleeve *F* is pushed in. When this lever is pushed in the rollers *G* are thrown outward and

forward against the ring *H*, carrying the cone *E* forward into contact with the middle cone *B*, and then carrying the middle cone into contact with the outer cone *D*. Having these cones come into contact singly prevents the clutch from engaging too suddenly. The inner cone *E* is made to revolve with the outer cone *D* by means of lugs *I* which project outward from the ends of the cone *E* and ride between lugs *J* located on the inside of the casing. The faces of these lugs *J* are turned true and serve to hold the ring *H* centrally. The casing screws onto the outer cone *D* and is locked in place by set-screws.

The inner end of the locking screw *K* enters one of the slots in the outside of the ring *H*, causing this ring to revolve with the casing. The adjustment of the clutch is made by inserting this screw into one of the slots. The rollers *G* and the pivots on which they are supported are of large diameter and bearing area to afford long life and easy operation. In throwing the clutch out the rollers *G* strike the lugs *M* and pull the cone *E* forward to give the required clearance for the oil films between the surfaces of the cones. The face angle of the cones is large enough to enable them to disengage instantly. The throw-in mechanism is very powerful, the multiplication between the horizontal force on the shifter sleeve *F* and the pressure on the cone faces being approximately 100 to 1 for all sizes of clutches.

"NATCO" HIGH-SPEED MULTIPLE DRILLS

The National Automatic Tool Co., Richmond, Ind., has recently added to its line two high-speed multiple drills which embody many features of high productive value. These meet the demand for powerful machines capable of drilling up to 7/8-inch holes in cast iron at heavy feeds. The "Natco" No. 18 drill shown in Fig. 1 is of the table feeding type, the head being tongue grooved and bolted solidly to the column. It is designed to drive eight 1/2-, twelve 3/8- or twelve 5/16-inch drills in cast iron at a feed of 5 inches per minute with the drills running at a peripheral velocity of 75 feet per minute. Under a test it carried a much heavier complement of drills than the above with ease under the heaviest feeds. The "Natco" multiple drill embodies weight, proper distribution of metal to insure maximum rigidity, proper speeds and feeds for high-speed drills and, above all, a machine with all its parts designed to deliver the power necessary to obtain the above results.

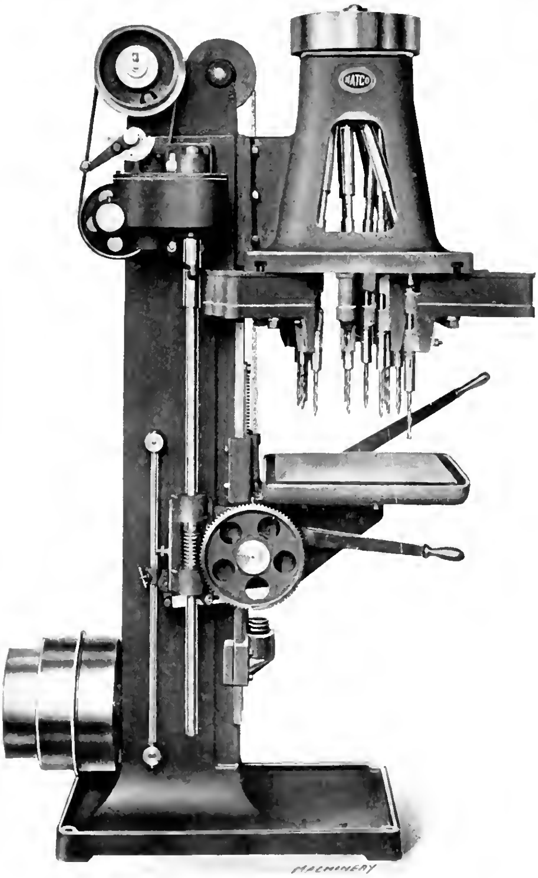


Fig. 1. No. 18 "Natco" High-speed Multiple Drill

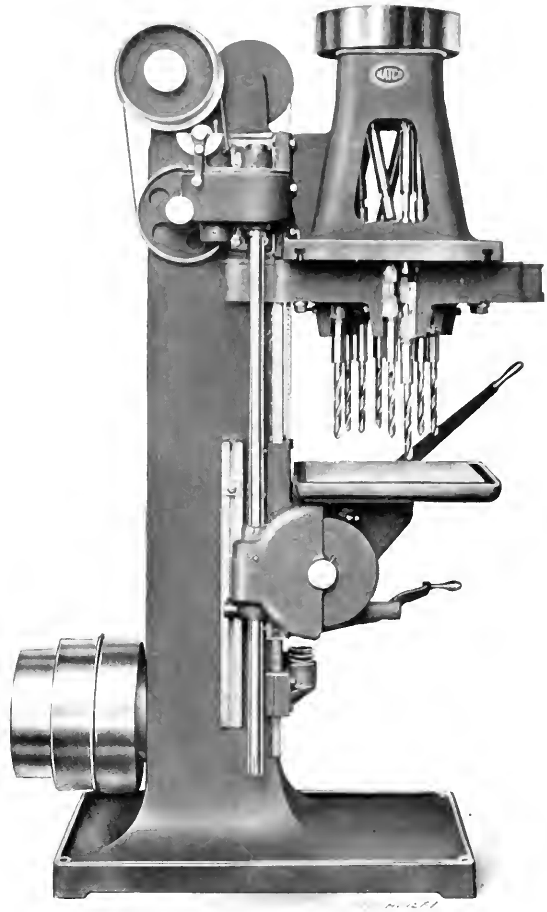

Fig. 2. No. 20 "Natco" High-speed Multiple Drill

The column is of heavy box section, the metal being so distributed as to insure a maximum of strength and rigidity. It has a wide face to which a steel rack is securely fastened. The drive is by means of a two-step cone and continuous belt. The idler pulleys are of large diameter and are mounted on Hyatt high-duty roller bearings. The cone pulley on the base is also mounted on Hyatt high-duty roller bearings. This insures a high transmission efficiency. The knee has an extended top providing a support where it is needed most and the main part is of box section which insures a very stiff support for the work to be drilled. It is counterbalanced with sectional weights which may be added to or removed to suit the work being drilled. The table is made with a large oil channel around the outer edge to catch the overflow of lubricant, and a screen oil pocket in this channel prevents chips from choking up the pipe. The feed box is located near the top of the column on the side, which provides three changes of feed that may be made while the machine is running. The feed gears are hardened and run at moderate speeds in a bath of oil. All the bearings are bronze bushed. The feed worm-gear is made of bronze, the worm being provided with an extra heavy ball thrust, and the bearings at this point are bronze bushed. A guard is provided which completely covers these parts.

The rack pinion shaft is made of crucible steel and the pinion is cut from the solid. This construction insures great strength. The right-hand end of this shaft is provided with an adjustable hand lever or a four-arm pilot for rapid, easy advance and return of the table. The power feed which is of the worm knockout construction may be tripped by hand or automatically at any point. The table returns automatically to its "home" position after being tripped. Pressing down on the feed lever releases, and pulling up engages the feed. This machine is provided with a 9 by 15-inch rectangular head which can be equipped with from two to sixteen adjustable spindles. All gears in the head are hardened and ground and run in oil. All bearings are bronze bushed. The head may be equipped with various combinations of arms or cluster boxes. The drill spindles are made of special steel hardened and ground and provided with ball thrust bearings at the lower end and lock-nuts at the upper end to take up any end wear that may develop. The spindles are made to carry either straight shank or Morse taper shank drills, as required, and the machine may be provided with a reservoir to carry lubricant to the point of the drills.

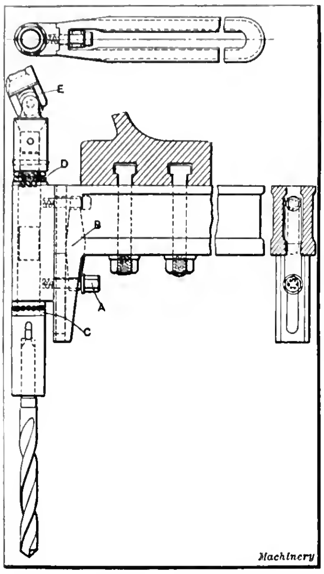

Fig. 3. "Natco" Spindle Adjustment

The bronze bearings which carry the drill spindles are provided with vertical adjustment to compensate for variation in the drill collets. This adjustment is quickly and easily secured by simply loosening one nut which is always accessible, regardless of how close the spindles may be clustered together. This spindle adjustment—which is a patented construction—holds the bearing rigidly to the end of the arm, and the arm may be moved to cover any layout within the range of the head. The construction is illustrated in Fig. 3. In making the adjustment, it is only necessary to loosen the nut *A*, as mentioned. This allows the steel beam *B* to rock on its fulcrum and loosen the bearing to provide for making the adjustment. The ball thrust bearing on this spindle is shown at *C* and the lock-nuts and washer for taking up end wear are illustrated at *D*. It will be seen that an oil chamber is provided in the bronze bearings in order to insure adequate lubrication of the spindles. The universal joints used on the "Natco" multiple spindle drills are milled from the solid and carefully hardened. One of these joints is shown at *E* in Fig. 3. This is composed of only five pieces and does not depend upon a cross-pin that may be broken, or upon screws that may work loose. The weight of this No. 18 drill is 1400 pounds without the adjustable arms.

The "Natco" No. 20 drill shown in Fig. 2 is a heavier machine equipped with larger sizes of heads and a greater number of spindles. It is an extremely powerful machine capable of driving up to 7/8 inch high-speed drills in cast iron. The table feeds the work up to the drills, the head being tongue grooved and bolted securely to the column. It was designed to drive from six to eight 3/4-inch drills or their equivalent in cast iron, at a feed of 5 inches per minute with the drills running at a peripheral velocity of 75 feet per minute. The No. 20 drill embodies all the essentials for high-speed drilling results, namely, weight, proper distribution of metal to insure rigidity, proper speeds and feeds for high-speed drills.

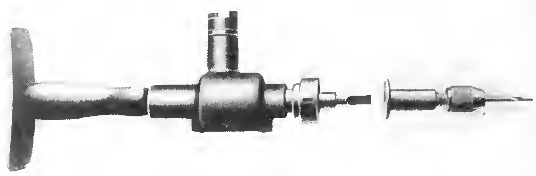
The column is of heavy box section, and has a wide face to which the steel rack is securely fastened. The drive is by means of a two-step cone and continuous belt, the two-step cone being mounted on Hyatt roller bearings. The idler pulleys are of large diameter and also mounted on Hyatt roller bearings. The knee has an extended top, providing a support where it is most needed, and the main part is of box section. It is counterbalanced and is provided with a new friction power feed which is an entirely new principle applied to multiple spindle drills. The advantage of the friction power feed is that the drills can be brought up against the work before throwing in the feed, thereby saving time in bringing the work to the point of the drills. It also eliminates any danger of breakage to the power feed mechanism, because should anything become caught, the friction would slip when the pressure reaches a certain point. The friction is adjustable to compensate for the different loads that are being drilled. The rack pinion shaft is made of crucible steel and the pinion is cut from the solid, insuring great strength. The right-hand end of this shaft is provided with either an adjustable lever or four-arm pilot for rapid, easy advance or return of table. The power feed may be tripped by hand or automatically at any point, the table returning automatically to its "home" position. The table is made with a large oil channel to catch the overflow of cutting lubricant and a screen pocket prevents chips from choking up the oil pipe.

The feed box is located on the side of the column near the top. It provides three changes of feeds. The feed gears are hardened and run at moderate speeds in a bath of oil. All the bearings are bronze bushed. Several sizes of heads are provided, all of which may be equipped with various combinations of adjustable arms or cluster boxes. Some of the heads are equipped with the "Natco" independent drill speed feature which gives two independent changes of speed in the head for each step on the cone, thereby making possible the drilling of large and small holes in the same operation at correct cutting speeds. All gears in the head are hardened and ground and run in oil. All bearings are phosphor-bronze bushed. The smaller sized heads are arranged with from two to sixteen adjustable spindles and the larger sizes have from two to twenty-four adjustable spindles. The adjustable arm, drill spindles and universal joints are of the same construction as illustrated in Fig. 3 for the description of the No. 18 drill. The main points of advantage of the No. 20 drill over the No. 18 is greater capacity, the independent drill speed feature, larger sizes of heads, greater number of spindles and the new friction power feed. The weight of the No. 20 drill is 2300 pounds without the adjustable arms.

COATES FLEXI-SHAFT SCREW-DRIVER

The power-driven screw-driver which forms the subject of this article is a recent product of the Coates Clipper Mfg. Co., Worcester, Mass. This tool is driven by one of the flexible shafts manufactured by this company, which transmits power to the screw-driver through a worm and worm-wheel. The thrust of the worm is taken by a ball bearing so that the tool runs very smoothly at all times.

The blade of the screw-driver remains stationary until



Coates Flexi-shaft Screw-driver

pressure is applied to the breast-plate. This pressure engages a friction clutch and starts the tool operating. The clutch may be adjusted so that it will release at different pressures according to the work which is being handled. This feature prevents marring the slots in the heads of the screws when they have been driven home. When the pressure on the breast-plate is released, the clutch is disengaged.

Different sizes of screw-driver blades may be mounted in the tool to adapt it for different classes of work. The tool may also be used for drilling operations. For this purpose, a drilling attachment is provided which has a slot at its

upper end into which the blade of the screw-driver fits. The arrangement will be readily understood from the illustration without requiring further description.

GREENFIELD NO. 1 PLAIN GRINDER WITH HYDRAULIC TABLE FEED

The Greenfield Machine Co., Greenfield, Mass., is now building a plain grinding machine for handling cylindrical work up to 12 inches in length and up to 4 inches in diameter. For those plants manufacturing small parts which can be finished by grinding, this machine has several features that commend it. The most noteworthy point in the design is the application of a hydraulically operated table. This method of driving does away with all gears, clutches, etc., usually employed for this purpose and it is claimed by the manufacturers that it is far superior in smoothness and evenness of operation. The machine is adapted for either straight or taper grinding and is essentially a manufacturing machine. Front, rear and plan views are shown in Figs. 1, 2 and 3; and Fig. 4 shows the way in which the hydraulic table mechanism operates.

The method by which the table operates is clearly shown

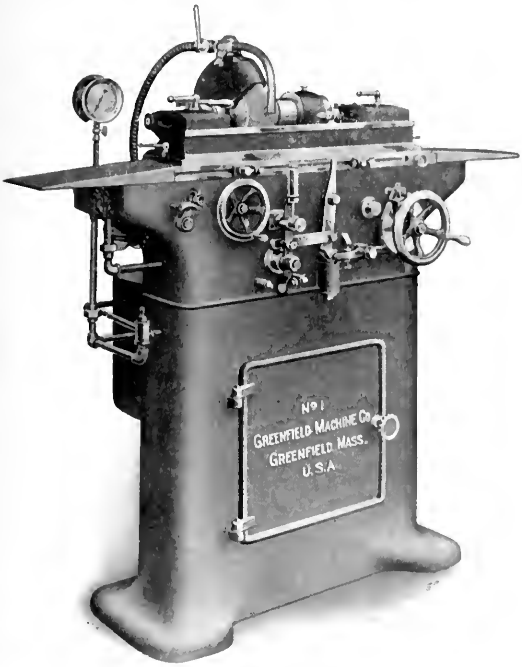


Fig. 1. Front View of Greenfield Grinder

in Fig. 4. In the base of the machine there is an oil supply tank, which supplies oil to the hydraulic cylinder. This oil is pumped by means of a rotary pump which will be seen at the rear of the machine in Fig. 2. Referring to this illustration it will be seen that the oil piping extends around the left-hand end of the machine to the relief valve. This valve is usually set to give about 75 pounds pressure which is indicated on the gage directly above. The oil held back under pressure by the relief valve goes to the operating valve, which is illustrated in Fig. 4. In one position the oil passes to the left of the piston within the cylinder, which is shown in Fig. 3, forcing the piston toward the right until the operating valve is shifted—either by hand or automatically—when it reverses by causing the oil to flow into the cylinder from the opposite end and thus moves the piston and table, to which it is attached, in the other direction. The speed with which the table is traversed is governed by a supply valve which controls the amount of oil passing to the cylinder, and any desired speed between 0 and 254 feet per minute may be obtained with a pressure of 75 pounds. It will be noted that all working parts of this mechanism are lubricated by a continuous bath of oil.

The mechanism for operating the automatic cross feed will be seen at the extreme right of the machine in Fig. 1. The pawl which operates the feed is moved by the horizontal lever, which, in turn, is actuated by the V bottom of the vertical shifting lever. Just beneath the horizontal lever there is an adjusting screw which governs the amount of motion of this lever. By turning this screw the action of

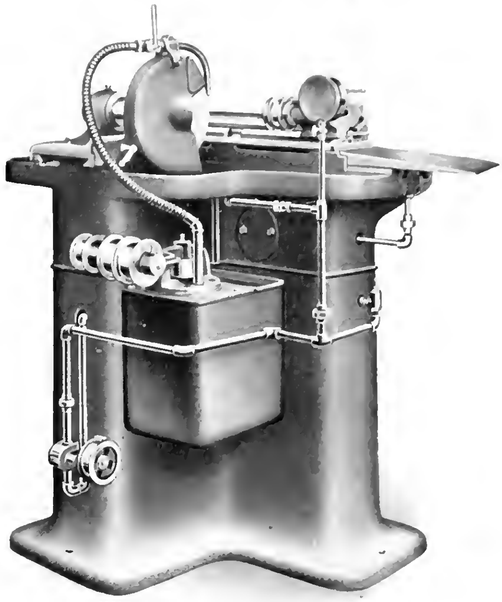

Fig. 2. Opposite Side of Machine shown in Fig. 1

the pawl may be regulated to enable it to pick up the required number of teeth on the ratchet wheel, each notch on which represents a movement of the head of 0.00025 inch. Revolving with the ratchet wheel there is a mechanism which is provided for the purpose of throwing out the pawl, thereby stopping the cross-feed when the work has been ground to the desired size. On the front of this mechanism there is a casehardened knob with a knurled edge, upon the face of which the figures "1" and "1/4" are stamped. A little lever or key projects from this mechanism, and when the figure "1" is turned so that it is in line with the key, the depression of the key moves the mechanism 0.001 inch or four notches

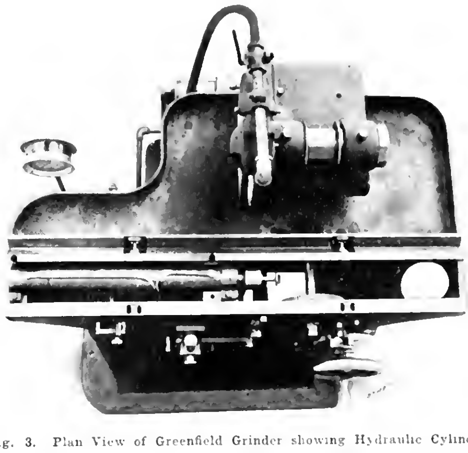

Fig. 3. Plan View of Greenfield Grinder showing Hydraulic Cylinder

of the ratchet wheel. When the knob is turned so that the figure "1/4" is in line with the key, the depression of the key moves the mechanism 0.00025 inch or one notch of the ratchet wheel.

In practice, this would be used as follows: after one or two cuts have been made across the work, it is calipered and the

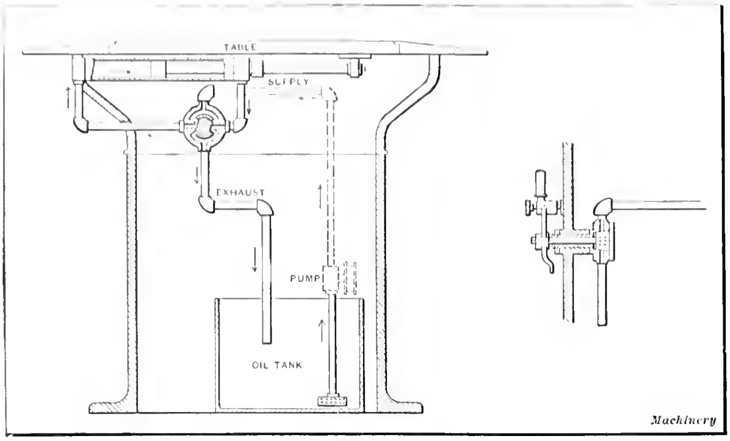

Fig. 4. Diagram showing how Oil circulates to operate the Table Traverse

amount of stock still to be removed to bring it to the desired size is determined. The mechanism is then brought around until the shield on the ratchet wheel touches the pawl; this shield is then set back the proper amount by depressing the key. For instance, suppose it is found that 0.0025 inch is still to be removed from the work. The shield mechanism is brought forward so that the shield just touches the pawl, after which the knurled knob is turned until the figure "1" is brought in line with the key. The key is then depressed twice, which will move the mechanism back 0.002 inch. The knurled knob is then turned until the figure "¼" is in line with the key and depressed twice more which will move the shield back 0.0005 inch. When this has been done the machine is again started and when the necessary 0.0025 inch has been removed from the work, the cross-feed will be automatically disengaged. In producing duplicate work, this device will have to be set only once and will then throw out on each piece at the same point so the required dimension is obtained. An occasional depression of the key in the "¼" position will take care of the wear on the wheel. A feature of this grinder is that all handles and levers for controlling the mechanism are within easy reach of the operator. Provision is made for delivering an ample supply of water for cooling the work, and the design has been worked out in such a way that the tendency of the water to be fanned away from the wheel is overcome. The principal dimensions of the machine are as follows: Extreme distance between centers, 12 inches; swing, 4 inches; maximum travel of table, 14 inches; diameter of grinding wheel, 10 inches; face of grinding wheel, ¾ inch; speed of wheel, 2100 revolutions per minute; number of work speeds, 3; floor space occupied, 70 by 29 inches; net weight of machine, 1335 pounds.

WARNER & SWASEY NO. 4 TURRET SCREW MACHINE

The Warner & Swasey Co., Cleveland, Ohio, has recently added to its line a No. 4 universal turret screw machine. The improvements incorporated are: the power longitudinal feed for the carriage, the arrangement on the carriage for chasing threads, and the fact that the carriage and turret are

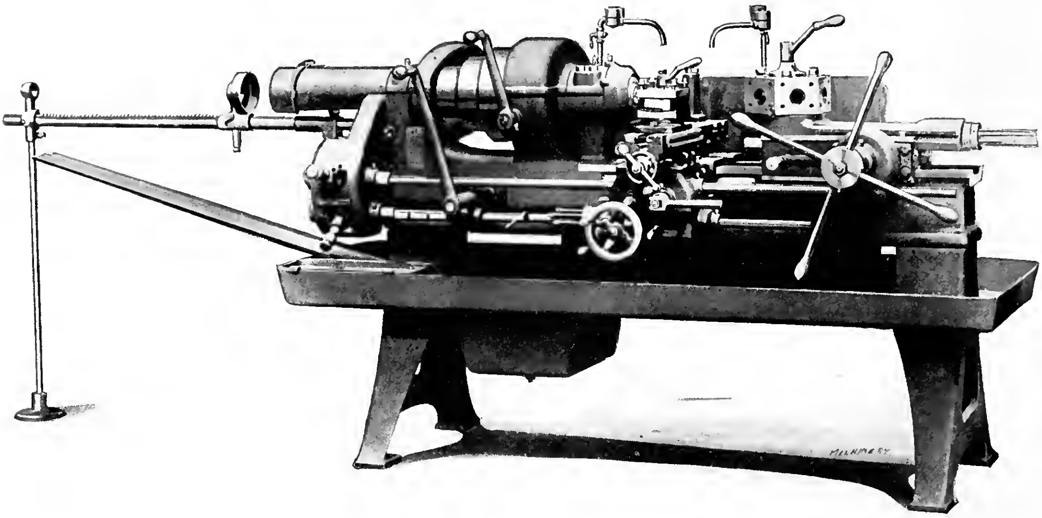

Fig. 1. Warner & Swasey No. 4 Universal Turret Screw Machine with Bar Equipment and Cone Pulley Drive

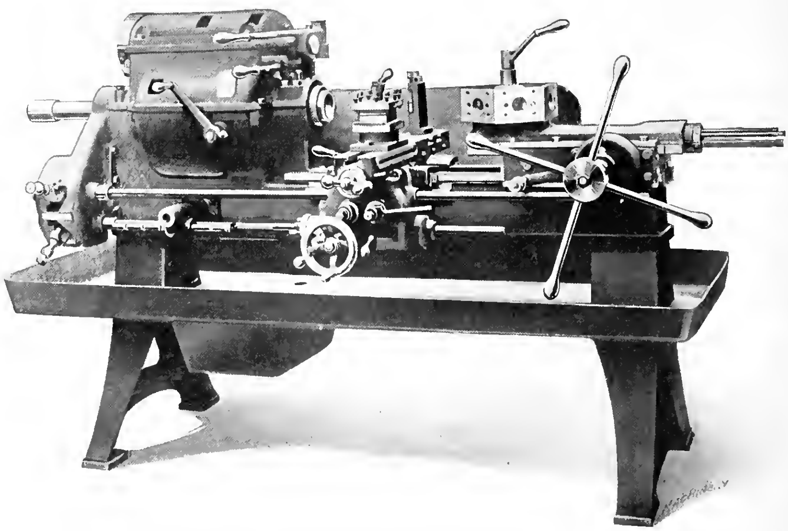

Fig. 2. Warner & Swasey No. 4 Universal Turret Screw Machine with Single Pulley and Geared Head

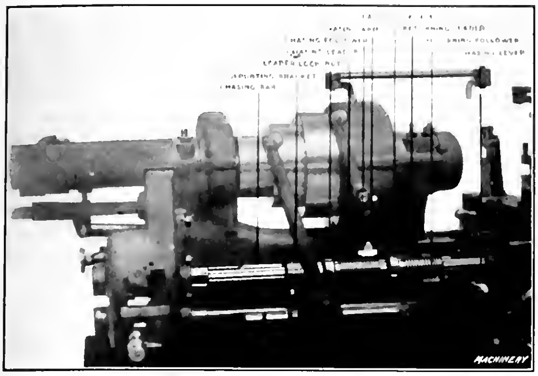

Fig. 3. Chasing Attachment

driven by separate shafts. These features add greatly to the efficiency of the machine and have been developed as the result of this company's wide experience in building turret screw machines.

For a long time screw machines have been built with power cross feed on the carriage, but this is the first machine to be fitted with power longitudinal feed. In order to add greatly to the possibility of working with the carriage, it is driven by a separate feed shaft. Another important feature is the fact that the feeds of this carriage can be reversed entirely independently of the feeds of the turret; thus, the turret can be fed toward the chuck while the carriage feeds away from the chuck if necessary. In this way, two diameters can be turned at once, or the outside of a piece may be turned with the carriage while the hole is being bored from the turret. The longitudinal feed to the carriage has six independent adjustable stops for gaging the length turned. These stops trip the power feed and act also as dead stops.

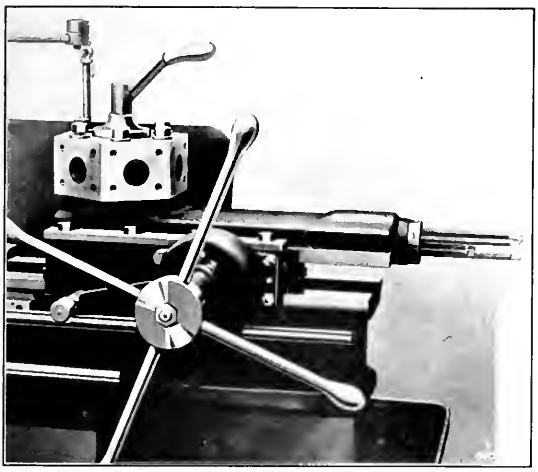

Fig. 4. Turret, Turret Saddle and Adjustable Stops

To return to the chasing attachment: This is well shown by Fig. 3. By placing the chasing lever in its horizontal position, the chasing follower is brought into engagement with the chasing leader. When the thread has been chased the chasing lever is lifted, thus bringing the returning follower into engagement with the returning leader and throwing the chasing follower out of engagement with its leader. As the returning leader and follower are threaded in a direction opposite to that of the chasing leader and follower, the carriage is thus returned to its starting point. It is not necessary to reverse the countershaft nor spindle for returning the chasing tool to its starting point. Each leader and follower cuts threads in multiples of 1 and 4 of its own pitch.

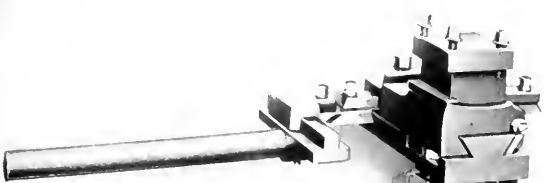

Fig. 5. Taper Attachment

The turret slide, shown in Fig. 4, has a length of feed of 10 inches, which is an extremely long travel for this size machine. It has also a very long bearing in its saddle. The saddle is provided with a supplementary taper base, and the slide is fitted with taper gibs on each side, these being fitted

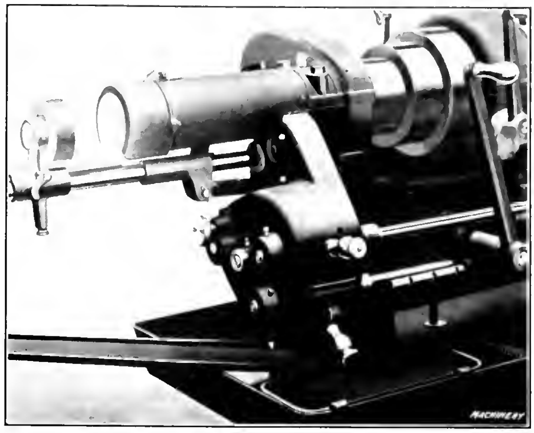

Fig. 6. Head—showing Cone Pulley and Feed Box

for realignment of the turret after it has worn slightly, although in the ordinary course of events it will not be necessary to adjust any of these parts for a very long time. The power feed to the turret is through a taper friction instead of the ordinary worm and worm gear.

Fig. 5 illustrates the taper attachment. The cylindrical arm of this attachment fits into a corresponding boss on the back of the bed. At the other end of the arm is the T-block, and the base of the attachment bolts into the T-slots at the

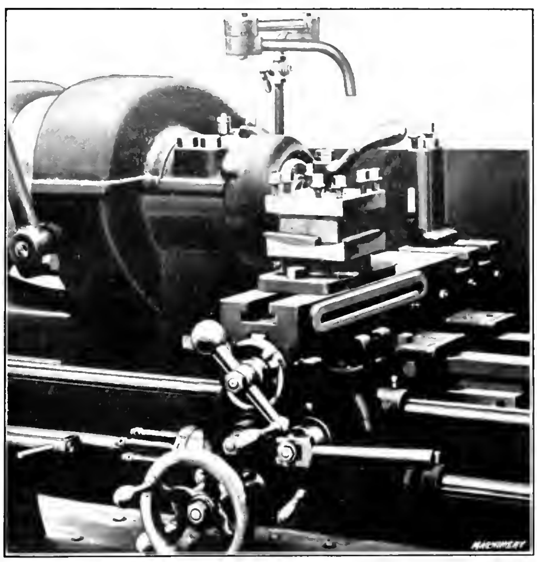

Fig. 7. Carriage with Cross-slide and Square Turret

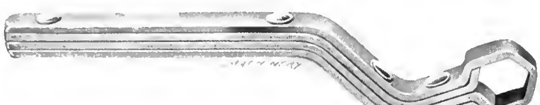
rear of the cut-off slide. To this base is fitted the tool-block itself, this being, in turn, operated by the taper bar at the back, this taper bar being adjustable for tapers up to 3 inches to the foot. In doing taper work it is not necessary to disconnect the cross feed screw, inasmuch as the taper is not obtained from the cut-off slide itself, but from the tool-block of the attachment. This tool-block is arranged for either

inside or outside tapers. The taper attachment does not interfere with the operation of the turret or the square turret. Both cylindrical and taper work can be done on the same piece with the carriage, without removing the taper attachment.

The machine can be fitted with geared head, driven by single pulley as shown in Fig. 2 or with the three-step cone head shown in Fig. 6, the latter being the standard. The automatic chuck and wire feed handle bar stock up to $1\frac{1}{2}$ inch capacity. The machine swings 16 inches over the bed and $8\frac{1}{2}$ inches over the carriage cross-slide; the total longitudinal travel of the carriage is 17 inches and the cross travel, 8 inches; and the longitudinal travel of the turret is 10 inches.

WALDEN WRENCH

A recent product of the Walden Mfg. Co., Worcester, Mass., is a wrench for adjusting the reverse and brake pedal bands of the Ford automobile. This wrench is of exceptionally simple construction, being made of three pieces of steel which are secured together by four rivets. The head of the wrench is formed by a single piece of steel which is bent to the



Simple Form of Walden Wrench

required shape with the ends extended to form a handle. Two center pieces are held between the ends which form the outsides of the handle. The forward ends of these center pieces are bent so that they form one angle of the "hex." The peculiar shape of the handle is for the purpose of providing the necessary clearance, and the Walden Mfg. Co. is prepared to make wrenches of this type of a form which will give the necessary clearance around the nuts of other machines.

"SATCO" DRILL HOLDER

The Steel-Art Tool Co., Machinery Hall, Chicago, Ill., is now manufacturing the "Satco" safety drill and tool-holder

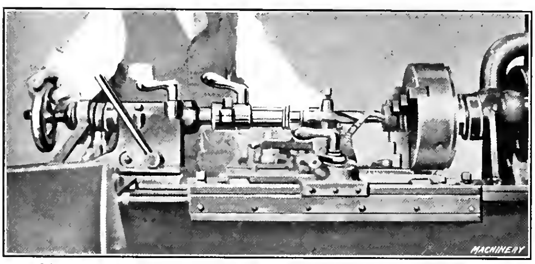


Fig. 1. "Satco" Drill Holder performing a Drilling Operation

for lathes, four applications of which are shown in the accompanying illustrations. This tool will hold taper, square and straight shank drills, taps, reamers, boring-bars, and various other lathe tools. It is quickly attached to or detached from the machine, and the tool can be instantly re-

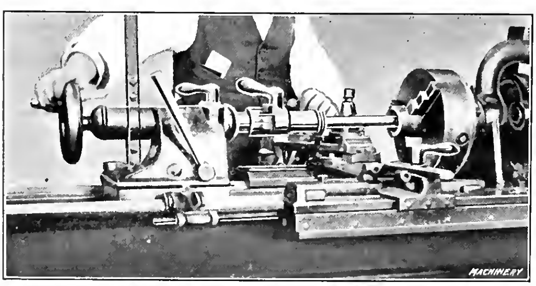

Fig. 2. Boring-bar held in the "Satco" Drill Holder

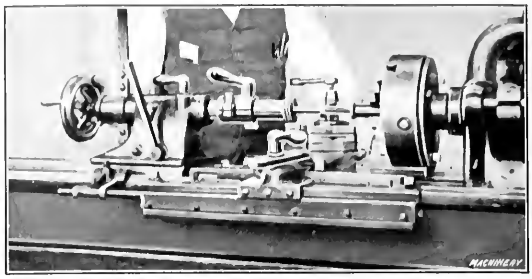

Fig. 3. The "Satco" Drill Holder is well suited for Reaming Operations

leased from the holder without requiring the use of a hammer and drift.

Referring to the illustrations, it will be seen that the holder is provided with a split bushing which fits over the tailstock spindle. With the tool-holder in place on the spindle, the cap-screw is tightened to bind this bushing in place. The tool fits in a socket at the opposite end of the holder and when it is required to remove it, it is merely necessary to turn the small lever on the holder. This draws a wedge up against the end of the tool shank and forces it out of the socket in the holder. This arrangement forms a substitute for the

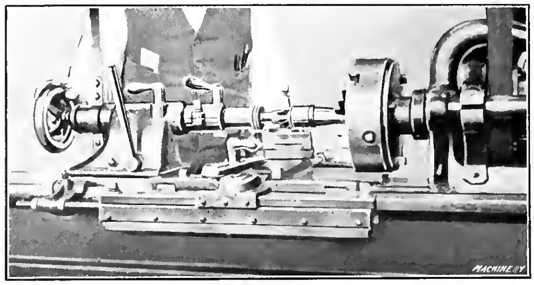

Fig. 4. Taper Reamer mounted in the "Satco" Drill Holder

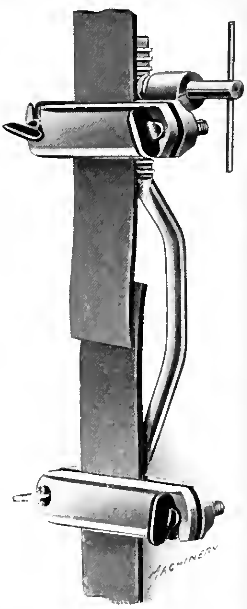
use of a drift and hammer and eliminates the possibility of accidents which occasionally occur in removing tools in this manner.

SOUTHWICK "LITTLE GIANT" BELT TIGHTENER

The George W. Southwick Co., 35 Warren St., New York City, has recently brought out the "Little Giant" belt tightener which forms the subject of this article. The most noteworthy feature of this device is that the belt can be brought to the proper tension and the ends fastened while they are held in position over the pulleys. This eliminates all guesswork in regard to the amount to be cut out of the belt to take up the slack. Another feature is that the pull exerted by this device comes centrally so that the tension is uniform and draws the ends of the belt squarely together.



Southwick Belt Tightener

Referring to the illustration, it will be seen that this belt tightener consists of two clamps which are secured in place on the belt by means of thumb-screws, one of these clamps being stationary while the other may be adjusted by means of a rack and pinion. The gear is turned by a worm which is operated by the handle at the top of the tightener. By this means the required tension of the belt is obtained. These belt tighteners are made in four sizes

with capacities for belts up to 4, 6, 10 and 14 inches in width.

The location of a belt does not affect the efficiency with which a fastening can be made, and it is claimed by the manufacturers that this tightener can be adjusted to the belt and the belt drawn to the required tension and made ready for the fastening in less than three minutes. An important feature of this device is the offset in the draw-bar which permits of the use of a block for hooks and a clamp for cemented joints. The manufacturers of this tightener believe it will be greatly appreciated by those who use the wire hinge joint for fastening the ends of their belts, from the fact that before the belt is removed from the pulley the proper amount to be removed can be determined and when the belt is replaced on the pulley the ends can be drawn together and the rawhide fastening pin can be quickly inserted through the interlocking wire loops.

MILLERS FALLS POWER HACKSAW

The Millers Falls Co., Millers Falls, Mass., is now building the No. 90 "Star" power hacksaw which is illustrated herewith. This machine is equipped with a geared drive which gives an exceptionally uniform cutting stroke and a quick return stroke. The saw is returned at twice the cutting speed. The usual provision is made for lifting the saw clear of the work on the return stroke and an attachment

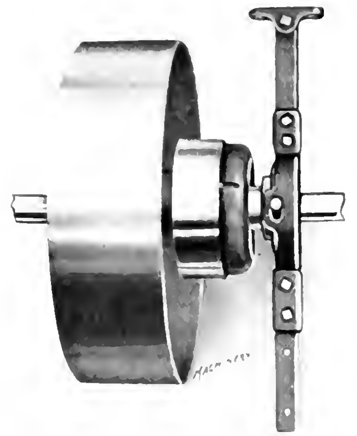
Millers Falls No. 90 Power Hacksaw

is provided which enables the saw to be suspended above the work when it is necessary to make measurements or to adjust the position of the work in the vise. By simply turning a small lever, the operator is able to lift the saw out of engagement with the work for the purpose of making such measurements or adjustments. Another feature of this machine is a support on the cut-off side which prevents the material from dropping when the cut is nearly finished. An adjusting screw in the head provides for taking up wear on the arm and the vise nut in the bed is removable so that it may be replaced when necessary. The working parts of the machine are located under the bed where they are protected from dust and dirt. The machine stops automatically when the cut is completed.

The principal dimensions of this power hacksaw are as follows: ratio of back gears, 3 to 1; height from floor to top of bed, 28 inches; floor space occupied, 20 by 16 inches; suitable speed, 60 strokes per minute; size of driving pulley, 6 inches in diameter by 2 inches face width; cutting capacity of machine, 5 by 5 inches; length of blade, 12 inches, net weight of machine, 215 pounds.

EDGEMONT FRICTION CLUTCH

In the December, 1912, number of MACHINERY, the plate type friction clutch manufactured by the Edgemont Machine Co., 2700 National Ave., Dayton, Ohio, was illustrated and described. Since that time this company has brought out an enclosed friction clutch which forms the subject of the present description. This clutch was designed to meet the demand for a powerful friction clutch of simple design that could be adjusted without removing the cover and still have none of the parts exposed in a way which would make them likely to catch belts or the clothing of men employed to look after the shafting.

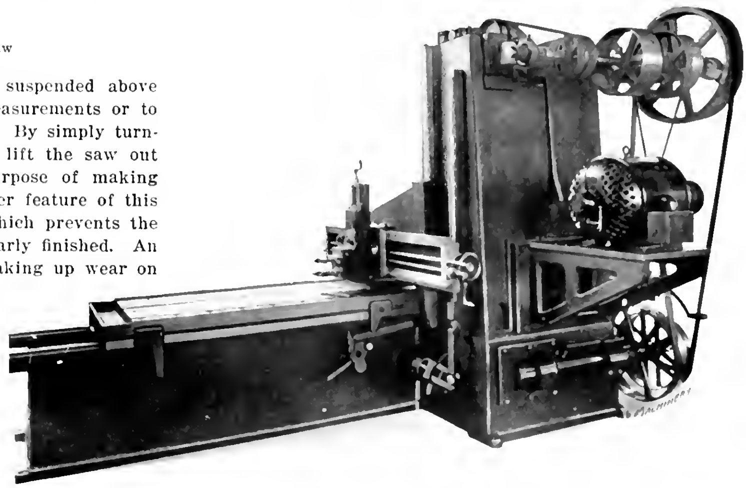


Edgemont Friction Clutch

This new Edgemont clutch is equipped with an improved expanding type of friction with metal-to-metal contact. Ample provision is made to adjust for wear and the sleeves are made in sizes to provide for using them in connection with standard wood or steel pulleys, rope sheaves, sprocket wheels or gears. These clutches are made in fourteen different sizes which have a range for transmitting from 2 to 25 horsepower.

CLEVELAND OPEN-SIDE PLANER

The Cleveland Planer Works, 3150-3152 Superior Ave., Cleveland, Ohio, has recently built a special open-side planer for use on the United States Government torpedo boat destroyer, tender No. 2, *Melville*. The installation of this planer between decks made it necessary for the over-all height not to exceed 8 feet 5 inches, which is 16 inches lower than the height of the regular 36-inch machine of this type. The design was finally worked out in such a way that the



Cleveland Open-side Planer built for the U. S. Government

machine was built to meet the requirements and still have the full planing capacity of the standard machine.

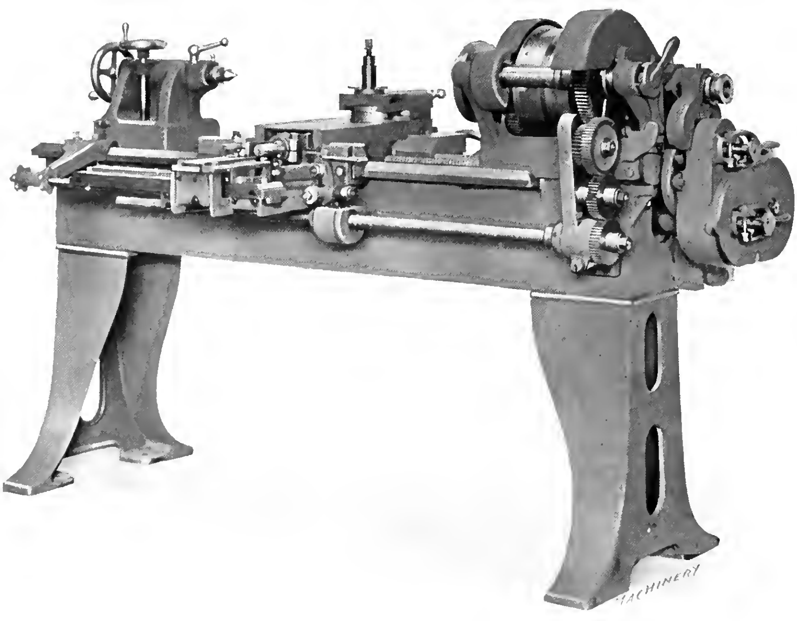
Owing to the weight of the Cleveland open-side planers, no provision is necessary for bolting them to the foundation when set up under normal conditions. In the present case, however, it was necessary to provide for anchoring the planer owing to the roll of the ship. Referring to the illustration, it will be seen that power is provided by an individual electric motor which was built by the Reliance Electric & Engineering Co. under government specifications.

WHITCOMB-BLAISDELL RELIEVING ATTACHMENT

The Whitcomb-Blaisdell Machine Tool Co., 134 Gold St., Worcester, Mass., is now equipping lathes of its manufacture with the relieving attachment shown in the accompanying illustration. The features of this equipment are that it is of simple design, that it can be used for relieving either spiral or straight fluted cutters, and that the full range of the compound rest is available in connection with the attachment.

Referring to the illustration, it will be seen that the relieving attachment is geared to the lathe head by a train of spur gears carried by a suitable bracket. Change gears are provided so that for each revolution of the lathe spindle the relieving attachment makes anywhere from three to twenty-seven strokes. By compounding the gearing, the tool may be made to lag sufficiently for relieving spiral fluted cutters.

The horizontal shaft carries a cam as shown, and as the shaft rotates, this cam rocks the bellcrank on the relieving attachment. This bellcrank, in turn, rocks a second crank which is carried on the end of the transverse shaft. The oscillation of this shaft is transmitted through a pair of bevel gears to a small vertical spindle, at the upper end of which there is a disk almost half of which has been milled away. The flat side of this disk contacts with a pin in the tool-slide, and as the shaft oscillates the disk causes the slide to be moved forward. The movement of the slide is against the tension of a spring and when the shaft oscillates back—thus releasing the pressure of the disk on the pin in the slide—the slide and tool are withdrawn from the work. As the power to the vertical spindle carrying the disk is through bevel gears, it is possible to set the compound rest to any required angle as previously mentioned. By adjusting the throw of the cranks which operate the relieving attachment, the amount of relief can be varied as required.



Relieving Attachment for Whitcomb-Blaisdell Lathes

BESLY NO. 41 DISK GRINDER

The accompanying illustration shows an improved direct-connected motor-driven disk grinder developed by Charles H. Besly & Co., 120-B N. Clinton St., Chicago, Ill., and designated as the No. 41 Besly grinder. Heretofore, disk grinder bearings have usually been grease lubricated, owing to difficulty in automatically lubricating the thrust bearings with liquid oil. In this new grinder, the Besly Co. has worked out a system of ring oiling for both the radial and thrust bearings. Owing to the extremely severe duty and accuracy required of the modern disk grinder, the design and construction of the spindle and its mountings is especially important. In the manufacture of the No. 41 Besly grinder the motor is equipped with special end castings carrying extra large bearings suitable for disk grinder service. All wearing parts are renewable. The rotor shaft is of hard crucible machine steel, the wheel collars are drop-forged from hard crucible steel, and the bearing bushings are cast iron, lined with high-grade bearing metal. These bushings are ground over the outside and carefully fitted into bored and reamed holes in the motor end casings, so that new bearings may be inserted when necessary, without affecting the alignment of the spindle.

Charles H. Besly No. 41 Disk Grinder

End thrust in both directions is taken on hardened and ground tool steel thrust collars of large area, running at each end of the right-hand bearing bushing. End play of the spindle is taken up on these thrust collars by means of adjusting collars which are threaded on the spindle. With this construction the heating of the bearings when running does not tend to tighten and bind them, because the longitudinal expansion from heat is greater in the spindle than in the bearing bushing. However, the expansion is so nearly uniform that the change in adjustment due to temperature changes is practically nil. Therefore this machine can be run safely with all end play

taken up, providing for the grinding of work within closer limits. The motor is 7½ horsepower, running fully enclosed for alternating current. When operating on 60 cycle current, this machine carries 20-inch disk wheels and runs 1200 R. P. M. When operating on 25 cycle current, the machine runs at 1400 R. P. M., and is equipped with 18-inch disk wheels to give the correct abrasive speed. The machine may be equipped with any type of work table. As illustrated, it carries on the right a geared lever feed table and on the left a plain tilting table. It is started and stopped by means of a single-throw switch located inside of the base casting. The floor space occupied is 28 by 28 inches and the weight of the machine with all equipment is 2000 pounds.

REED-PRENTICE AUTOMATIC LATHE FOR STRAIGHT TURNING AND FACING

An automatic lathe for straight turning and facing operations on forgings and castings, which was recently built by the Reed-Prentice Co., Worcester, Mass., for the Ford Motor Co., is shown in Fig. 1. These machines are of unusually rugged construction to insure an absolute absorption of vibration and to withstand the severest service which can be demanded of machines of this type. The power is in excess of any demand made upon the lathe. The wide double belt drives to a large diameter pulley, and then through a pair of herringbone gears running in oil, to the main head spindle. This arrangement gives a constant spindle speed, no mechanical changes being provided. A feature of these lathes is the one-feed and one-speed idea which guarantees a maximum production when the machine has been set at the proper feed and speed for a given operation. Change gears can be used if desired to vary the feed to suit the class of work, although when once set up the feed is rarely changed. In order to obtain the desired spindle speed the countershaft speed must be changed accordingly.

The object of this machine is to furnish a second operation machine that will produce a large quantity of work

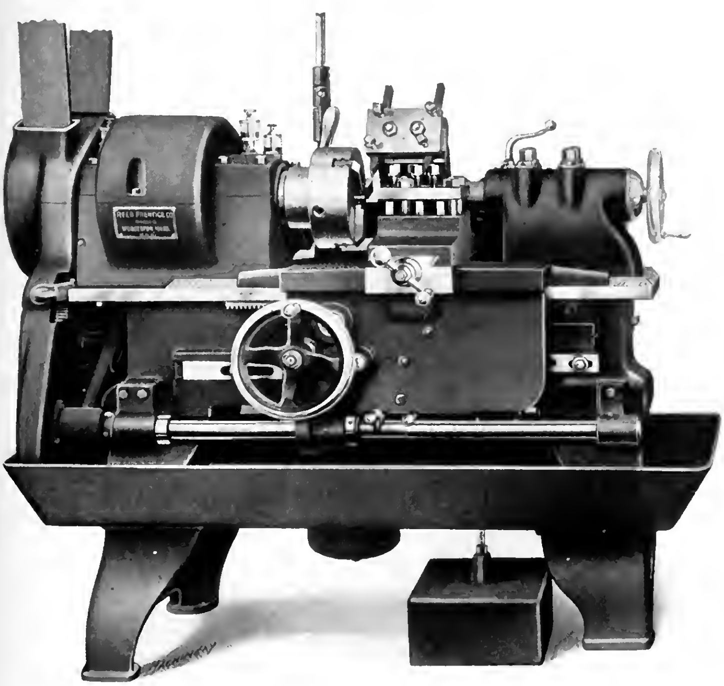


Fig. 1. Reed-Prentice Automatic Lathe for turning and facing Forgings and Castings

which will be equal in quality to that produced on the best types of engine lathes. In the construction of this machine careful consideration has been exercised in the distribution of material. The head spindles are made of heat-treated chrome-nickel steel, the bearings are hardened and run in phosphor-bronze journals, and sight-feed oilers are used for lubrication of all head bearings. The driving pulley which is mounted on a shaft at the rear of the head, and which arrangement entirely eliminates any belt tension on the main spindle, is well guarded to protect the operator, the same guard entirely covering all end works gearing.

The tailstock is extremely rigid, being of the four-bolt type. It is made in one piece in preference to the regulation two-piece tailstocks, as this prevents any chance of sideways shift of the tail spindle. The carriage and apron are also very

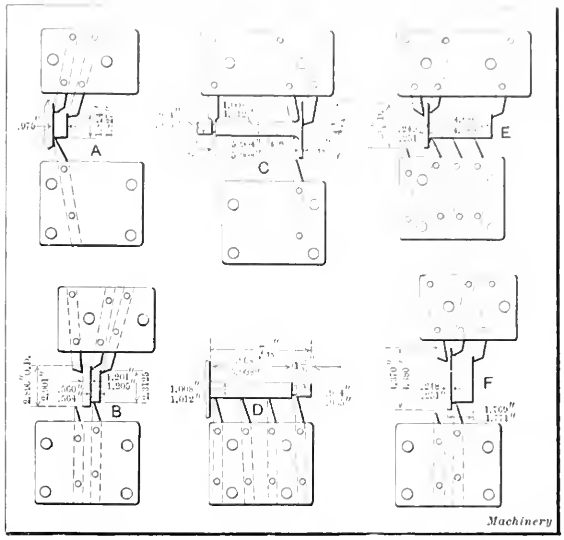

Fig. 2. Examples of Work done on the Reed-Prentice Lathe

heavily constructed, the rack pinion being made of hardened steel, engaging with a hardened rack on the bed. A cam feeding-in attachment is incorporated in the construction of the apron and carriage, which arrangement constitutes an adjustable bracket on the side of the bed carrying cam surfaces, and a link motion inside of the apron that transmits a cross-feed action to the front tool-block. The longitudinal travel of the carriage causes the link motion and cam surfaces to deliver this feed-in motion to the block, feeding the tools into the work to a predetermined diameter.

The back arm facing device is an attachment mounted on a large shaft or bar, which is supported in bearings cast integral with the head and tailstock, and bored in perfect alignment with the main spindles. A cam attached to the rear of the carriage actuates the bar by means of a roll carrier arm which projects from the bar, and is in contact with the cam surface. The longitudinal travel of the carriage which carries the rear cam causes a rotating motion to the bar, and this motion feeds the facing tools in toward the center of the spindle. It will be noted that the longitudinal travel of the carriage actuates both the feeding in of the front tools and the feeding in of the facing tools. When the work is completed the feed is automatically tripped, and the carriage and all tools almost instantly return to their starting position.

The complete cycle of operations on a piece is as follows: The work mounted on an arbor is placed between centers, the countershaft started, and the feed latch lifted into position. Both feeds are thus started, the work progressing until all diameters are turned and all shoulders and ends faced down, after which the feed is automatically tripped, and all tools return to their starting position. This completes the cycle of operations, and the machine is then ready to receive another piece

which has already been pressed on another arbor. Thus it will be seen that it is quite possible and practical to permit one operator to have charge of two or more machines. It will be noted from Fig. 1 that the entire machine is very compactly designed to eliminate any spring due to long arbors or excessive overhang of tail spindle. The floor space occupied is 5 feet by 3 feet 4 inches.

Figs. 2 and 3 illustrate the adaptability of the machine to the usual run of work. It happens that the pieces shown are all steel forgings and in most cases the production obtained on this new Reed-Prentice lathe has been practically double that previously obtained. Referring to Fig. 2, at *A* the hub and back of the bevel gear blank are finished, three tools being provided for this purpose—two tools for facing and one for turning. The actual time required to finish these pieces is ½ minute. The steel gear blank shown at *B* is turned and faced with three tools for facing and two tools for turning. The actual time required to finish these pieces is also ½ minute.

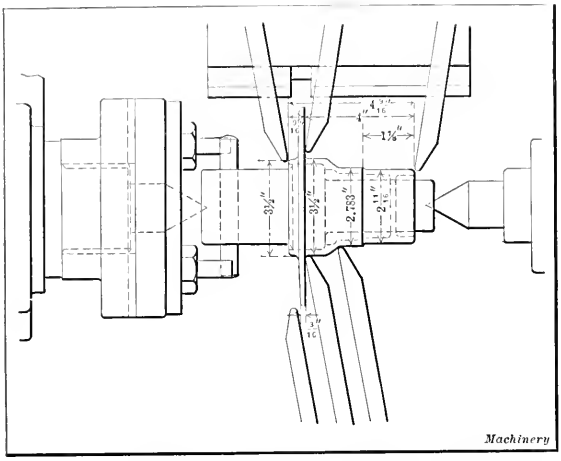

Fig. 3. Machining a Wheel Hub on the Reed-Prentice Lathe

The flange of the piece shown at *C* is turned and faced and the stem notched as shown, in 1½ minute. The stem is turned in a previous operation, while the flange is held in the chuck and the stem supported on centers. Four tools are used for this turning operation as shown at *D* and the time required is 45 seconds. Another example of turning and facing is shown at *E* where it will be seen that three turning and three facing tools are employed. This piece is finished in 1¼ minute. A somewhat similar operation is illustrated at *F*, in which three facing tools and two turning tools are employed. The time required to finish this piece is 1¼ minute. Fig. 3 shows the way in which a wheel hub is turned and faced on the Reed-Prentice automatic lathe, the actual time required to finish this hub being 2½ minutes. These are merely examples of work which tend to show that this type of lathe is adaptable for use in the production of small pieces in a great number of factories.

MARVIN & CASLER CENTER INDICATOR

A rotary center indicator particularly adapted for use on the Casler offset boring head has recently been placed on the market by the Marvin & Casler Co., Canastota, N. Y. This instrument is designed to indicate the center of any rotating spindle or shaft. It is small, compact and strongly built so that it is not likely to be injured by careless handling. When used in connection with the Casler offset boring head, it enables the operator to locate holes without removing the boring head from the spindle of the machine.

The indicator consists of a shank *A* which is gripped in the chuck of the boring head or a draw-in collet in the spindle. A pointer *B* is held against the faceplate *C* by means of a spring carried in the shank of the tool. The contact surfaces between the pointer and faceplate are hardened, ground and lapped to an accurate finish. The pointer is free to float in any direction over the surface of the faceplate and the head *D* is ground to a diameter of 0.250 inch. When used in the chuck of a boring head, the chuck is first

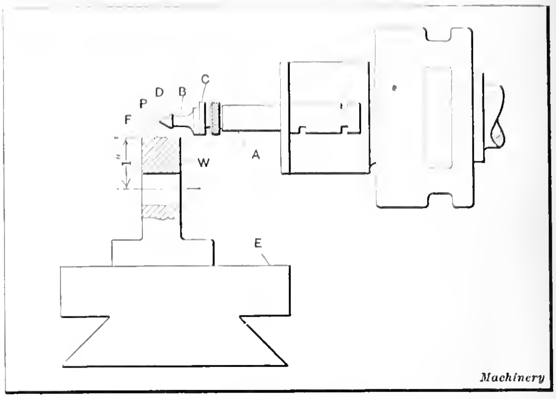

Fig. 1. Diagram showing how Marvin & Casler Center Indicator operates

brought concentric with the head. It is not necessary to have the shank of the indicator run true, as it is designed to operate satisfactorily without paying attention to this point. The pointer *B* is next brought in contact with a finished surface *F* near the center of the hole which is to be bored, after which the pointer *B* is moved to one side of the faceplate *C* so that it will describe a circle when the spindle is rotated. With the spindle rotating, the table *E* carrying the work *W* is slowly raised. Under these conditions, the head *D* of the pointer will strike the finished surface *F* of the work and be forced back toward the center of the faceplate *C*. The distance which the head is forced back at each revolution becomes less as the work is raised, until the pointer has finally been brought to the exact center of the faceplate *C*.

The operator continues to raise the table until the pointer runs true, *i. e.*, does not recede from the work. The graduated dial indicating vertical movement of the table can now be set to zero and as the diameter of the head *D* is exactly 0.250 inch, the table can be raised ⅛ inch, which will bring the center of the spindle in line with the finished surface of the work. For the case shown in the illustration, a further movement of 1 inch will bring the spindle on a horizontal line, passing through the center of the hole to be

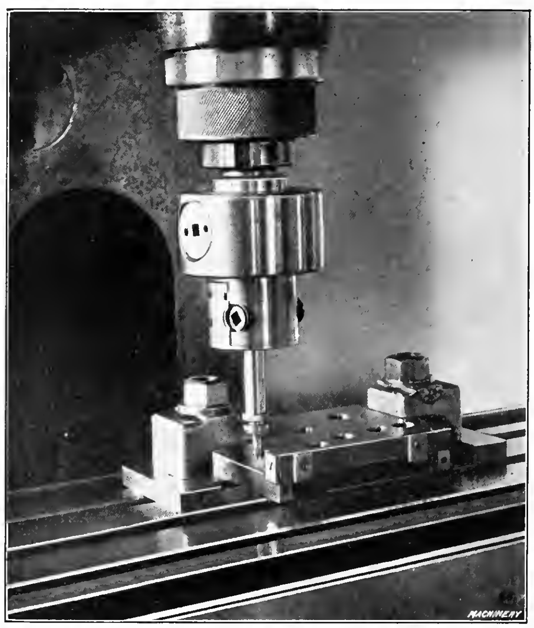

Fig. 2. Marvin & Casler Center Indicator in Place on the Machine

bored. It will be evident that lateral distances can be determined in a like manner by setting the pointer B to engage with any vertical finished surface on the work.

NEW MACHINERY AND TOOLS NOTES

Autogenous Welding Outfit: Tolman Mfg. Co., Boston, Mass. An equipment consisting of the usual pair of oxygen and acetylene cylinders connected to a cutting torch.

Pipe Cutter: Borden Co., Warren, Ohio. A pipe cutter in which the frame of the tool clamps onto the pipe. The cutters are carried in a ring and are fed in by spring pressure as the ring is revolved about the pipe.

Drop Hammer: Henderson Machine Co., 5032 Germantown Ave., Philadelphia, Pa. A steam- or air-lift drop hammer adapted for the rapid handling of work where it is necessary to raise the hammer a slight amount and drop it repeatedly.

Combination Vise and Drilling Machine: Diamond Expansion Bolt Co., 90 West St., New York City. A tool known as the "trident" combination drill press and vise which consists of a vise, anvil and a drilling machine mounted on a swivel base.

Rack-cutting Attachment: Kearney & Trecker Co., Milwaukee, Wis. A milling machine attachment adapted for milling racks, sawing off stock, milling slots which have to be accurately indexed, cross-milling operations and similar classes of work.

Graphite Lubricant: Lumen Bearing Co., Buffalo, N. Y. A semi-fluid graphite lubricant prepared in such a way that the graphite is held in suspension when mixed with lubricating oil or grease. This product has been given the trade name of "Lesoyl."

Offset Pliers: H. D. Smith & Co., Plantsville, Conn. Slip-joint offset pliers which are drop-forged and made with a serrated opening between the jaws. The gripping surfaces at the ends of the jaws are checkered and there is a wire cutter at the rear.

Bending Machine: Garrison Brass & Machine Works, New York City. A machine for cold-bending rods or tubes of steel or brass. The machine is also applicable for use in bending band iron into different forms for handles, coils, hooks and similar parts.

Punching Machine: Cleveland Punch & Shear Works Co., Cleveland, Ohio. An open-gap punching machine of unusually heavy construction which was built for the Cambria Steel Co. The machine will be used in the fabrication of splice bars and tie plates.

Die Cutting Machine: Alfred H. Schütte, New York City. In operating this machine a light sheet-metal templet the shape of the die to be cut is secured on top of the die blank. This serves as a guide for the cutting tool which is made with a single relieved cutting tooth.

Hydraulic Press Valve: Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mt. Gilead, Ohio. A pilot-operated hydraulic press valve for use in operating high-pressure hydraulic presses where a very large volume of water is required. The valve is controlled by two small pilot valves.

Drilling and Boring Machine: Pawling & Harnischfeger Co., Milwaukee, Wis. A horizontal drilling and boring machine which has a working area of 60 square feet. The design follows the general lines of the No. 3 machine which has been built by this company for some time.

Washer Making Machine: Joseph M. Mason Machine Co., Philadelphia, Pa. A washer making machine provided with a carrier plate that removes the product after it has been stamped. In addition to cutting washers, the machine is suitable for making various small hardware specialties.

Motor-driven Planer: Niles-Bement-Pond Co., 111 Broadway, New York City. A 72-inch planer equipped with electric motors for operating the feed mechanism and power traverse of all the heads. This machine is equipped with the Niles-Bement-Pond Co.'s standard reversing motor drive.

Gear Testing Machine: Feicht-Bevington Mfg. Co., Cleveland, Ohio. A machine for testing the accuracy of gears. Readings can be made to 0.0005 inch and the dial graduations are large so that they are easily read. The multiplying levers of the indicators on this machine have a ratio of 250 to 1.

Boring Tool: Allen & Curtiss, South Bend, Ind. A boring tool intended for use on the lathe, milling machine or drill press, which is provided with simple means of adjustment. The body is slotted to receive the cutting tool which is adjusted by two set-screws tapped into the body at the ends of the slot.

Muffle Furnace: Eclipse Fuel Engineering Co., Rockford, Ill. A vertical muffle furnace for heating high-speed steel tools. The muffle is 5 inches inside diameter and 11¼ inches high. The furnace is heated by six burners which deliver the heat to the annular space between the muffle and the lining of the furnace.

Die-sinking Machine: Jackson Machine Tool Co., Jackson, Mich. A duplex die-sinking and cherrying machine which was formerly manufactured by the Melling-Northrup Co. and taken over by the present builders about six months ago. Numerous improvements have been made which add to the efficiency and durability of the machine.

Elevator Guide Planing Machine: Niles-Bement-Pond Co., 111 Broadway, New York City. A planer designed for machining elevator guides. It measures 52 inches between the housings and the maximum distance from the table to the cross-rail is 18 inches. The table is 20 feet long and material ranging from 2 to 6 inches in height can be accommodated.

Electric Annealing Furnace: Electric Furnace Co. of America, Alliance, Ohio. An electrically-heated furnace for use in annealing brass and German silver blanks. The framework is made of steel and is 15 feet long by 8 feet wide by 7 feet 6 inches high. Doors are provided at both ends of the furnace and a mechanical pusher actuated by compressed air operates the charging mechanism.

Multiple-spindle Chucking Machine: C. M. Conradson, Madison, Wis. A hydraulically-operated six-spindle automatic chucking machine for boring and turning operations. It is equipped with tools for cutting both vertically and horizontally, and has a wide range. Both the spindle speeds and feeds may be changed at any time while the machine is under cut, which is an especially valuable feature when operating on pieces of large diameter.

Manufacturing Lathe: Greaves-Klusman Tool Co., Cincinnati, Ohio. An automatic machine in which the use of cam drums or pins for moving the tool-slides has been eliminated. The feed movement is secured through large diameter screws of coarse pitch which work in long nuts set close to the guides. The shifting mechanism which controls the feeds, speeds and indexing is operated by dogs on a drum which shift levers connected to positive clutches.

Grinding Machine: Landis Tool Co., Waynesboro, Pa. A grinding machine designed with a stationary work-table and a traversing grinding wheel. Wherever possible, ball bearings have been used in preference to plain bearings, and forgings have been used in place of castings for those parts of the machine which are subjected to severe strains. The grinding spindle runs in bearings which are self-adjusting to compensate for expansion due to an increase of temperature. These bearings can also be adjusted to take up wear. These machines are built to swing 10 and 12 inches and to take from 18 to 96 inches between centers.

SWEDISH ENGINEERING CONVENTION IN THE UNITED STATES, 1915

Plans are being made for a meeting or convention of Swedish engineers visiting the United States in 1915 on account of the San Francisco Exposition and engineers of Swedish birth permanently residing in this country. The meeting will be held in early September in Chicago, where papers will be read by visiting engineers as well as by resident members of the organization. All engineers of Swedish birth are invited to enroll. The fee for enrollment is $5. The secretary of the Eastern Organization Committee is Erik Oberg, associate editor of MACHINERY; home address 185 Sixty-eighth St., Brooklyn, N. Y. The chairman of the committee is C. J. Mellin, consulting engineer, American Locomotive Works, Schenectady, N. Y.

* * *

The Marconi Telegraph-Cable Co. in connection with the Marconi Wireless Telegraph Co. of America, has announced that the Marconi high-power trans-oceanic stations now being constructed in the vicinity of New York are nearing completion, and that public messages for direct wireless transmission between the United States and Great Britain and Ireland will be accepted soon. The tariff for full rate marconigrams will be seventeen cents a word, and for the other classes of service the wireless rates will show a corresponding reduction from regular cable rates.

* * *

The forest departments of the states of Washington and Oregon intend to discontinue the use of barbed wire for fences. The claim is that barbed wire has no advantage over smooth wire, that it injures stock, and that it is more likely to be broken down by snow. Stockmen in Oregon, who recently constructed fences of smooth wire with some misgivings, now say that they will never use barbed wire again.

G. E. HIGH VOLTAGE OUTDOOR OIL SWITCHES

The general principles of operation of indoor and outdoor oil switches are the same, but some of the details of construction are obviously different. In addition to performing the usual duties, the outdoor switch must be so constructed that successful service will result while exposed to the effects of the severest weather; neither rain, snow nor sleet should be able to interfere with satisfactory operation. All moving and operating parts must be totally enclosed and fully protected. The Type F, Form K-22 oil switches illustrated herewith meet these conditions fully. They are built in single-pole elements and are operated by hand, solenoid or air. The mechanism for each element is self-contained and mounted on the top of a steel tank. The switches trip free from the operating mechanism, so that the automatic switches cannot be held closed on overload or short circuits; and all the switches, non-automatic or automatic, are always opened at the same quick rate of speed. The standard hand operating lever consists of a removable wooden handle attached directly to the switch mechanism. This handle is removable to guard against unauthorized operation. The solenoid mechanism is similar to the hand mechanism, except that a direct-current solenoid with a rod for connecting to the mechanism is used instead of the operating handle. The air-operated mechanism is rather special and needs individual consideration.

Since the insulating properties of oil are superior to those of air, the bushings are inserted through the cover at an angle converging at the lower end, which materially reduces the size of the oil tank necessary for any given voltage. The bushings extend below the oil level down to the stationary contacts of the switch, and an iron cap forms the top of the bushing. The bushings are supported by metal clamps bolted to the tank cover and may easily be removed for inspection or repair. The contacts are of the well-known "sliding-wedge" construction. Each phase contains two contacts in series. The stationary ones consist of widely flared fingers and extra long arcing tips of drop-forged copper. The movable element of the contact is a wedge-shaped copper blade.

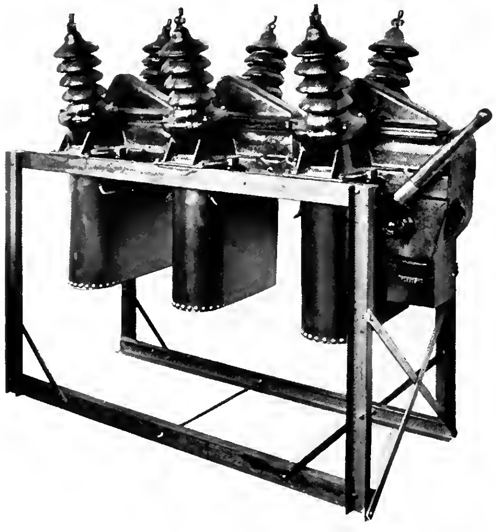

Fig. 1. Triple Pole Single Throw Oil Switch for 300 Amperes at 22,000 Volts

This blade moves in a vertical plane, being drawn up by the switch mechanism when the switch is closed and dropped by gravity assisted by springs when the switch opens. As the wedge-shaped movable contact enters the stationary flared contact, a steady and increasing pressure is exerted on the contact surfaces, which insures good contact, especially since these surfaces are kept clean and bright by a rubbing motion each time the switch operates. By the use of the sliding wedge contact, the arcing set up by opening the switch under load occurs between the extended portion of the stationary contact fingers and the upper extremity of the movable blade, which sections are not in contact when the switch is fully closed.

The switches are, as a rule, tripped on overload by trip coils acting directly on the switch toggle and operated by bushing type current transformers, although the other methods of tripping oil switches in general use can, of course, be

Fig. 2. Solenoid Operated Oil Switch for 100 Amperes at 130,000 Volts

applied. These transformers consist of the switch stud as the primary and a copper ribbon wound on an iron core around the bushing as the secondary. From one to six transformers with from one to three trip coils may be used on a three-phase circuit, depending on the protection required. The bushing transformer has been designed to furnish at a lost cost a series transformer for high tension systems. It may also be used to furnish current for ammeters where only approximate accuracy is required. These switches have been developed by the General Electric Co., Schenectady, N. Y., and are for use on lines from 22,000 volts upward.

* * *

When the additions and alterations to its huge grain elevator at Kansas City now under way are completed, the Missouri Pacific-Iron Mountain R. R. will have one of the largest plants of its kind in the world. As originally constructed, the elevator consisted of ten concrete circular storage tanks, with a capacity of 80,000 bushels each, or 800,000 bushels in all, and the elevator building proper, with a capacity of 200,000 bushels, a total plant capacity of 1,000,000 bushels. Forty additional concrete circular storage bins, 22 feet in diameter and 84 feet deep, with a capacity of 25,000 bushels each or 1,000,000 bushels all told, are under construction, besides nineteen smaller bins, with a capacity of 7000 bushels each or 133,000 bushels total. The latter are what is known as "interstice" storage bins, and they will occupy the space formerly left vacant between the circular bins of this style of elevator. The elevator will have a total of sixty-nine units of storage space, with a capacity of 2,133,000 bushels, which is more than double its present capacity.

* * *

Interesting sidelights are being thrown upon the results of the great national aeroplane subscriptions inaugurated two years ago, when, as the result of voluntary contributions by citizens, 208 aeroplanes were presented to the French army. It is alleged that certain manufacturers of aeroplanes seized on this opportunity to dispose of machines that were not of the most recent and improved types, and that many of the machines bought for the money collected by the national subscription were not new. The French army has acquired nearly one thousand aeroplanes since the beginning of 1911. The Blériot Works alone have built 181 military aeroplanes and Farman 105. This indicates why the aeroplane industry in France has developed to such an extent as compared with that in other countries.

WHAT TO PATENT

BY CON WISE

This is not an attempt to catalogue the numerous things for which the world is clamoring and which are sure to bring unlimited wealth to the patentee at a moment's notice. It is an attempt to start a discussion as to what inventions it is worth while to protect. The big values are in basic patents skillfully followed up by minor combination patents taken out at such intervals that they practically extend the life of the original patent. As F. W. Harris pointed out in the July number of MACHINERY, it is possible to obtain a patent that has no value except to the holder of the bottom patent or else which makes the bottom patent unworkable. If the holder of one patent won't buy, then the other is worthless, but there are a number of men who have made a comfortable living following up inventions in this way. Hardly any inventor is far-sighted enough to protect himself fully in his original patent and still fewer attorneys are shrewd enough to secure this protection, or it may be that they are just shrewd enough to see the possibility of getting another patent to take out if their client should happen to think of an improvement which he might also protect. For this very reason it is wise to file an application on as broad a ground as possible and then take advantage of the slow procedure of the patent office, to consult as many people as possible as to the working out of your idea.

Suppose, for example, you have invented a one-legged shop stool which maintains its balance by means of a gyroscope under the seat (any one that wishes to borrow this invention is welcome—I haven't money enough to pay the fees). You might as well write up a description, make a drawing yourself and mail the whole thing to the patent office, paying due regard to the rules which they publish, and which are clear enough so that you cannot go far wrong; then put the thing up to people who might buy your stools in some quantity. You will have to do this eventually, so you might as well begin that way. You may find that there is no market for a stool of any kind in a shop unless you create the market yourself. Will your capital hold out while you are making shop superintendents see the value of having men sit at their work? Possibly someone may object to your stool on the ground that their work requires that their men should have a back to lean against, and yours won't stand leaning against. Someone else may sit down and prove to you by mathematics that the seat of your stool will have to be four feet seven and a quarter inches in diameter to cover a gyroscope that will keep it steady, and that it will require a fifty horsepower motor to keep it running, and they won't believe to the contrary even if you bring around a sample to show them. After you have tried to play salesman for about a week you will get a totally different view of what you have invented—that is unless you were entirely crazy about it. You need not fear that anyone will take you up and actually order one of the things. No inventor ever sold anything he invented—he knows too much about it. Wait till you hear some professional salesman sell a hundred of your one-legged milking stools to some rich agriculturist, one for each cow. Then you will realize that inventing and selling are for two entirely different sets of consciences.

But to get back to the subject. It is hardly to be expected that anyone without abundant time and funds at his command will make fundamental inventions in the future with any great frequency. The field is pretty well covered and large concerns are spending large amounts of money trying to do just that. The field for the individual inventor has narrowed down to improvements on already existing devices, which may be sold to the holders of the fundamental patents or which may be worked with small capital. For example, one of my neighbors has recently made a fortune out of a labelling machine. There are and have been for years patents galore on such a machine, but there have been very few machines because those that would work were too expensive and those that were reasonable in price would not label. This man studied the situation and finally bobbed up with a simplification of the complicated machine. He had not really invented a new machine, but none of the old ones were worth anything at all, so he was able to gather in the previous patents for a song and then he came out with a patent that with the others, made a pretty strong combination. Mind one thing though, he knew the ins and outs of the machines that had been built before, because he had built a number of them. Don't try to invent something that you don't know anything about yourself. You may find that what you are trying so hard to invent has been invented before and used and forgotten. Of course it gives more play to your imagination to get up something about which you know nothing, but it also gives more play to the pocket-book. If your job is chucking pulleys invent a new chucking drill or a chuck or something that you are familiar with; don't start to invent a dish washer let your wife do that.

Just because you can get a patent allowed is no sign it is worth the paper it is written on. I do not doubt you could get a patent on a dining room chair with a bouquet holder on one side, and your next-door neighbor could probably get one on the same chair with a holder on each side, but what would they be worth, unless it was the fashion to wear flowers that way? And if you get a patent that is good for something it is worth nothing to you unless you can sell it. The place to sell it is where they are taking out patents as a regular thing. They have ten chances to one of anyone else, of being able to use it. It may be that they want to ward off an attack by some competitor, or it may just supplement some more important invention of their own, or it may point a way to them that is worth following up. In any of these cases they would much prefer to put the thing through the office in their own way and at their own expense.

* * *

DENATURED ELECTRICITY

An interesting method of preventing the improper use of electric current has been devised by an Italian engineer. The practice of making especially low rates for current to be used in electric power, heating and cooking devices is becoming more and more general, but with the ordinary constant potential current it is difficult to detect the use of lighting devices on circuits intended only for power and heating purposes. This engineer advocates the use of special circuits on which the current is subject to extreme fluctuation of voltage at rapidly recurring intervals, which would make it practically impossible to use lamps, because of the flicker in the lights. As the current is not entirely interrupted and the normal voltage is almost immediately restored the proper operation of power or heating apparatus is not interfered with and the rightful use of the circuits for their respective purposes is assured.

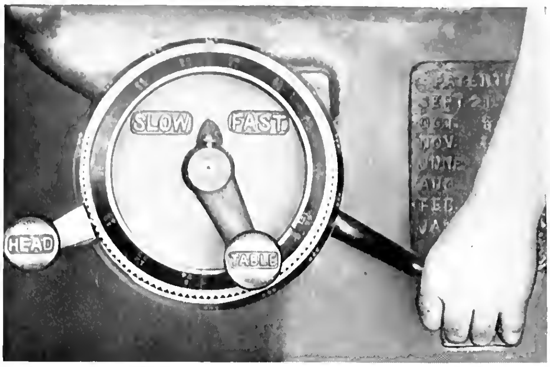
* * *

Henry J. Gaisman of New York City lately received a check for $300,000 for his invention of means for identifying photographic negatives at the time of exposure. Mr. Gaisman's invention was bought by the Eastman Kodak Co. of Rochester, N. Y. It comprises a window in the back of the camera which when opened exposes a red strip of paper on which a legend can be written with a stylus. The writing makes a break in a strip of chemically-prepared paper underneath, and sufficient light is admitted to print the writing on the negative. Hence when the negative is developed the writing develops also, and it appears on the prints made from the negative. The value of the invention will be apparent to all who have taken any photographs; oftentimes it is difficult to identify the various negatives even if careful memoranda are made of each at the time of making the exposure.

* * *

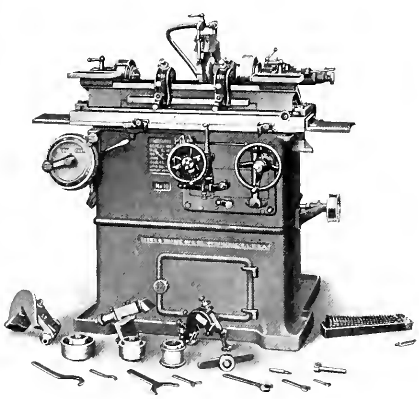
The three-hundredth anniversary of the invention of logarithms by John Napier is celebrated this year. Napier published in 1614 his work, "Description of the Admirable Canon of Logarithms," in which the statement appeared on the title page that he was the author and inventor, which was the fact, as he was the inventor of the method of logarithmic calculation and of the word logarithm itself. The debt owed to Napier by the scientific world can hardly be overestimated. The advent of logarithms marked an epoch in the history of science. Napier was born in 1550 at Merchiston Castle, near Edinburgh, and died in 1617.

Work Control in Four Motion[s]



1st—Starting the Table—The first piece is in position; take, for example, a $1\frac{1}{2}''$ diameter shaft. Pull up on the long lever and the mechanism for rotating the work and traversing the table starts. The grinding wheel is already running, for it is independent of the work, and does not stop when the work is stopped.

2nd—Speeding Up Rotation—The lever marked "Head" has previously been set to give a trial speed of rotation of 172 R. P. M., as indicated by figures on outer dial. This is too fast, so the lever is moved around the dial until the speed is right. The decrease is gradual and not by jumps.



No. 10 Plain Grinding Machine
Capacity: To 6″ diameter and 20″ length

This simple control system increases output by reducing setting-up time, by making correct speed and feed combinations quickly available, and by providing for rapid changes for different diameters on the same piece.

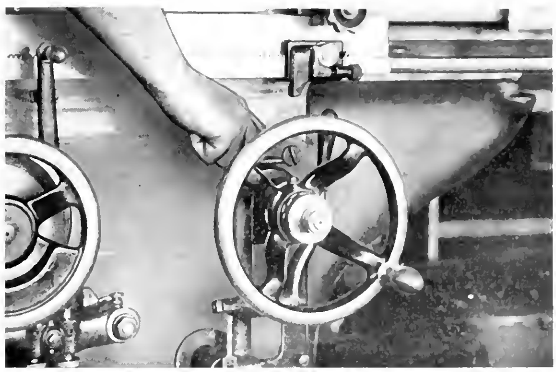
BROWN & SHARP[E]

PROVIDENCE

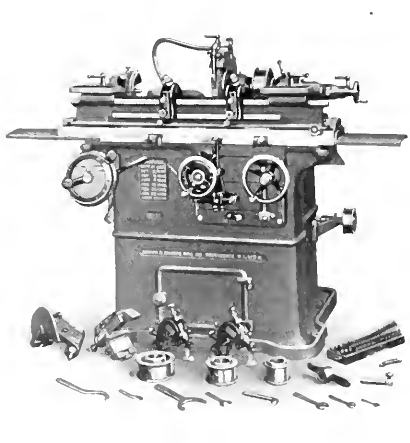
Makes Rapid Grinding Easy

3rd Regulating Table Traverse—The trial rate of table traverse of 80″ per minute is found too slow, so the lever marked "Table" is moved in the proper direction until the speed and feed are in the correct combination. The Head and Table Levers are independent so any desired combination can be obtained.

4th—Shifting to a Finish Feed—After the work is brought quickly to size with a rapid-table travel, the lever behind the hand wheel on the right is turned. This slows down the table in the ratio of 1 to 2½, so the work receives a smooth finish, without disturbing the lever for roughing table traverse.



There are many other interesting production features in addition to the above. Have you ever investigated our Universal Back Rests and Automatic Cross Feed? We should be glad to send descriptive matter.



No. 11 Plain Grinding Machine
Capacity: To 6″ diameter and 32″ length

EXHIBITS AT PANAMA-PACIFIC INTERNATIONAL EXPOSITION

More than sixty thousand exhibits have already been accepted by the division of exhibits of the Panama-Pacific International Exposition and there is every likelihood of this number being increased to eighty thousand before the last of the final allotments of space have been made. The first installation was started on May 27 in the palace of machinery when a 500 H. P. Diesel engine was placed in the center of the building. On the following day five thousand cases of exhibits arrived at the exposition and these are now being placed in their respective positions. It can be safely asserted that the finest collection of electrical and machinery exhibits ever assembled under one roof will be displayed in the palace of machinery. About five thousand exhibits will be shown there. Although the building is 967 feet long and 367 feet wide, the space has been over-applied for.

A feature of the palace's display will be the fact that every operating exhibit—and practically all of them will be in operation—will be equipped with "safety-first" appliances. The exhibitors have also cooperated with the officials in so associating their exhibits with others that complete operation will be possible, and the merits of the various exhibits will be well displayed. Machines will be shown in parts, with cross-sections, and the various workings of the different parts of the interior construction open to the view. The products of the machines shown in the various stages of manufacture, from the raw material to the finished article, will call particular attention to the machine.

Electric current for any use desired will be available to exhibitors in all of the buildings. The charge will be small, based on the actual cost. Steam will be supplied in the palace of machinery from the Gas and Fuel Building which is adjacent. When the product of the machines is turned over to the exposition, the air, steam and electricity will be supplied free. This applies to boilers, engines, compressors, ice machines, gas producers, machine tools, etc., which may be placed as exhibits in the service of the exposition.

Fuel oil will be supplied in part from stills in a model oil exhibit, which will be located in a building east of the palace of machinery and operated by the United States Government. Engine tests will be made on the different grades of refined oil coming from this interesting exhibit which will be open to the public. A large number of manufacturers are arranging to send their expert shop men with the exhibits so that the public may gain a clear idea of the efficient methods by which the finished products are made. The latest types of conveying machinery will be so arranged and the construction and operation so clearly shown that the carrying of small packages, as well as large and bulky boxes on the same conveyor to any height or distance will be as well demonstrated as it would be in a modern and up-to-date factory. Working exhibits of the latest type of hydraulic motors, such as impulse wheels and turbines, with the necessary regulating and control apparatus will be shown connected with pumps and electric generators with the working parts of the wheels and turbines exposed through glass plates.

In the palace of mines and metallurgy will be intensely interesting exhibits of all phases and features of the mining and metallurgical industries. The United States Steel corporation and its subsidiary companies intend having a comprehensive exhibit of its operations and will begin with the ore fields and carry on an educative picture of its operations in ore mining, rail and water transportation, dock operations, coal, coke and pig-iron production, steel manufacturing in its various lines, and will also present the processes of manufacturing of many of its subsidiary companies' products; also how it utilizes its by-products and the display of many of the uses in which its general products are employed, typifying the advancement in uses of this country's resources.

Two hundred and thirty-six national and international organizations have already accepted the invitation of the exposition to hold their 1915 conventions in San Francisco, and many thousand visitors will thus attend as delegates and representatives of these organizations.

VANADIUM STEEL FOR BLOW-PIPE HEADS

An interesting characteristic of chrome-vanadium steel has been demonstrated by tests made on blow-pipes used in glass factories by glass blowers. The pipes used by incandescent lamp manufacturers have been soft steel or Norway iron, inasmuch as they are easy to weld and do not oxidize rapidly. But blow-pipes made of common steel or iron must be frequently repaired, because the hot glass clings to them so tightly that they have to be hammered to remove it, but not so with chrome-vanadium steel. The glass cracks off freely and consequently the repairs on the chrome-vanadium steel pipes are less than on pipes made of iron or machinery steel.

* * *

PERSONALS

Jesse W. Reno of New York was awarded the John Scott legacy medal and premium by the city of Philadelphia, acting on the recommendation of the Franklin Institute, for his escalator.

E. K. Morgan has been promoted from the position of foreman to superintendent of the Rockford Drilling Machine Co., Rockford, Ill. Mr. Morgan takes the position of John S. Langwill, lately deceased.

F. C. Kent, formerly general superintendent of the Pierce-Arrow Motor Car Co., Buffalo, N. Y., is now connected with the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, in the capacity of works manager.

Dudley A. Johnson has been made manager of the Chicago branch of the Joseph Dixon Crucible Co., succeeding the late Sam Mayer. Mr. Johnson was assistant to Mr. Mayer for a number of years and has had extensive experience in the lead pencil and stationery business with other concerns.

Adolph Spielman, inventor of an electrically-driven portable machine for cutting cloth up to 150 thicknesses to any desired pattern at one time, was awarded the John Scott legacy medal and premium by the city of Philadelphia, acting on the recommendation of the Franklin Institute.

Charles Eisler, for the past two years employed as designer of general tools and special machinery by the United Incandescent Lamp & Electrical Co., Ujpest, Austria-Hungary, and previously as general tool-room foreman with the Metzger Motor Car Co., Detroit, Mich., has taken a position as special machine designer with the Westinghouse Lamp Co., Bloomfield, N. J.

Thomas H. Mirkel, Jr., formerly general manager of the Southwark Foundry & Machine Co., Philadelphia, Pa., and for the past four years vice-president and general manager of the Poole Engineering & Machine Co., Baltimore, Md., joined the Treadwell Engineering Co., Easton, Pa., July 1. Mr. Mirkel will represent the company in Philadelphia and vicinity, and will have offices in the Mutual Life Bldg., Tenth and Chestnut Sts., Philadelphia.

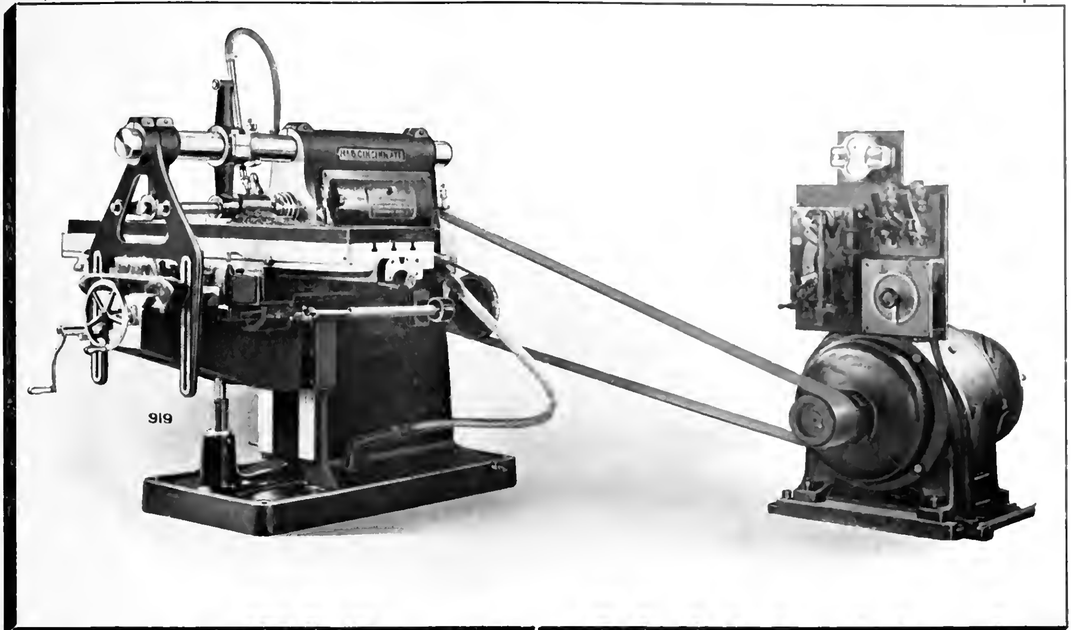
Henry J. Marks, manager of the New York office of the American Engine & Electric Co., has been made sales manager of the company. Mr. Marks is a member of the American Society of Mechanical Engineers, and of other engineering societies, and has had about twenty years active experience in the operation, manufacture, design and sale of steam engines. He will divide his time between the New York office, 90 West St., and the main office of the company at Bound Brook, N. J.

Charles S. Batdorf of New York was awarded the John Scott legacy medal and premium by the city of Philadelphia, acting on the recommendation of the Franklin Institute, for his coin counting and wrapping machine, which accurately counts and wraps coins of one, five, ten, twenty-five or fifty cent denominations into crimped cartridges containing twenty, twenty-five, forty or fifty coins as desired. The machine handles 350 coins a minute and automatically rejects counterfeit coins.

Albert Pott, sales manager, Baird Machine Co., Bridgeport, Conn., sailed July 15 on the steamship *France* for a two months' trip through Great Britain and France, to visit the company's foreign representatives and to get in touch with foreign trade in general. The company has experienced a revival of its foreign trade in the past few months, and Mr. Pott is making the trip at this time in order to become thoroughly acquainted with any new phases of foreign business, and to provide for its extension.

Albrecht F. Leue, recently purchasing agent of the Triumph Electric Co., Cincinnati, Ohio, resigned June 30 to enter upon the practice of law. Mr. Leue was born in Cincinnati in 1877, and graduated from the University of Cincinnati in

Milling Extraordinary



THE Cincinnati No. 5 Plain High Power Milling Machine has removed as high as 37½ cubic inches of steel per minute — the heaviest recorded cut ever handled by a Knee and Column Milling Machine—and not once nor twice only; this was a frequent performance in our Demonstrating Room during a period of nine months. This is MODERN MILLING!

"Stream Lubrication," the patented Cincinnati Work and Cutter Cooling System, makes this heavy cutting not only possible, but practical. The essential factor is the hood which keeps the cutter in an inverted bath, effectually cooling every part of it.

"COLD CHIPS" tells the whole story. You should send for a copy. There is something of interest on every page.

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

1898. He entered the employ of the Triumph Electric Co. in January, 1900, being engaged successively in the stock, order, correspondence and advertising departments; he has been purchasing agent since April, 1906. He studied law at the Y. M. C. A. night law school, Cincinnati, and was admitted to the Ohio bar in 1905. It is Mr. Leue's intention to give special attention to commercial and corporation law work.

* * *

OBITUARIES

Charles S. Barton, president of the Rice, Barton & Fales Machine & Iron Co., Worcester, Mass., died July 11 of a cancer in the throat, aged fifty-six years.

John S. Langwill, superintendent of the Rockford Drilling Machine Co., Rockford, Ill., died June 22 from cerebral hemorrhage, following an illness of about three months. He is survived by his widow and one child.

Morris G. Loder, sales manager of the Carborundum Co.'s branch store in Cleveland, Ohio, died after a long illness July 9 at his home in Cleveland, aged forty-one years. He was born at Strongsville, Ohio, near Cleveland. For some years he was connected with the purchasing department of the Deering Harvester Co., Chicago, Ill., and entered the employ of the Carborundum Co. as sales manager of the Cleveland branch store in 1902. He is survived by Mrs. Loder, his mother, three brothers and a sister.

COMING EVENTS

September 5-11.—Foundry and machine exhibition, showing machinery, tools, equipment and supplies for the foundry and machine shop, Chicago, Ill. C. E. Hoyt, secretary, Foundry & Machine Exhibition Co., 1949 W. Madison St., Chicago, Ill.

September 15-18.—Twenty-second annual convention of the Traveling Engineers' Association at the Hotel Sherman, Chicago, Ill. W. O. Thompson, secretary, c/o New York Central Car Shops, East Buffalo, N. Y.

September 17-22.—Autumn meeting of the Iron and Steel Institute in Paris, France. Offices of secretary, 28 Victoria St., London, S. W., England.

September 20-25 (1915).—International Engineering Congress, San Francisco, Cal., in connection with the Panama-Pacific International Exposition. W. F. Durand, chairman, Foxcroft Bldg., San Francisco, Cal.

SOCIETIES, SCHOOLS AND COLLEGES

Upper Iowa University, Fayette, Iowa. Catalogue 1913-1914.

University of Utah, Salt Lake City, Utah. Catalogue for 1914-1915, and announcements for the School of Arts and Sciences, School of Education, State School of Mines, School of Medicine and School of Law.

National Association of Corporation Schools. Papers, reports and discussions of the first annual convention, Dayton, Ohio, September 16-19, and proceedings of the organizing convention, New York City, June 24, 1913. 438 pages, 6 by 9 inches. Lee Galloway, secretary, New York University, New York City.

Johns Hopkins University, Baltimore, Md. Five lectures by Logan G. McPherson, as follows: "The Economic Transition," "Railway Competition and Combination," "Government Ownership of Railways," "The Valuation of Railways," and "The Service of Accounts and Statistics." 110 pages, 6 by 9 inches.

American Institute of Metals. Transactions of the seventh annual meeting held in Chicago, Ill., October 13-17. Edited by W. M. Corse, secretary. 381 pages, 6 by 9 inches, exclusive of bulletins 20 to 26, containing abstracts of metallurgical patents, notes and reports during 1913, together with a list of members. Published by the American Institute of Metals, Buffalo, N. Y. W. M. Corse, secretary and treasurer, 106 Morris Ave.

NEW BOOKS AND PAMPHLETS

Report of the Commissioner of Education for the Year Ending June 30, 1913. Volume I. 931 pages, 6 by 9 inches. Published by the United States Bureau of Education, Washington, D. C.

Acoustics of Auditoriums. By F. R. Watson. 34 pages, 6 by 9 inches. Illustrated. Published by the Engineering Experiment Station of the University of Illinois, Urbana, Ill., as Bulletin 73.

International Conference of Mine-experiment Stations. By George S. Rice, 99 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 82.

Lumbering Industry of the Philippines. By John R. Arnold. 22 pages, 6 by 9 inches. Published by the Department of Commerce, Bureau of Foreign and Domestic Commerce, Washington, D. C., as Special Agents Series, No. 88.

The Effect of Titanium on the Magnetic Properties of Iron. By Kenneth P. Applegate. 19 pages, 6 by 9 inches. Published by the Department of Electrical Engineering, Russell Sage Laboratory, Rensselaer Polytechnic Institute, Troy, N. Y., Engineering and Science Series, Bulletin 5.

Relative Effects of Carbon Monoxide on Small Animals. By George A. Burrell, Frank M. Seibert and I. W. Robertson. 23 pages, 6 by 9 inches. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 62.

Investigations on Drain Tile. 112 pages, 6 by 9 inches. Published by the Engineering Experiment Station of the Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa, as Bulletin 36, authorized by the American Society for Testing Materials.

Effect of an Iron Core on the Secondary Currents of a Telephone Transformer. By Eugene C. Helwig. Published by the Department of Electrical Engineering, Russell Sage Laboratory, Rensselaer Polytechnic Institute, Troy, N. Y., as Engineering and Science Series Bulletin 6.

The Electrical Resistance and Temperature Coefficient of Copper-Nickel-Manganese Alloys. By George L. Gray. 26 pages, 6 by 9 inches. Published by the Department of Electrical Engineering, Russell Sage Laboratory, Rensselaer Polytechnic Institute, Troy, N. Y., as Engineering and Science Series Bulletin 4.

Metric-English and English-Metric Lengths. By G. A. Rosetti. 80 pages, 3½ by 4 inches. Published by E. & F. N. Spon, London, and Spon & Chamberlain, New York City. Price, 40 cents.

This useful work gives equivalents in millimeters (to five significant figures) of English lengths from 1/64 inch to 10 feet, advancing by 1/64 inch; and equivalents to the nearest 1/64 inch of all metric lengths from 1 to 3200 millimeters, advancing by millimeters.

The Tractive Resistance of a Twenty-eight-ton Electric Car. By Harold H. Dunn. 53 pages, 6 by 9 inches. Illustrated. Published by the Engineering Experiment Station, University of Illinois, Urbana, Ill., as Bulletin 74.

The bulletin records the results of tests made with a twenty-eight-ton electric car of the double-end type for the purpose of determining the resistance offered to its motion when running on straight level track in still air at uniform speed, and to ascertain the relation existing between that resistance and the speed of the car.

Location of Motorcycle Power Plant Troubles Made Easy. Chart arranged by Victor W. Page. Size, 31 by 22 inches. Published by Norman W. Henley & Son, New York City. Price, 25 cents.

This chart contains a sectional view of the power plant of a motorcycle, the name of each part being plainly indicated. The descriptive part of the chart contains a list of the common derangements that interfere with the proper action of the engine and auxiliary systems, enabling the user to discover quickly the trouble under different conditions.

Link Motion, Valve Gears and Valve Setting. By Fred H. Colvin. 101 pages, 4 by 6 inches. 45 illustrations. Published by Norman W. Henley & Son, New York City. Price, 50 cents.

This practical work on locomotive valve motion was first published in 1905, and the present edition is the third enlarged and revised. Contents by chapter heads are Locomotive Link Motion; Valve Movements; Setting Slide Valves; Analysis by Diagrams; Modern Practice; Slip of Link Block; Slide Valves; Piston Valves; Setting Piston Valves; Other Valve Gears (comprising Joy-Allen, Gooch, Allfree-Hubbell, Walschaerts, Baker, and Southern).

Fitchburg Plan of Cooperative Industrial Education. By Matthew R. McCann. 28 pages, 6 by 9 inches. Illustrated. Published by the Bureau of Education, Washington, D. C., as Bulletin 1913, No. 50.

The bulletin describes the successful high school cooperative course begun in Fitchburg, Mass., in 1908, in which high school students work in the shops one week and go to high school the following week, alternating with another student so that the places in the shop and the school are constantly filled. This method has proved so successful that it has been widely noticed and is known generally as the "Fitchburg plan."

Methods of Oil Recovery in California. By Ralph Arnold and V. R. Garfias. 57 pages, 6 by 9 inches. Illustrated. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Technical Paper 70, Petroleum Technology 16.

The report was published by the Bureau of Mines, as one of a series describing the investigations conducted by the bureau in an effort to minimize waste in the production of petroleum from lands belonging to or controlled by the United States government. It treats of the factors controlling production, recoverable oil, oil pumping, plunger pumps, air lifts, bailing, swabbing, tunneling, generation and distribution of power, including steam engines, gas engines, electric motors and windmills.

Mechanical Movements, Devices and Appliances. By Gardner D. Hiscox. 409 pages, 6 by 9 inches. Published by Norman W. Henley & Son, New York City. Price $2.50.

This treatise, describing mechanical movements and devices used in machinery, which is practically a mechanical dictionary, was first published in 1899. It has been well received and the present edition is the fourteenth enlarged. The scope of the work is indicated from the fact that 1890 movements are illustrated and briefly described under the following heads: The Mechanical Powers, Transmission of Power, Measurement of Power, Steam Power, Steam Appliances, Motive Power, Hydraulic Power and Devices, Air Power Appliances, Electric Power and Construction, Navigation and Roads, Gearing, Motion and Devices Controlling Motion, Horological, Mining, Mill and Factory Appliances, Construction and Devices, Drafting Devices, Miscellaneous Devices.

Magnetic and Other Properties of Electrolytic Iron Melted in Vacuo. By Trygve D. Yensen. 73 pages, 6 by 9 inches. Published by the Engineering Experiment Station, University of Illinois, Urbana, Ill., as Bulletin 72.

The efficiency of electrical machinery depends largely upon the magnetic quality of the iron used in the pole pieces and armatures. Many investigations have been conducted with a view to decreasing the hysteresis and eddy current losses of iron and to increase its permeability. The bulletin records the results obtained by melting electrolytically refined iron in a vacuum furnace. It is possible by this means to obtain iron with a carbon content of 0.01 per cent or less without oxidation of the iron. The maximum permeability of this iron at ordinary temperatures is shown to be 19,000, occurring at a flux density of 9500 gausses. The hysteresis loss is from one-half to one-third of that for the best transformer steel used at the present time.

Methods of Machine Shop Work. By Frederick A. Halsey. 286 pages, 6 by 9 inches. 285 illustrations. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $2.50.

This interesting and valuable book contains the substance of a number of lectures delivered by the author before the students in mechanical engineering at Columbia University during the past three years. These lectures were published in the belief that they would prove useful elsewhere in the trade as well as in engineering schools and to apprentices. The volume presupposes a fair knowledge of the common machine tools and their general construction, use and application, such as an apprentice would have acquired during one or, at most, two years' work in a modern machine shop. The chapters are headed as follows: Two Systems of Machine Production; Precision Work and Workmanship; Measures of Length; Measurement of Errors; Gages, Fits and Limits; Driving Systems for Machine Tools; Turning and Boring; Floorplate Work; Drilling; Milling; Gear Cutting and Grinding. The book gives a good general idea of the most important machine shop methods and operations. It is to be regretted that ten pages of Chapter III are devoted to an attack on the metric system, a digression hardly warranted in a work of this kind.

Motorcycles, Side Cars and Cycle Cars. By Victor W. Page. 550 pages, 5 by 7¼ inches. 350 illustrations. Published by Norman W. Henley & Son, New York City. Price, $1.50.

This book deals with the construction, management and repair of motorcycles and cycle cars. The subject is handled as far as possible in a non-technical manner, and while some technical information and data are given, the material for the most part is of a practical nature and should be readily assimilated and understood by anyone. The instructions given for the control, maintenance and repair of the machines dealt with should be valuable to any user of motorcycles or cycle cars, and the discussions of mechanical principles will appeal to a still wider circle of readers, including dealers and those connected with the trade in various capacities. An effort has been made to discuss the salient points of representative domestic and foreign makes and to show clearly the mechanical points and distinctive features of each. The book is divided into eight chapters, headed as follows: Motor Cycle Development and Design; Motor Cycle Power Plant Group; Construction and Design of Engine Parts; Lubrication, Carburetion and Ignition; Power Transmission System Parts; Design and Construction of Frame Parts; Constructional Features of Cycle Cars; Motorcycle Maintenance, Operation and Repair.

Brass-Furnace Practice in the United States. By H. W. Gillett. 298 pages, 6 by 9 inches. Illustrated. Published by the Department of the Interior, Bureau of Mines, Washington, D. C., as Bulletin 73, Mineral Technology 14.

The bulletin records the investigations made by the Bureau of Mines, with a view of eliminating waste in America's miscellaneous mineral industries. There are in America about 3600 plants melting brass and bronze, and 1000 of these melt

nonferrous alloys exclusively. It was shown that in the melting of nonferrous alloys 90 to 95 per cent of the heat units in the fuel do no useful work. On the basis of $120,000,000 being the value of the metal melted each year a 2½ per cent melting loss, equivalent to 5 per cent loss on metal bought means an annual loss of $3,000,000 in metal alone. Reducing the average metal loss to that of the present best practice would mean a saving of over $1,500,000 a year. The bulletin treats of the magnitude of the brass industry; the general types of furnaces in use; describes pit furnaces; natural-draft, pit, coke or coal furnaces; forced-draft coke or coal pit furnaces; oil or gas pit furnaces with burners; tilting furnaces; tilting forced-draft coke furnaces; tilting oil furnaces; open flame tilting furnaces; reverberatory furnaces; cupola furnaces; and semiproducer furnaces. Possible improvements in furnaces and accessories are discussed. The causes of disease and danger, and essentials for health and safety are also dwelt upon, forming an important and valuable conclusion to the work.

Spur and Bevel Gearing. 306 pages, 6 by 9 inches, 142 engravings. Published by the Industrial Press, New York City. Price, $2.50.

During the past six years MACHINERY has published over 125 25-cent reference books. These well-known books include the best of the material that appeared in MACHINERY during the past years. Many subjects, however, cannot be adequately covered in all their phases in books of this size, and in order to meet the demand for more comprehensive and detailed treatments on the more important mechanical subjects, it has been deemed advisable to bring out a number of larger volumes, each covering one subject completely. The book under review is one of these volumes. In bringing out this book the first consideration was to make its contents meet the practical needs of the machine building trade. Mere theory and academic discussions have been avoided. The rules, formulas and instructions are illustrated whenever practicable, and examples are given to show applications to everyday problems. Theoretical considerations, however, have not been neglected in cases where they are necessary to fully explain a practical process. Hence, this book on spur and bevel gearing is a treatise on both the practice and the theory along such lines as will make it especially useful to practical men. The book contains fifteen chapters headed as follows: Principles and Dimensions of Spur Gearing; Materials used for Gears; Strength and Durability of Spur Gearing; Simplified Formulas for Strength of Gears; The Stub-tooth Gear; Noisy Gearing; The Design of Spur Gearing; Methods of Cutting Spur Gear Teeth; Production and Heat-treatment of Gears; Bevel Gear Rules and Formulas; Strength and Design of Bevel Gears; Methods for Forming the Teeth of Bevel Gears; Milling the Teeth in Bevel Gears; Long and Short Addendum Gears; Skew Bevel Gears.

NEW CATALOGUES AND CIRCULARS

Cutler-Hammer Clutch Co., Milwaukee, Wis. Bulletin 15020 on magnetic couplings, clutches and brakes for rubber mill service.

James Clark, Jr., Electric Co., 520 W. Main St., Louisville, Ky. Leaflet showing "Willey" direct- and alternating-current sensitive drills.

Brown Hoisting Machinery Co., Cleveland, Ohio. Catalogue S of "Brownhoist" suspended concrete bins for coal, ashes, ore and other materials.

William Gaertner & Co., 5345-5349 Lake Park Ave. Chicago, Ill. Catalogue of universal laboratory supports, balances, weights, glassware and supplies.

J. Davidoff, 563 Forty-eighth St., Brooklyn, N. Y. Circular of the Davidoff automatic driving belt, clutch and cam protector for preventing accidents on type-setting machines.

Yale & Towne Mfg. Co., Stamford, Conn. Pamphlet entitled "Safety First" illustrating and describing a simple device for the prevention of accidents on power presses.

S. K. F. Ball Bearing Co., 50 Church St., New York City. Leaflet treating of the operating principle of S. K. F. ball bearings and the advantages to be secured through their use.

Marvin & Casler Co., Canastota, N. Y. Leaflet descriptive of rotary center indicator, an instrument designed to indicate quickly and accurately the center or axis of a rotating spindle or shaft.

Kasenit Ltd., 8-9 Ludgate Square, Ludgate Hill, London, England. Circular of the Keen impact ball tester described in the July, 1913, number of MACHINERY. Kasenit Ltd. is marketing the tester abroad.

Newark Gear Cutting Machine Co., 67 Prospect St., Newark, N. J. Leaflet advertising "Newark" gears. This company makes gears of all kinds of the highest degree of precision, for heavy duty and for ordinary work.

Warner & Swasey Co., Cleveland, Ohio. Catalogue of No. 4 universal turret screw machine for manufacturing duplicate parts from bar stock, castings and forgings. The machine is provided with power traverse for both carriage and turret simultaneously.

National Machinery Co., Tiffin, Ohio. National Forging Machine Talk No. 4 discusses the importance of large die opening and shows how this effects economy in the forging machine. National heavy-pattern forging machines are made with four-five- and six-inch die openings.

F. W. King Optical Co., Euclid Arcade, Cleveland, Ohio. Circular of the "I-Safe" goggle for workers in steel works, foundries, machine shops and wherever eyesight is endangered by flying particles; also of colored glasses for electric arc and oxy-acetylene welding operators, etc.

Chicago Pneumatic Tool Co., Fisher Bldg., Chicago, Ill. Bulletin 34-N, describing class "N" "Chicago Pneumatic" steam and power driven enclosed compressors. Simplicity, rigidity, exceptionally large bearing surfaces, automatic lubrication and indestructible flat disk valves are the salient features of this type of compressors.

Stow Mfg. Co., Binghamton, N. Y. Catalogue 14, 96 pages, 6 by 9 inches, describing the general line of portable tools of this company's manufacture, including flexible shafts, drill presses, tapping and reaming machines, grinders, motors and electric drills, boring machines, etc. The company also makes motors and grinders of the stationary type.

Sprague Electric Works of General Electric Co., 527-531 W. 34th St., New York City. Bulletin 48901, describing the construction and giving dimensions of electric winches and winding drums. These machines are designed for use on work for which the ordinary overhead hoist is not adapted. The application for hauling cars, locomotives in repair shops, and heavy trucks up inclines at ferries, is illustrated.

Joseph T. Ryerson & Son, Chicago, Ill. Bulletins 9071 and 13071, illustrative of the Ryerson high-speed friction saw and the Lennox serpentine shear, respectively. Books Nos. 4 and 8 of the Technical Library Series, treating of internal furnace boilers with Morison corrugated furnaces, and concrete reinforcing, respectively. The last book shows steel bars, expanded metal and corrugated sheet steel centering used in reinforcing concrete.

Allen-Bradley Co., Milwaukee, Wis. Bulletin B-571 illustrating type CR speed regulators for reducing the speed of two- and three-phase slip ring motors and containing tables of dimensions and prices. The features claimed for this device are compactness, overload capacity, and infinite speed adjustment between minimum and full speed of motor, regardless of load. The company will gladly furnish additional details to those interested.

Cleveland Twist Drill Co., Cleveland, Ohio, has issued a special anniversary number of its monthly house organ "Drill Chips" which contains an interesting description of the making of a twist drill, from the inspection of the bar stock in the laboratories to the testing of the finished product. The booklet is illustrated with views taken in the plant of the Cleveland Twist Drill Co., and the information contained is of considerable general interest.

Colburn Machine Tool Co., Franklin, Pa. Bulletins 68, 69, and 71, illustrating and describing Colburn vertical boring and turning mills of 42, 48, and 60-inch capacities, respectively. Bulletins 55, 67 and 70, treating of special attachments for Colburn boring mills including pulley crowning attachment, faceplate jaws and chucks, adjusting and safety devices, etc. Bulletins 53, 62, and 64 on Colburn D-5 heavy-duty drill press of 36-inch swing and attachments.

Tate-Jones & Co., Inc., Pittsburg, Pa. Catalogue on heat-treating furnaces, telling of the uses, features of construction and points of advantage of Tate-Jones annealing, packhardening, casehardening, general hardening, muffle, lead hardening, crucible oil-tempering and other furnaces. The various types of furnaces are illustrated and tables giving stock sizes of each are included. The book is an attractive publication, illustrated with good half-tones and tastefully arranged.

Halcomb Steel Co., Syracuse, N. Y. Booklet on "Ketos" tool steel, containing 49 pages, 4¼ by 8 inches. "Ketos" steel is of especial value for use in intricate tools where the labor cost greatly exceeds the cost of the steel. The features claimed for it are durability, keen cutting power, and non-shrinkage and non-warping properties. The book is illustrated with views showing a number of intricate tools made from "Ketos" steel without distortion, warping or cracking troubles.

Link-Belt Co., Chicago, Ill. Section A of catalogue 110 on Ewart detachable link-belt, and sprocket wheels, containing complete information on detachable link-belt and illustrated with halftones made from unretouched photographs of chain links, full size. Rules for obtaining the working strains and horsepower of link-belts are given, and directions for determining the position of link-belt on sprockets showing whether the hook or the bar of the chain should run first. Users of link-belt will find this sectional catalogue a valuable instruction book.

Colonial Steel Co., Pittsburg, Pa. Catalogue 13 descriptive of the process of manufacturing Colonial tool steel. 49 pages, 5 by 7 inches, printed in colors. The method of manufacturing tool steel is described step by step, and the illustrations show the iron being melted in the crucible furnace, drawing the ball, drawing off the slag, packing the crucibles, casting the metal into molds, stripping ingots from molds, hammering, and inspection. Information is also given on annealing, hardening and tempering carbon steels, and selecting tool steel.

J. H. Williams & Co., 61 Richards St., Brooklyn, N. Y. Booklet outlining the company's plan of pensioning employes and its life insurance and vacation allowance systems. A fund is set aside by the company for payments on account of the pension, life insurance and vacation systems. Any employe who has reached the age of 65 and has been for twenty-five years continuously in the employ of the company may be retired on a pension. Employes may also be retired at 55 at the option of the company. Special provision is made for those engaged in hard physical service in the forge, blacksmith and polishing departments. All employes who have worked continuously for three or more years for the company are entitled to have insurance paid to their beneficiaries in case of death. Employes who have worked two or more years for the company are given one-half week's pay as a vacation allowance and those who have been five or more years with the company are allowed one week's pay.

Kearney & Trecker Co., Milwaukee, Wis. Catalogue on "Milwaukee" milling machines, 86 pages, 6 by 9 inches. This book contains a complete description of the line of milling machines and their various parts and attachments manufactured by this company. The "Milwaukee" milling machines are made in both horizontal and vertical types. A special feature of the horizontal type is the double over-arm which provides exceptional rigidity to the cutter and insures positive alignment of the arbors. The cascade system of lubrication is also an exclusive feature of the "Milwaukee" milling machines. The lubricant is stored in a reservoir at the bottom of the machine, and pumped to the top, from where it "cascades" down over all gears and bearings, providing a continuous system of lubrication. There is a separate lubricating system for the cutter, which operates only when the spindle is rotating. Special safety provisions have been made, all gears, belts, pulleys, etc., being carefully guarded.

R. K. Le Blond Machine Tool Co., Cincinnati, Ohio, has brought out a treatise on Le Blond milling machines, and milling practice. This book contains 220 pages, 6 by 9 inches, and sells at 50 cents per copy. It contains information on kinds of milling, feeds and speeds, cutter design, milling machine construction, care and adjustments of milling machines, dividing heads and systems of indexing, spiral cutting, and data on bevel, worm and spur gearing. The section on milling practice shows a variety of interesting examples of milling, including slab and face milling, form milling, surface milling, straddle milling and a great many special jobs. A number of tables giving the equivalents of millimeters in inches and inches in millimeters, Morse tapers, cutting speeds, decimal equivalents, angles for fluting spiral milling cutters, sines and cosines, tangents and cotangents, etc., are included. The table of leads obtainable with the change gears furnished with Le Blond spiral cutting head covers twenty-nine pages. This book should be of great value to all engaged in milling machine practice, and practically indispensable to those using Le Blond milling machines.

TRADE NOTES

Bosch Magneto Co., 223 W. 42nd St., New York City, has taken over the Rushmore Dynamo Works of Plainfield, N. J., which will be operated in conjunction with the company's factory in Springfield, Mass., in the manufacture of Bosch lighting and starting systems.

Adams-Campbell Co., Los Angeles, Cal., has just completed a modern factory building at 1730-1734 S. Los Angeles St., and will install additional equipment in shop, foundry and plating plant, for the manufacture of brass goods, sheet metal and wire novelties, for tool and die making and general machine work.

National Business Bureau, Fourteenth St. and Pennsylvania Ave., Washington, D. C., offers its services to corporations and various business interests in matters affecting trade conditions and business relations. The bureau advises its subscribers of all legislation, past, present and pending, affecting tariff, banking currency, income tax, etc.

Clipper Belt Lacer Co., 1020 Front Ave., Grand Rapids, Mich., shipped a carload of No. 2 "Clipper" lacers and hooks to its European agents, Schuchardt & Schutte, Berlin, Germany, the latter part of June. This was the company's first shipment abroad, and was placed through the efforts of W. K. Lee, who is spending some time in Europe in the company's interest.

Michigan Electric Welding Co., 514 Hart Ave., Detroit, Mich., has completed an addition of 4017 square feet area, making the total increase of floor area within the year 8070 square feet. Equipment has been added which increases the scope of the work. The company manufactures automobile parts and does butt and spot job welding. Drag links and brake rod assemblies are its specialties.

Titanium Alloy Mfg. Co., Niagara Falls, N. Y., has organized a bronze department for the manufacture of titanium-bronze specialties under its various patents. William M. Corse, formerly works manager of the Lumen Bearing Co. of Buffalo, and lately general manager of the Empire Smelting Co., Depew, N. Y., will be associated with the company as manager of this new department.

Butterfield & Co., Derby Lane, Vt., and Rock Island, Quebec, are building an addition to their factory at Rock Island. The building will be 185 feet long, 60 feet wide and three stories high, and will be constructed of brick and concrete. A portion of the new structure will be used for manufacturing twist drills and milling cutters; it is hoped that the new factory will be in operation January 1, 1915.

H. A. Strauss Data-Card Service, Harris Trust Bldg., Chicago, Ill., has begun the publication of technical data cards 5 by 8 inches, which are intended to cover the entire field of engineering and the allied trades and sciences. The copy for the cards is done in India ink, free-hand. The cards are printed from zinc etchings reduced to the required size, and the data is thus presented in a very compact but readable style.

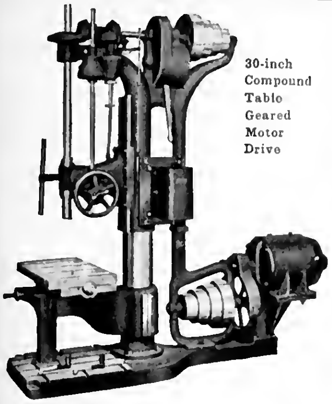
Classifying the Reader

One of the most interesting things about human beings is their variety. The moment you attempt to classify them specifically you find that your labels don't fit. Take the reader of MACHINERY for example. Each advertiser has a label in his mind, more or less definitely outlined, which, from his viewpoint, fits the average reader. We have no doubt that in general terms it does fit, but we know that the labels themselves differ, especially in the effort to define the habits and viewpoints of readers.

It is our business to know definitely not only *who* MACHINERY'S readers are, and *where* they are, but *what* they are. By which we mean that we must know their business and occupation as well as their name and address. In most cases we know who they are and their business or occupation long before they subscribe, because it is of the utmost importance for us to know it. The names of more than 90 per cent of new subscribers for MACHINERY *come out of our own working lists*, which is , we think, definite enough.

MACHINERY'S working lists are in two divisions. One division, comprising only principals and mechanical executives, contains nearly 65,000 names. The other, with nearly 180,000 names, is a list of designers, toolmakers, machinists and others variously occupied in the mechanical field. From the names in this list, MACHINERY'S mail-order work constantly segregates the intelligent, ambitious and progressive. Our readers are necessarily the brightest minds in the metal-working industries. The others neither read nor study and MACHINERY is not for them any more than Shakespeare is.

The labels which form unconsciously in the minds of our 470 advertisers agree in classifying the reader as a man engaged in mechanical work—proprietor, works manager, chief designer, master mechanic, foreman, head machinist, or by whatever titles the responsible men are designated. They differ only in trying to classify the reader rigidly as to his habit of reading advertising. Some read all the advertising regularly, but a great many, having familiarized themselves at one time or another with the tools advertised, read only the new points developed; while the busiest men in the field aim only to keep posted on the latest tools and practice and use the journal as a directory of the trade. No label fits them all. But the facts emphasize the vital importance to the advertiser of keeping his advertising always up to the highest standards, keeping it fresh and interesting and putting definite information into it.



30-inch Compound Table Geared Motor Drive

SNYDER DRILLS

None better, and few equal. Accurate in Construction, Rigid in Operation, Great Time Savers in Production. They have met the demands for all purposes, at all times, in all countries for the past thirty years. We have sold thousands of them, and none have been returned. On these statements our reputation, established for thirty years, is based.

Small Drills in Multiple

For drilling small holes, working fast and holding its accuracy, the Taylor & Fenn manufacturing Multiple Spindle Drilling Machine cannot be surpassed. It affords the right speed and the right feed for drilling up to 3/4" diameter, and a 1/2" hole one inch deep can be drilled in cast iron in four seconds. A series of gears and silent chains have proven much better and more efficient than belts for driving a machine of this type—they will not slip, there is less friction, and speed changes are more readily made.

The Oil Well Supply Co.,
Grant Hubley, Sec'y, Pittsburgh, Pa.,
writes as follows:

"The battery of twenty-five 27" Lodge & Shipley lathes as shown in the picture has been in service for four years, day and night, the output per lathe being materially increased, and the upkeep during these years has been practically nothing."

This bears eloquent testimony to the durability of Lodge & Shipley lathes and their value as manufacturing units.

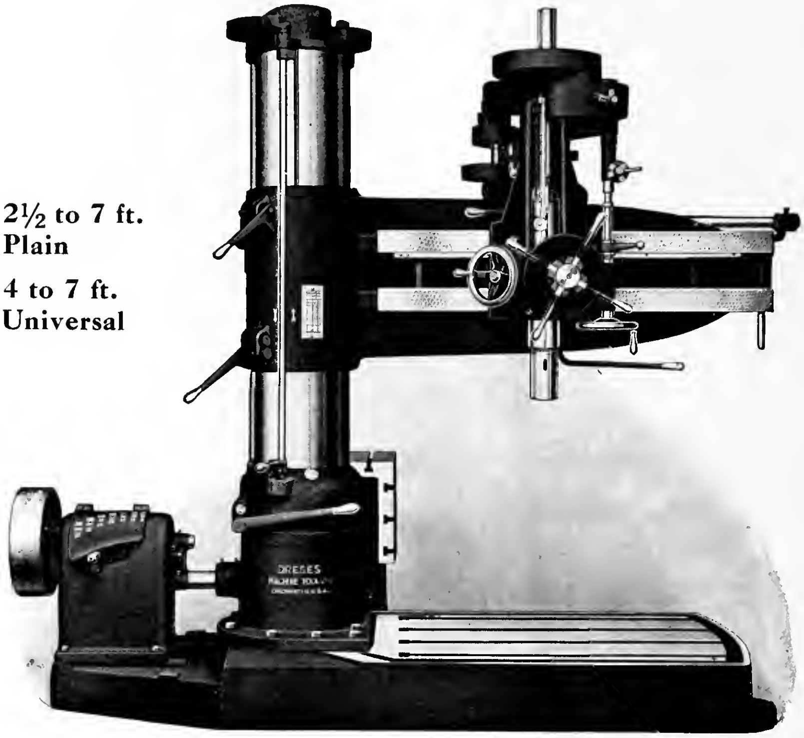
Originality in Design

DISTINGUISHES THE

New Line of "Dreses" Radials

**2½ to 7 ft.
Plain**

**4 to 7 ft.
Universal**



Here Are a Few of the New Features

Pulley shaft on speed variator has annular ball bearing, gears are of steel and hardened and run in oil baths.

Base has oil groove so designed to increase the working surface.

Column is greatly enlarged at lower end and has a third bearing in the middle, doubling the strength and rigidity.

Arm has double webbed box shaped lower rib, preventing twisting.

Head has a third bearing in the rear, adding to the support, preventing bending and straining of rear shaft and rapid wear of bevel gears and bearing. Friction bevel gears and worm wheel run in oil bath.

Quick return has four levers serving as pilot wheel to move spindle; each lever engages and disengages the feed.

Friction for starting, stopping and tapping is double expanding, powerful in gripping, easy to operate and adjust.

Steel gearing, hardened; phosphor bronze bushes; ball bearings in all places essential.

High spindle speeds.

Least friction and power consumption.

DRESES MACHINE TOOL CO.

FEATURES

which make such results possible:
High initial driving power.
Patented Double Band Frictions in tapping mechanism.
Frictions run at higher speeds than on any other Radial.
Very high gear ratios.
STEEL GEARS throughout.
All Bearings BRONZE BUSHED.

SHAPERS SHAPERS

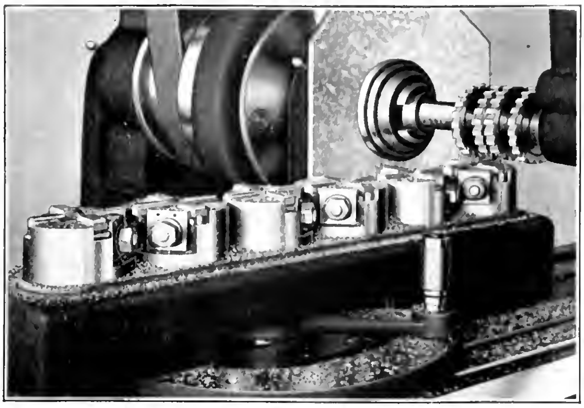
INTENSELY PRACTICAL



It doesn't require a "student of economics" to realize the practical working value of

THE LeBLOND RAPID POWER TRAVERSE

It has a cold dollars and cents appeal to the man who pays the bill.

The use of this feature enables the pieces illustrated to be finished at the rate of

40 SECONDS EACH.

Full Size Detail of Buttons

These pieces are milled from the solid in 40 seconds each. They are tough bronze buttons, to be used in ornamental iron work and are 1¼" long by ¾" wide (see full size detail). There are 8 milled surfaces on each piece. The cutters, 4" in diameter, run 240 R. P. M. at a feed of .041" per revolution. The fixture consists of a battery of six chucks, each holding four pieces or 24 at each loading. The chucks are indexed through 90 degrees with a single index crank. The cutters are so placed that one set of cutters finishes the ends of 2 pieces, while the other cutters are milling the length of the remaining pieces in the same chuck. After indexing through 90 degrees, the chuck is again passed under the cutters, completing the operations.

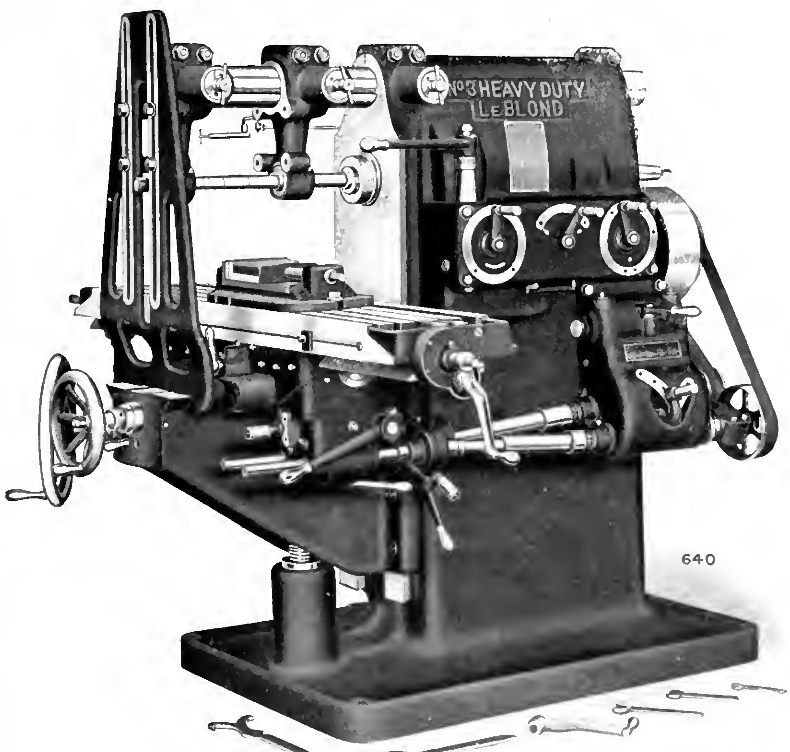
The table is returned and the space between the chucks traversed at the rate of 25 feet per minute by a movement of one lever.

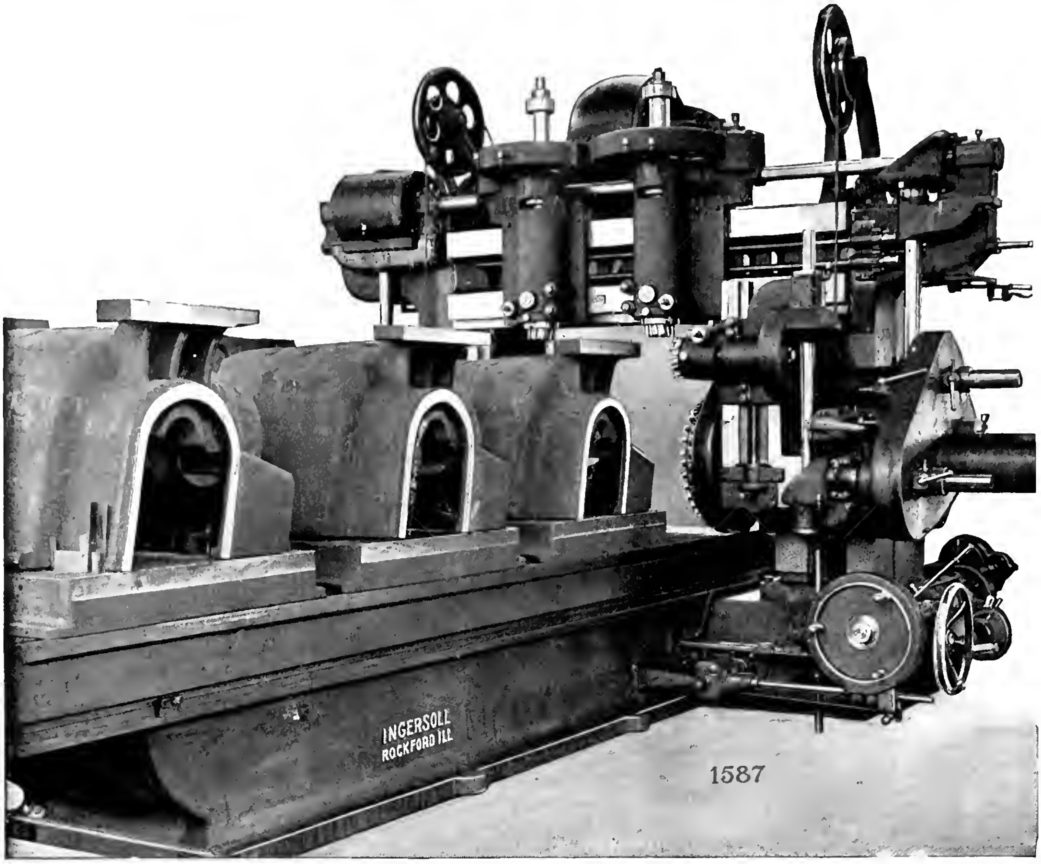
Apply the possibilities of this intensely practical machine to your work.

A miller not equipped **with the LeBlond Rapid Power Traverse** could never equal this production.

THE R. K. LeBLOND MACHINE TOOL COMPANY

Cincinnati, Ohio





Milling Engine Frames for Traction Engines

The demand for internal combustion traction engines for farm purposes has in a very short period grown from practically nothing to tremendous figures. Of the machine tools which have enabled manufacturers to meet this ever increasing demand, none has shown greater individual efficiency on duplicate work than the Milling Machine, and for finishing duplicate parts such as engine housings, frames, etc.—

THE INGERSOLL MILLING MACHINE

stands at the head. The work of these machines is at once a revolution and a revelation in manufacturing methods.

A recent installation is shown in the illustration—a 50″ x 16′ Five Spindle Ingersoll Milling Machine milling engine frames for the Rumley "Oil Pull Tractor"—and this is the third large Ingersoll Milling Machine to go into this plant. Repeat orders are concrete evidence that Ingersoll Milling Machines have not only made good but have become indispensable —in many places we have cut down planing time twenty-five to seventy-five per cent.

If you are interested in securing greater production and at the same time reducing cost of production, write us your requirements—no expense nor obligation attached. We should be glad to tell you what an Ingersoll Milling Machine would do on your work.

We specialize on Milling Machines exclusively.

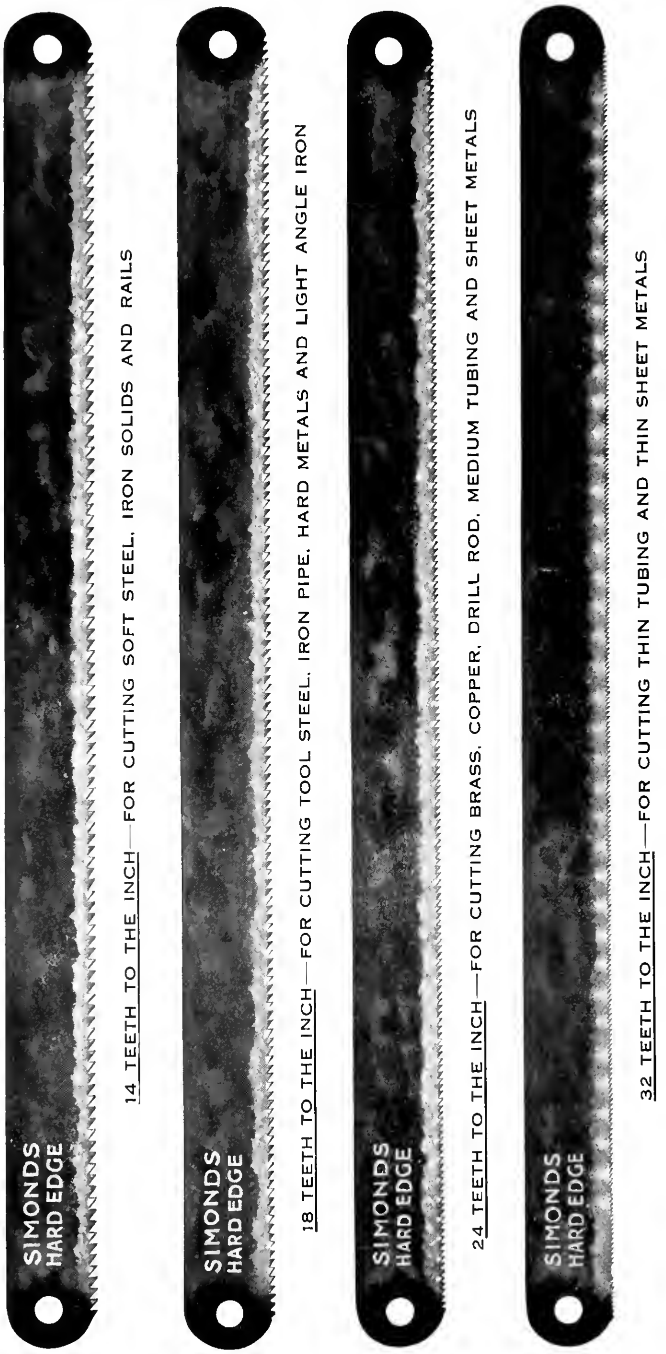
SIMONDS

Hard Edge Hack Saw Blades

(NON-BREAKING)



Yes! Hack Saw Blades have made some great strides in quality in the past year or two.

Formerly they broke; the new Simonds Hard Edge Blades overcome that difficulty—**they are practically unbreakable.**

Think of what a tremendous advantage that is, especially when this blade for all general work will cut as much—and as fast—as the all-hard blades you have used.

It's the newest blade on the market—and the most economical; it lasts longer and **will save you fifty per cent on your hack-saw blade purchases** in a year's time over other kinds of blades.

Select the kind of blade you require for your work—for general purposes 18 teeth are the best—and order a gross on trial from your supply dealer; if he does not have them we will send them to you on receipt of price; 8-inch \$4.80, 9-inch \$5.40; 10-inch \$6.00, or 12-inch \$7.20. No man ever made money buying poor goods; buy the best.

The "GIANT"

No. 5—With a 4 7-8" Post

A Keyseater of the Right Design

Many of the keyseaters on the market are made especially for certain lines of keyseating, and must be adapted for other work as it comes. This Keyseater will cut a keyway in any piece of work, of any size or shape, and the work can be fastened and released in the time usually required by other machines for "getting ready." In this machine the work is fastened by the bore alone; the hub does not need to be faced and a quantity of parts, spur gears or similar pieces, may be keyseated at the same time; taper keyseats as easily cut as straight keyways.

Accuracy is not a matter of guess on this machine, for the post which holds the work serves as a guide for the cutting tool. Six different sizes to handle the lightest and the heaviest work. When thinking of keyseating think of the **GIANT**.

Our catalogue describes all sizes. Want one?

Why the "Double-Point Dog?"

The upper point first touches the tumbler and having a long leverage on the belt shifting mechanism, it moves the belt gently and smoothly, even at the highest cutting speed. As soon as the belt has started to shift, the lower point comes in contact with a cam-shaped projection on the tumbler and completes the shift at a very high speed. The belt is thus shifted quickly and without a jerk, no matter at what speed the planer may be running. This is one of the exclusive features of

GRAY PLANERS

Write for catalog describing them all.

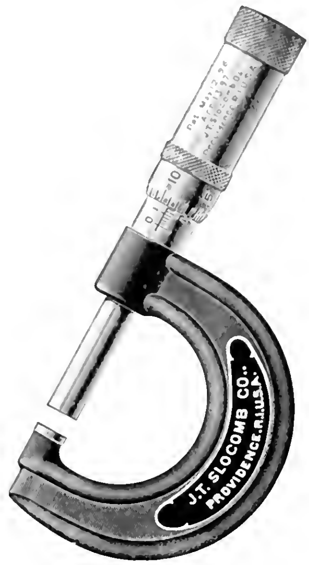
3150-3152 SUPERIOR AVENUE — CLEVELAND, OHIO, U. S. A.

JAMES G. DORNBIRER — GEO. W. FORD

"SLOCOMB"

The Longest Lived Micrometer that Can Be Bought

Some of the Reasons Why

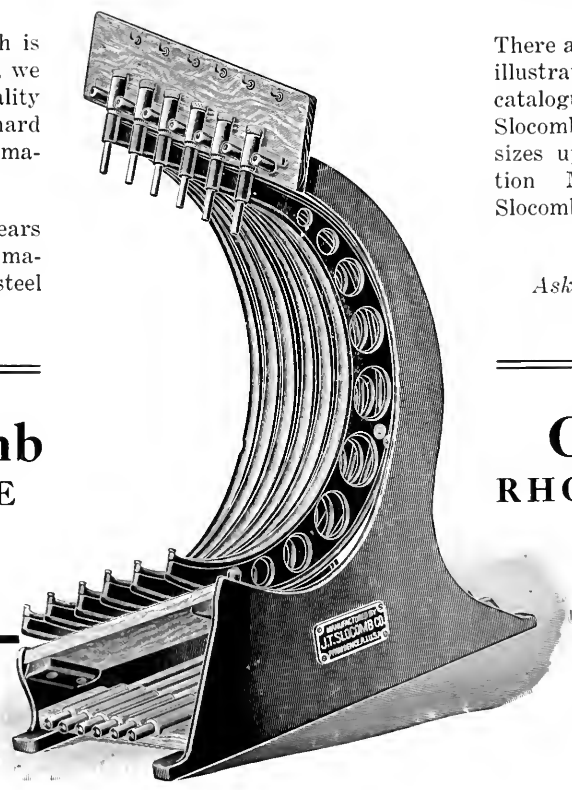


SLOCOMB MICROMETERS ARE USED ALL OVER THE WORLD

Slocomb Micrometers have many features exclusive to themselves—advantages which contribute accuracy and durability—constructional features not found in other micrometers.

The screw, or spindle, which is the heart of the micrometer, we make of the very highest quality unannealed tool steel—as hard as it can be and still be machined.

Naturally, this screw wears longer than one made of machinery steel or some other steel which cannot be hardened.



The Slocomb screw runs in a soft steel nut inserted in the frame and readily renewable. Wear takes place in the nut—the part which can be replaced at the least cost.

There are other features, too, all illustrated and described in the catalogue. It shows also the Slocomb combination sets in sizes up to 24″, the new Friction Micrometer and other Slocomb tools of precision.

Ask for Catalogue 14-M.

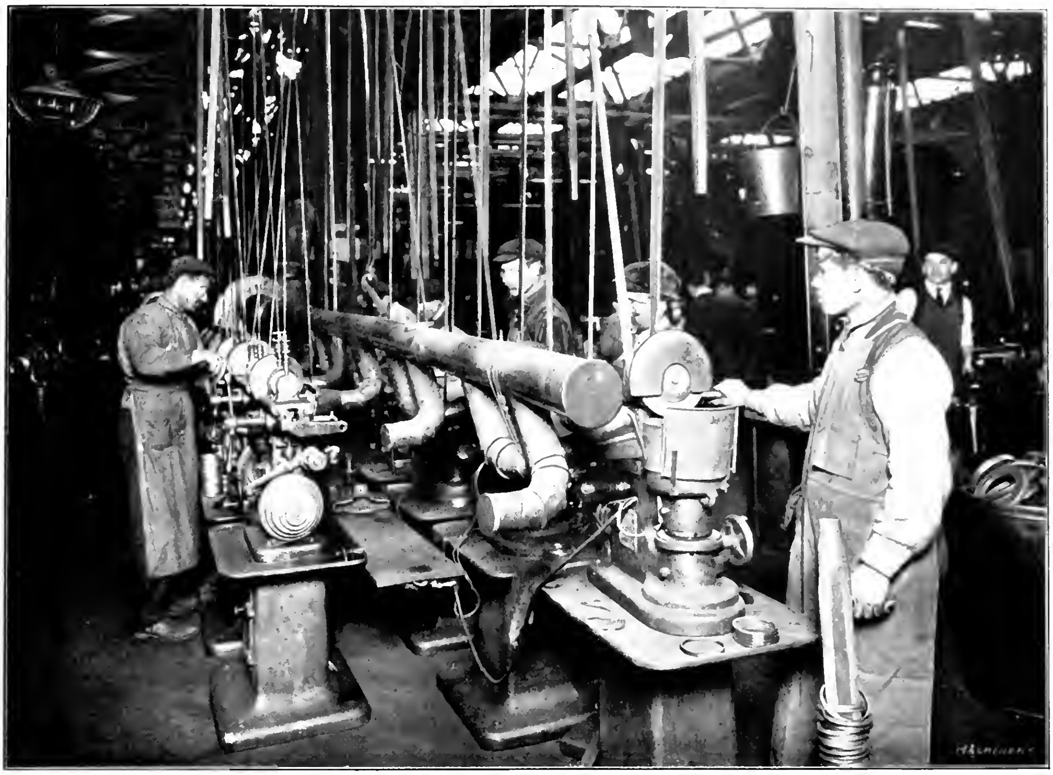
THE MARK OF TRADE THAT MEANS BEST GRADE

The "Heald" Installation at the Ford Plant



Piston Ring Grinding as it Should Be

The Heald Piston Ring Grinder is recognized as the one successful machine for this type of work. Learn more about it by getting our latest catalogue. Study it out for yourself.

There are thirteen Heald Piston Ring Grinders in the Ford plant used exclusively for grinding piston rings. Each machine turns out from 2000 to 2400 piston rings in eight hours, grinding one side of the ring only, two operators as well as two machines being required to complete a ring.

Heald Ring and Surface Grinding Machines have many features which adapt them for grinding surfaces on work, such as small washers, piston rings, thrust collars, etc.—a magnetic chuck for holding work, micrometer adjustment for obtaining the exact thickness, angular adjustment for grinding convex or concave surfaces, adjustable bearings for taking up all wear, variable cross feed to the grinding wheel, and a demagnetizing switch for the magnetic chuck. These all help production without sacrificing accuracy.

THE HEALD MACHINE CO. 20 New Bond Street **Worcester, Mass.**

CHICAGO OFFICE: 24 South Jefferson Street.

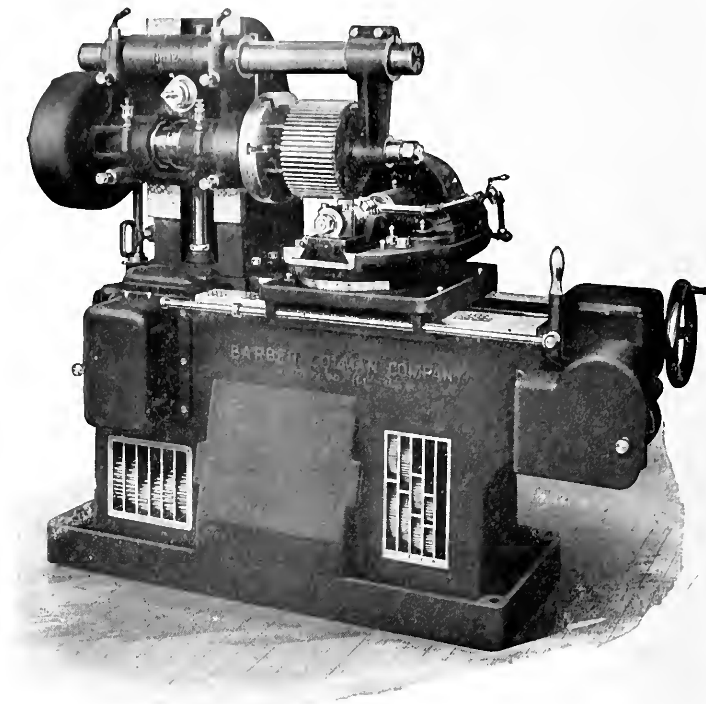
The B-C No. 12 Hobbing Machine



These Features Help Reduce Your Gear Production Costs

Machine is extra heavy and compact, with weight carefully and properly distributed. Bed and column are of rigid box section. Hob slide is close to the solid bed. Work sets close up to spindle bearings in the work slide.

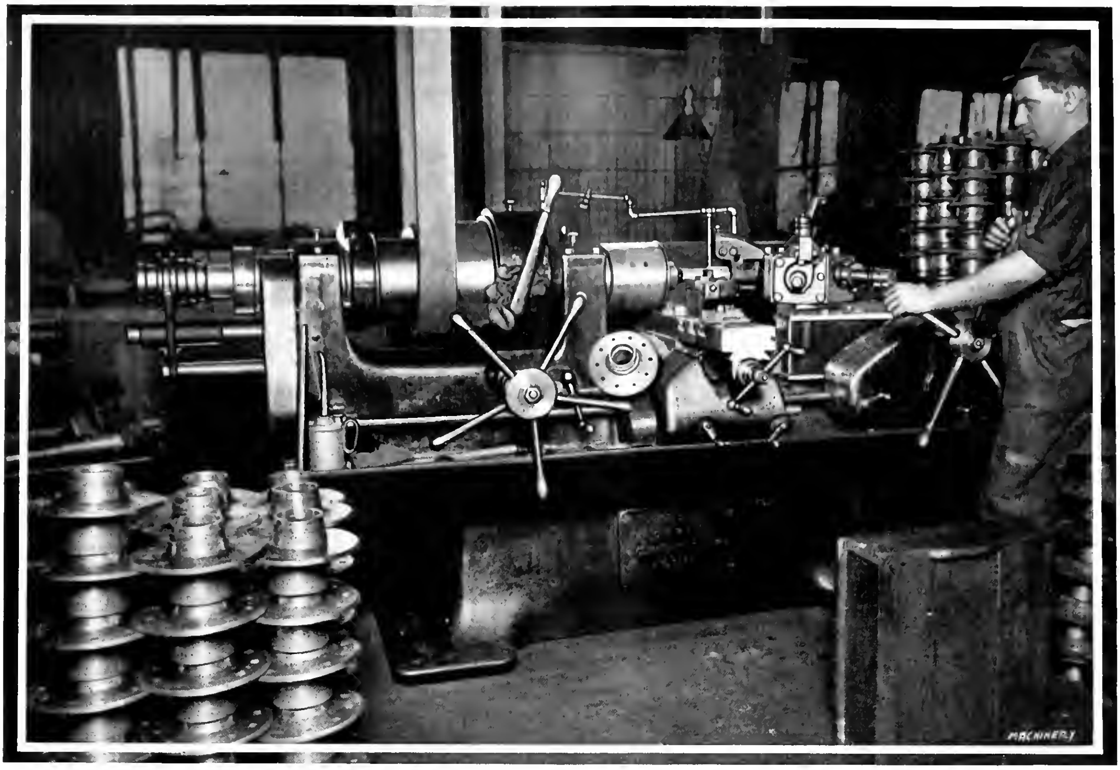
Control handles are on one side. Hob slide is mounted on horizontal ways. Work arbor is horizontal.

You can readily see how these features give ease of operation and ability to take fast, heavy cuts—and those are what increase your rate of production and so reduce production costs.

If you produce spur or spiral gears in quantities, you can cut costs by installing a B-C No. 12 Machine. Send samples or blue prints for estimated rate of production.

BARBER-COLMAN COMPANY

ROCKFORD, ILLINOIS, U. S. A.



MACHINERY

Grind Milling Cutters More Accurately

TO grind a milling cutter accurately is fully as important as to buy a correctly formed, properly tempered cutter in the first place, for the efficiency of the tool largely depends on how well it is sharpened. Union Milling Cutters and Union Cutter Grinders are an ideal combination—the Cutter correct to begin with and the Grinder to keep it so until it is worn out.

This Union No. 2 Formed Cutter Grinder is entirely new, and, we believe, a great improvement over the old form of grinder. The grinding wheel on this new machine is mounted on a stationary vertical arbor, and the work, which is on a horizontal table, is passed back and forth across the face of the wheel. A gauge is provided which regulates the cut so that each tooth of the cutter is ground on an exact plane with the center of the cutter and equally distant.

Cutters up to 8″ diameter by 3″ face can be sharpened on this Union Grinder, which has a 6″ wheel with a 4″ adjustment to or from the work.

"Union" milling equipment is unsurpassed.

May we mail further details?

Concerning Fay & Scott Gap Bed Lathes

Lathes are perhaps the most important factor of shop equipment, and for that reason it pays to make careful selection.

The Fay & Scott gap bed lathe has peculiar advantages for the everyday shop. It is an all-round lathe, suited for light or heavy work and is equipped with every appliance for turning out accurate work fast. Double back gears provide wide range of feed and speed changes, the bronze spindle bearings assure perfect alignment and there is plenty of power for the heaviest cuts.

Before you purchase the new lathe you will doubtless look into the merits of various makes. Ask us about the F & S line—you can learn more about the Fay & Scott Lathes in a half-hour's talk with our representative than from all the catalogs ever issued. Drop in and see us, or let us drop in on you.

Springfield Castings
Are All Semi-Steel
The ideal casting for Lathe and Shaper must be hard, to withstand wear; tough, to withstand shocks; and soft enough to machine and fit accurately. Pure cast iron will not sustain shocks nor heavy strains. Pure cast steel has not the wearing qualities. The ideal mixture is the proper combination of these two materials.
In Springfield Semi-Steel Castings we have combined the strength of steel with the wearing and machining qualities of cast iron. Of the application of this new material in all castings in Springfield Lathes and Shapers, we shall have more to say later on.
In the meantime, we shall be glad to answer specific questions.

Important Announcement

We take pleasure in announcing to our customers and friends that we have now brought out a complete line of Solid Reamers. The same guarantee is back of these tools that has been back of all McCrosky products for years, which means that any tool proving defective in either workmanship or material will be replaced at once, no charge.

Our earnest endeavor to deserve our rapidly increasing business, and our sincere purpose to render real service in the larger sense, have created a confidence in McCrosky products, which we believe wiil find expression in a ready demand for this new line of tools.

We are in a position to quote most attractive discounts on these tools. A yearly contract with us on your complete Reamer requirements should save you money.

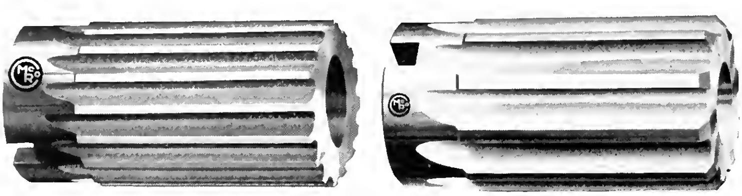
Ask for Bulletin A-4

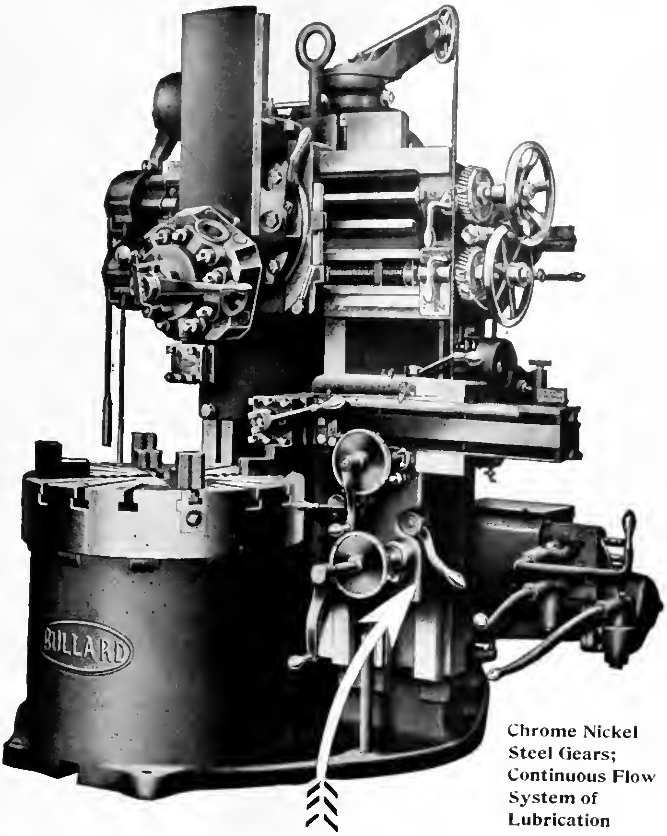
Our McCrosky and Ideal Adjustable Reamers, Wizard Quick-Change Chucks and Collets, McCrosky Expanding Mandrels, Wizard Variable Speed and Reversing Attachments, Searchlight Universal Lamp Brackets, etc., are fully described in our general Catalog No. 4. May we send you a copy along with the Solid Reamer bulletin? It may point the way to some big savings in your production cost.

THE McCROSKY REAMER CO.

MEADVILLE, PA., U. S. A.

EXPORT AGENT—Benjamin Whittaker, 21 State St., New York





THE SIDE HEAD

Of The Bullard Vertical Turret Lathe

is carried by a Side Rail or vertical guide-way (patented) secured to the bed and column in such manner as to rigidly support and absorb, without chatter or vibration, the most severe strains which may be imposed on the cutting tools.
There is no overhang of the Side Head Saddle (note wide bearing in illustration) and the feeding power is applied at a point close to the work, obviating any tilting and binding tendency under cutting strain.

This construction, the result of fourteen years' experience with the type, is absolutely essential if the Side Head is to be fully efficient.

It will never be necessary to replane a Bullard bed to maintain alignment and take up wear in the Side Head bearing surfaces—the Side Rail takes the thrust and has provision for realignment. The Bullard Side Head is usable and fully efficient throughout the full actual range of the machine.

Send for Book MV-25 for full details of this and other features.

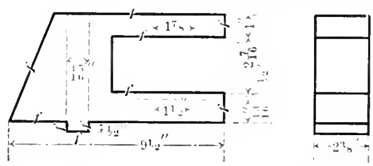
No Question Where This Job Belonged



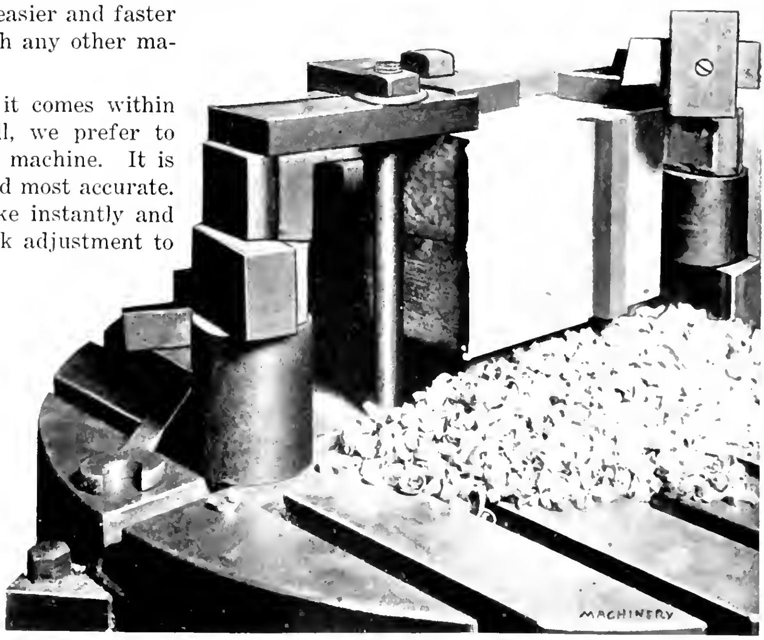
When this drawing for a hammered steel electric trolley jig was handed him, there was no question in the mind of the foreman for the Brown Hoisting Machinery Company (Cleveland, Ohio) where the job should be finished. He sent it to the Dill Slotter, where the tapered end, tongue and slotted section, 2⅞" wide by 5" long, were finished, two pieces at a time, easier and faster than was possible with any other machine or method.

He said: "Provided it comes within the range of the Dill, we prefer to take the work to this machine. It is fast, easy to set up and most accurate. We can stop the stroke instantly and we have a power quick adjustment to the circular table. It is an indispensable tool for our work."

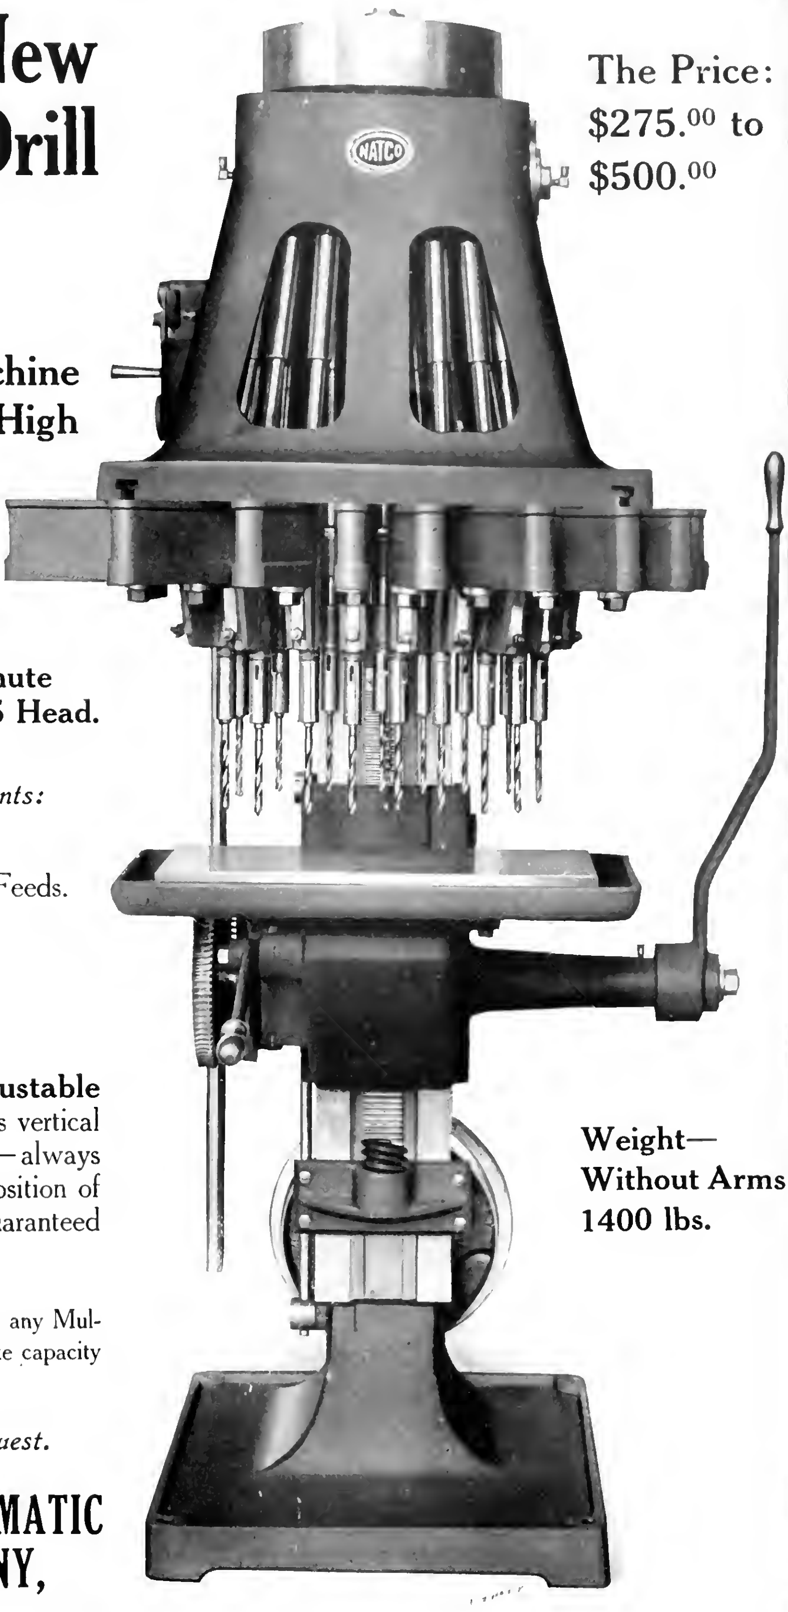
We'll gladly show you the many Dill Slotter advantages. May we?

The DILL SLOTTER PEOPLE

Kensington, Philadelphia, Pa.



Another New Multiple Drill



The Price:
$275.00 to
$500.00

A Powerful Machine that will drive High Speed Drills to best Advantage.

CAPACITY:

8½ x 12⅜ Drills at 5 inch Feed per minute in Cast Iron—9 x 15 Head.

Some of its Good Points:

Continuous Belt Drive.
Three Changes of Gear Feeds.
Pilot or Lever on Knee.
Automatic Drop Table.
Hyatt Roller Bearings.
All Gears Hardened.

A New Patented Adjustable Arm.—One nut controls vertical adjustment of spindles—always accessible regardless of position of Arms. Universal Joints guaranteed for 2 years.

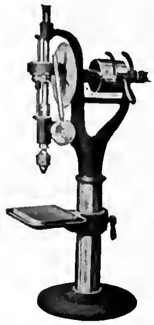
Weight— Without Arms 1400 lbs.

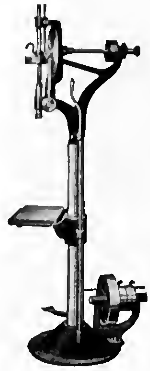
We invite a comparison with any Multiple Drill on the market of like capacity and price.

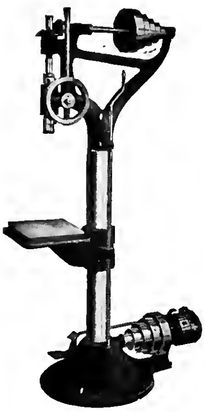
Further details on request.

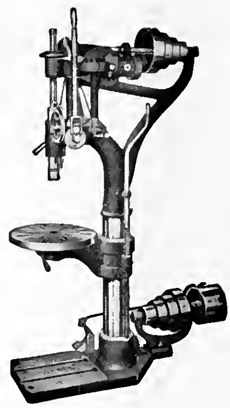
NATIONAL AUTOMATIC TOOL COMPANY,

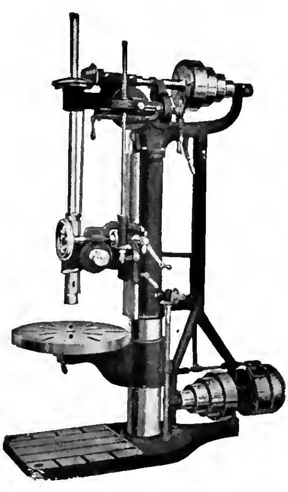
RICHMOND, INDIANA, U. S. A.

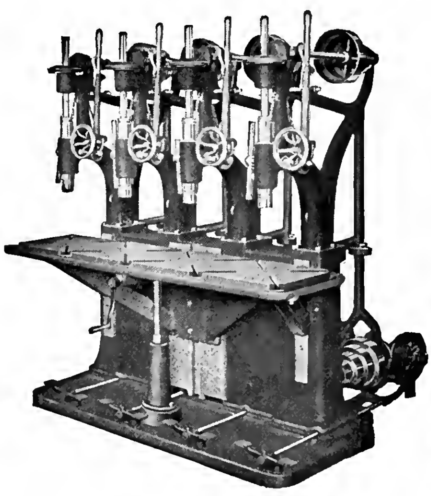










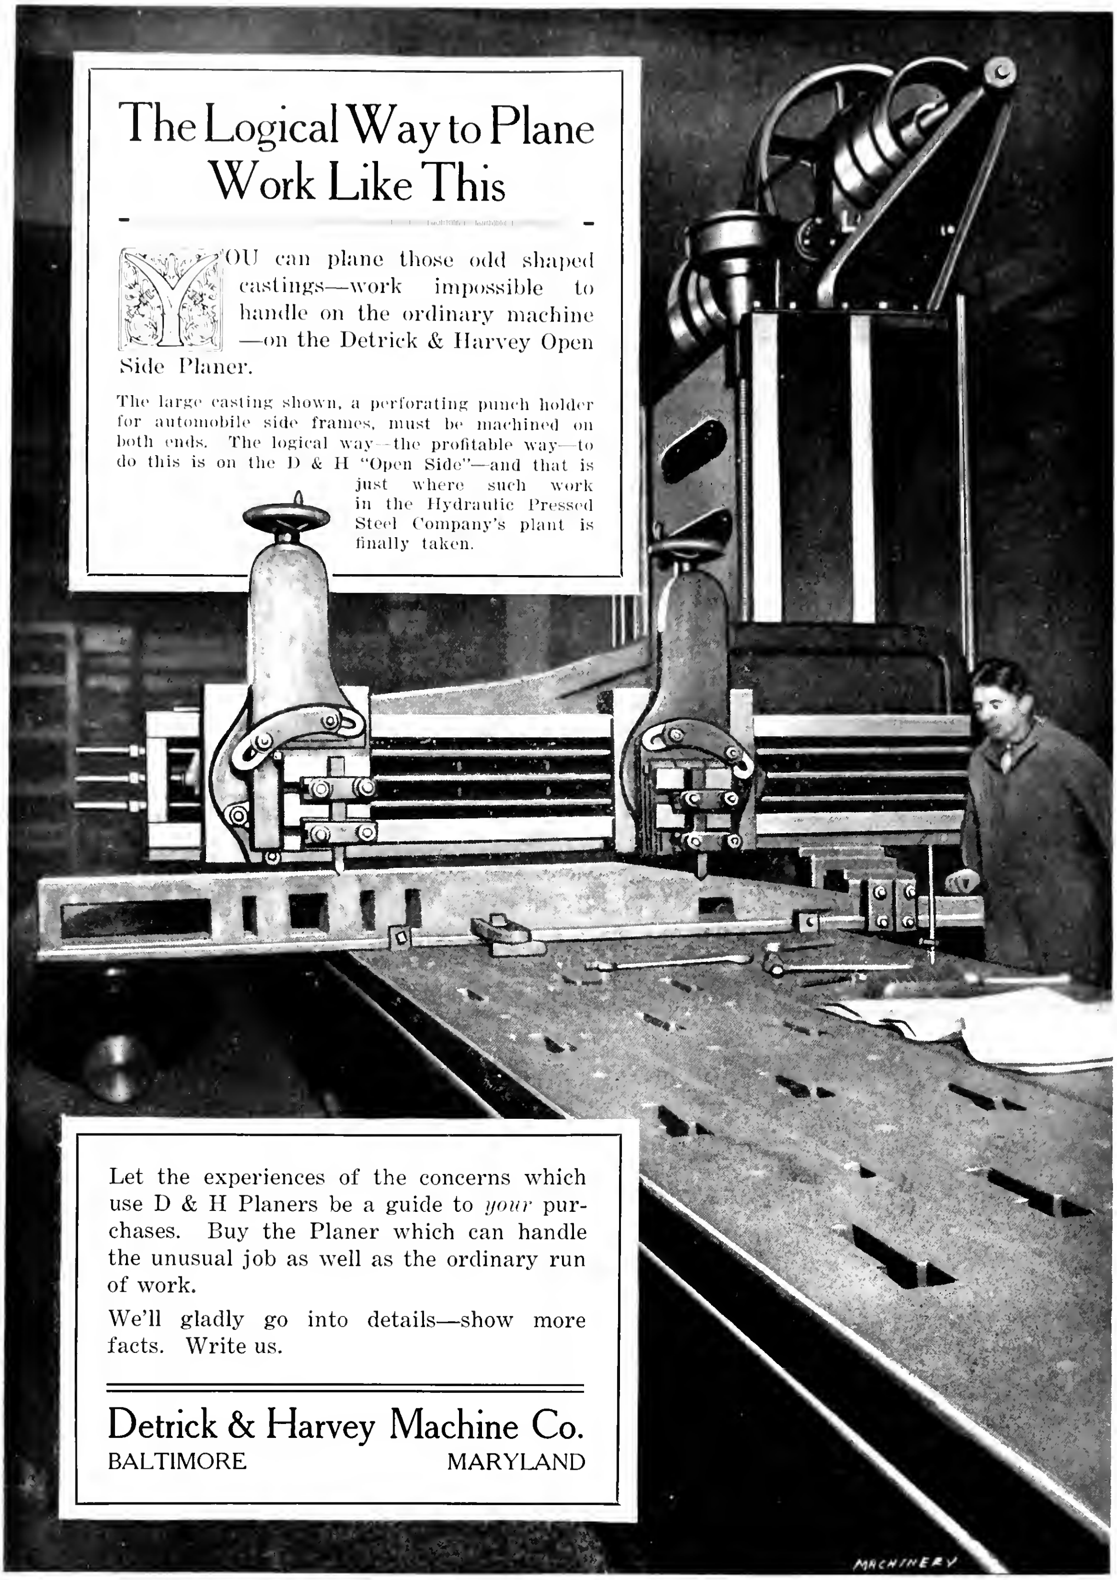


See pages 88-89

The Logical Way to Plane Work Like This

YOU can plane those odd shaped castings—work impossible to handle on the ordinary machine—on the Detrick & Harvey Open Side Planer.

The large casting shown, a perforating punch holder for automobile side frames, must be machined on both ends. The logical way—the profitable way—to do this is on the D & H "Open Side"—and that is just where such work in the Hydraulic Pressed Steel Company's plant is finally taken.



Let the experiences of the concerns which use D & H Planers be a guide to *your* purchases. Buy the Planer which can handle the unusual job as well as the ordinary run of work.

We'll gladly go into details—show more facts. Write us.

Detrick & Harvey Machine Co.
BALTIMORE MARYLAND

THE DETRICK & HARVEY OPEN SIDE PLANER

GEAR HOBBING

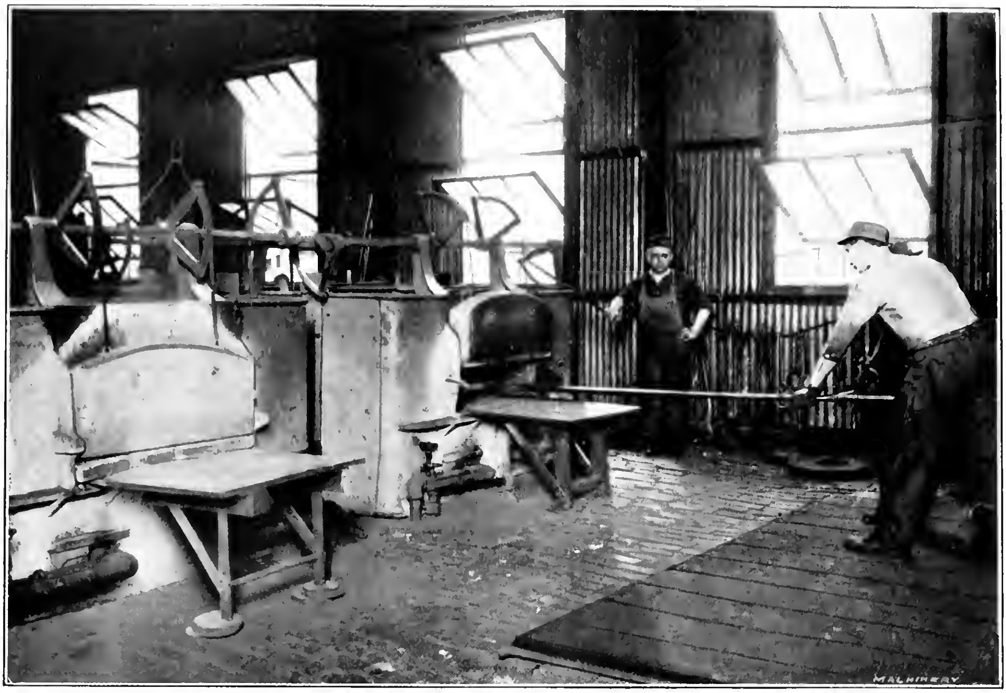
Tool and a Few Things it Makes Possible

When in operating position they present a true rack to the work. This rack is ground all over and any distortion in hardening is corrected, and being ground on the sides, the cutting edges of the tool generate without heating up the gears under operation. There is also this additional advantage—when worn out the tool may be returned and new racks inserted.

These hobs, with the rigid, powerful Lees-Bradner Gear Generating Machine, have set new standards of accuracy and production in automatically hobbing spur and spiral gears up to 14″ outside diameter. Worm gears up to 1″ C. P. and 14″ outside diameter and worms of any lead not over 1″ C. P., 8″ long and 8″ outside diameter can also be cut.

Let us send the Lees-Bradner booklets.

PANY, Cleveland, Ohio, U. S. A.



After You Have Turned It—What?

After you have turned up a difficult piece—a gear, a shaft, a universal joint—and your inspector has put the O. K. on it, what then? How about the heat treatment? Is it uncertain? Are there delays? Is there a loss in this department? Then it is high time you investigated

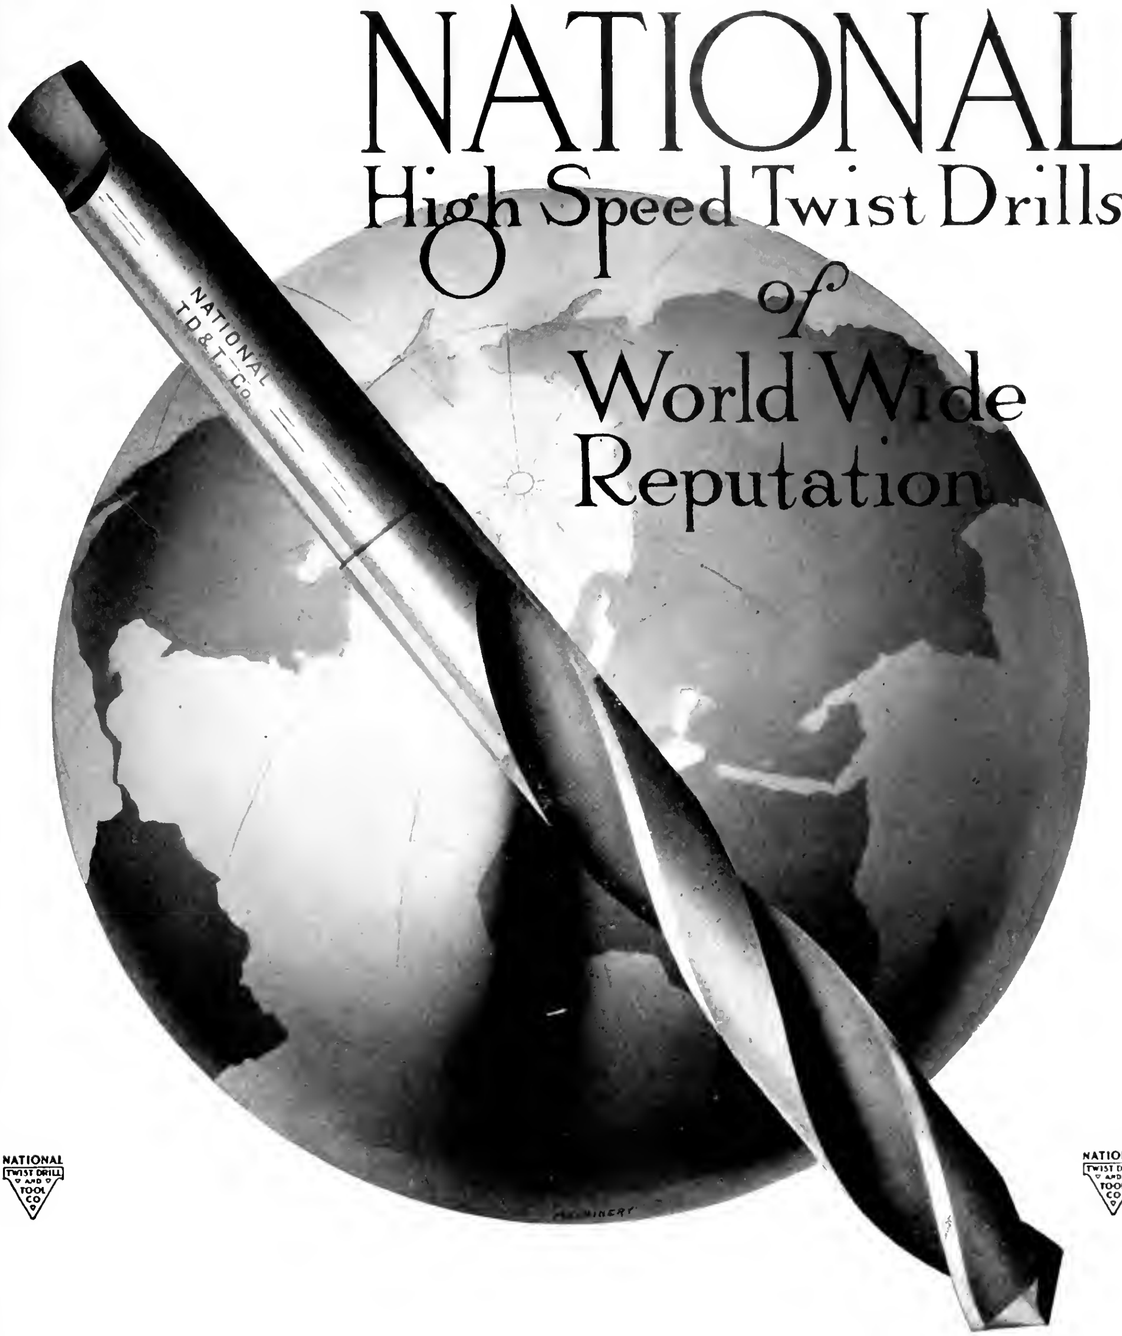
The Infuso Process

With new materials and new methods, perfected by specialists, "Infuso" makes easy results in heat treatments heretofore considered impossible. It reclaims materials scrapped by ordinary methods. It adds to the life of treated metals as much as 300 per cent in some cases. Intricate castings, or difficult heat treating, where only a part of the piece is hardened, we can treat by the "Infuso" Process—and guarantee results and minimum loss.

"Infuso" has accomplished such remarkable results for some manufacturers that they have closed up their expensive and uncertain heat-treating departments entirely. We give them the results they want—quicker, surer and cheaper.

Let us prove it on your samples. The booklet explains.

THE STEEL IMPROVEMENT COMPANY
CLEVELAND, OHIO, U. S. A.



NATIONAL TWIST DRILL AND TOOL CO

National Drills have an international reputation. They are used wherever there are machine shops. The final test, the service test, proves National Drills true to size, almost unbreakable in use and tempered to exactly the right degree.

National High Speed Twist Drills are more economical because they are more durable—the best reason in the world why you should use them.

Catalogue on request.

NATIONAL TWIST DRILL & TOOL COMPANY

DETROIT 120 White Street, NEW YORK, N. Y. OFFICES: 104 So. Jefferson Street, Chicago, ILL. MICHIGAN

operator received $2.75 per day; therefore, the comparative costs were:

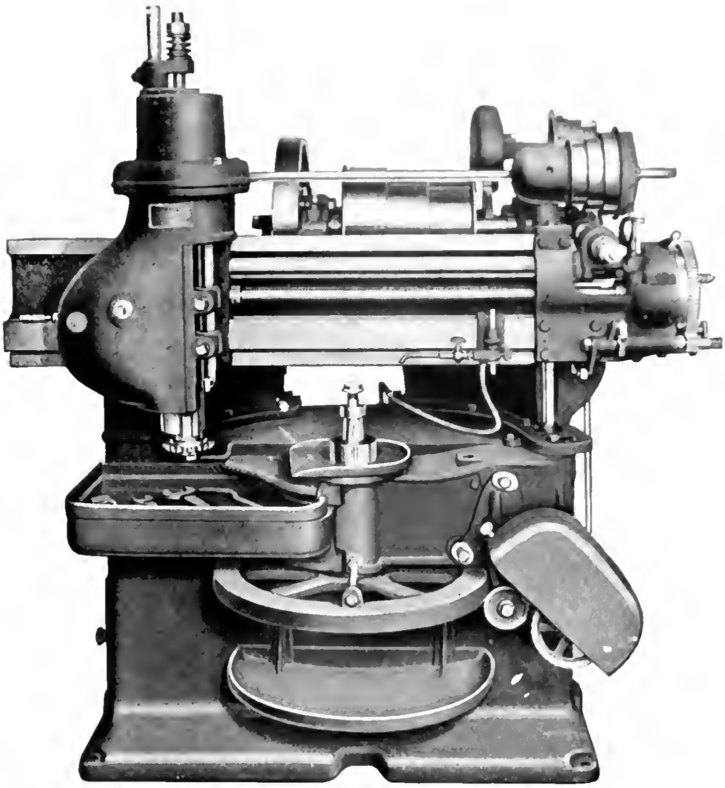
For 20 rotating gear cutters, 5 operators at $2.75......$13.75

For 14 Gear Shapers, 3 operators at $2.75 8.25

One operator could run four ordinary gear cutters while one operator could run five Gear Shapers.

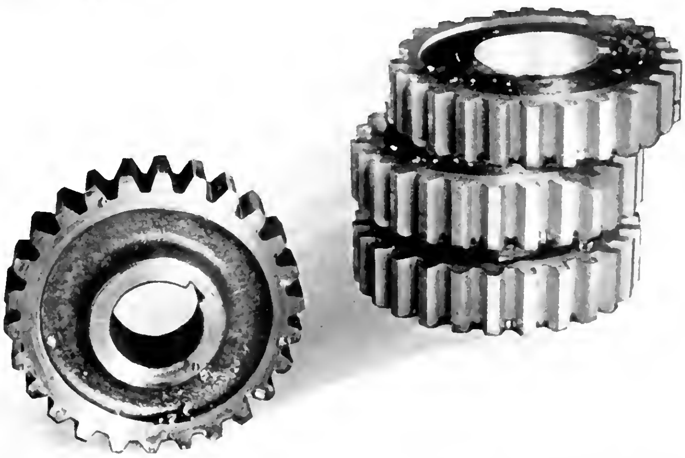
Now consider cutter costs. The rotary milling cutter costs $6.54 and cuts 300 gears before giving out. The Gear Shaper cutter costs $11.50 and cuts 600 gears before giving out.

Here are the figures for cutting a lot of 3000 gears:



Cost on ordinary gear cutters:—20 machines run by 5 operators for 3 days at $2.75	**$41.25**
10 cutters at $6.54	**65.40**
Total	**$106.65**
Average cost per gear	**.035**

Cost of cutting 3000 gears on the Gear Shaper:—14 machines run by 3 operators for 3 days	**$24.75**
5 Gear Shaper cutters at $11.50	**57.50**
Total	**$82.25**
Average Gear Shaper cost per gear	**.027**



And bear in mind that gears from the gear shaper were much better quality than those secured from the other types of machines. This concern now uses Gear Shapers exclusively for roughing and finishing transmission gears.

How do you do this work?

COMPANY, Springfield, Vermont

FOREIGN AGENTS:

Great Britain, Henry Kelley & Co., Manchester. Austria, White, Child & Beney, Vienna. Japan, Manning, Maxwell & Moore, Inc.

"I Bought These Three B & S Hammers Just After the Chicago World's Fair

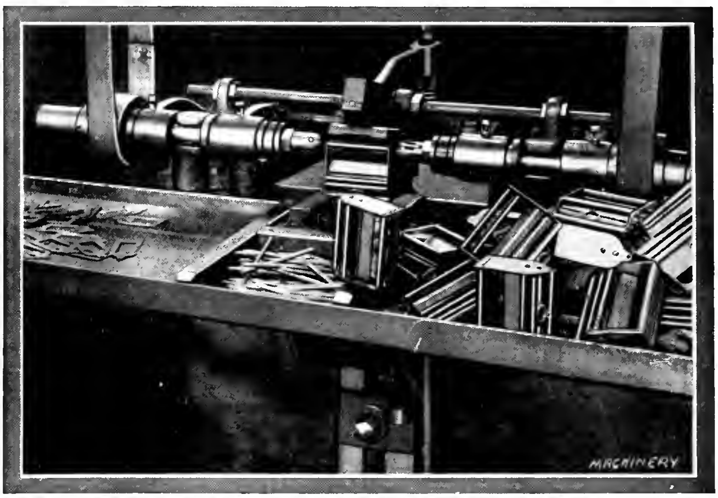
—I was making good money then for a youngster just out of his apprenticeship, and I bought the best tools I could get. I have put at least ten handles in the smallest hammer, and many in the others, too; but the hammers themselves are just as good as they were over twenty years ago, when I bought them."

G. O. Carlson, Die Sinker, Wethersfield, Conn., now runs a successful business of his own, and the longer he uses his Billings & Spencer Hammers the better satisfied he is with them.

This is the verdict of all users of B & S Tools. The longer you use them and the more of them you use, the better you'll like them. *May we send the catalogue?*

THE BILLINGS & SPENCER CO.
HARTFORD, CONN., U.S.A.

Riveting Both Sides at Once



This Grant Rivet Spinning Machine spins the heads on two rivets at opposite ends of the piece of work simultaneously. There's no reversing of the piece nor doing the job one head at a time—just a case of laying the work between the heads and putting your foot on the pedal. There are six 1-8 inch rivets in each one of these automatic stropping frames, and an unskilled operator heads them faster than they can be assembled by a girl.

There isn't a class of riveting where Grant machines won't fit, from work as large as agricultural implements, to as small as that of the clip cap on a fountain pen. Your work lies somewhere between these two extremes and we stand ready to demonstrate what a Grant machine will do with it. Costs nothing to have a few pieces riveted.

GRANT MANUFACTURING & MACHINE COMPANY
N. W. Station **BRIDGEPORT, CONNECTICUT, U. S. A.**

Thurlow Steel & Forging Co., Chester, Pa., has its plant in operation for manufacturing forgings, crankshafts, die blocks, bars, etc. The plant is equipped to produce forgings weighing from 1 to 10,000 pounds, the equipment including steam hammers and a 1000-ton forging press for heavy forgings and die work. Heat-treating furnaces have also been provided and a machine shop for roughing and finishing crankshafts, etc. The plant is under the management of John I. Rogers and Daniel C. Eagan.

Joseph T. Ryerson & Son, Chicago, Ill., announce the establishment of warehouses in St. Louis, Mo., for immediate service in their lines of finished steel to customers in the territory tributary to St. Louis. The plant, merchandise, equipment and good will of the W. G. Hagar Iron Co. have been taken over. The facilities of this plant will be immediately supplemented with complete modern warehouses and equipment for the handling and cutting of shapes, plates, reinforcing bars and similar heavy material.

Bertsch & Co., Cambridge City, Ind., builders of shears, punches, rolls, presses and special machinery for fabricating sheet metal, plates and structural steel, have erected new machine shop and foundry buildings. The foundry is of the monitor roof type having a fifteen-ton traveling crane in the center bay. The building is heated by hot air forced draft system. Fenestra steel window sash in the side walls and monitor admit a great volume of light. The machine shop is of the same general design, having large window area. The center bay is provided with a thirty-ton traveling crane and the building is heated and ventilated by the forced draft system.

Ansonia Mfg. Co., Ansonia, Conn., has purchased the Hampden Machine Screw Co. of Springfield, Mass., and the business and equipment will be moved to Ansonia immediately. Archibald R. Lemieux, who was secretary and manager of the Hampden Machine Screw Co., becomes general manager of the Ansonia Mfg. Co. The consolidation will enable the Ansonia Mfg. Co., maker of brass goods from sheet wire and rod, wind shields, pumps and auto accessories, to serve its customers better, generally.

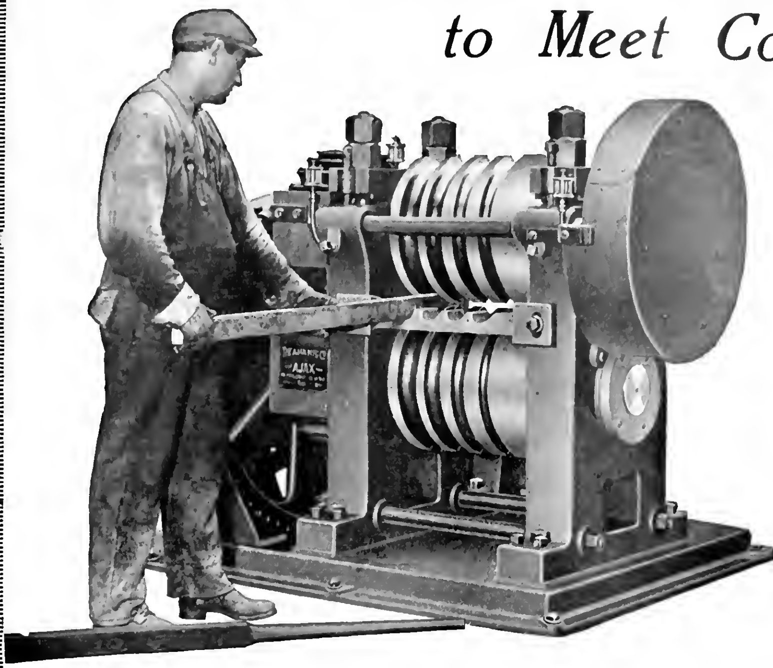
Keuffel & Esser Co., Hoboken, N. J., has moved its Chicago branch to the seven-story Keuffel & Esser Bldg., 516-520 S. Dearborn St. The company recently purchased this building and will occupy the greater part of it. It is situated near the "loop" half a block from an elevated station, mid-way between Van Buren and Harrison Sts., and near the important office buildings which house many of Keuffel & Esser's customers. A complete blueprint department has been installed, with much better facilities than that in the old location at 68 W. Madison St.

H. W. Johns-Manville Co., Madison Ave. and 41st St., New York City, is introducing a system for cooling and distributing drinking water known as the J-M system, which furnishes water at a temperature of 50 to 55 degrees F. Investigation made by Dr. Darlington, secretary of the welfare committee of the American Iron & Steel Institute, shows that water is most enjoyable at this temperature, having a stimulating action on the heart and relieving fatigue and exhaustion by equalizing the temperature of the body. The water is cooled by an A-S refrigerating machine and is then piped to bubbler fountains placed at convenient locations throughout the plant. A booklet describing the system in detail may be obtained on request.

Potter & Johnston Machine Co., Pawtucket, R. I., and the Windsor Machine Co., Windsor, Vt., have begun the erection of works at Tyseley, Birmingham, England, for the manufacture of Potter & Johnston automatic chucking machines, automatic center turning machines, automatic milling machines, automatic cutting-off machines, universal shaping machines and shaving machines, Gridley four-spindle automatic bar machines and automatic multiple-spindle drilling machines. All the foregoing machines are covered by British and foreign patents; and the establishment of the British works will enable the companies to better serve their ever-increasing number of European customers. In addition to the manufacture of the machines mentioned a specially organized toolmaking department for the prompt filling of orders for tools required by European customers will be established. The service of this department will avoid the delays caused in transport when shipped from American shops. The new works will be ready for occupancy next fall.

Billings & Spencer Co., Hartford, Conn., has bought the plant of the Columbia Motor Car Co. of Hartford, including 8¼ acres of ground. The purchase price was $350,000. The Billings & Spencer Co. has outgrown its present quarters, and the purchase of the Columbia factory will afford room for much needed expansion. The tract has a frontage of 221 feet on Laurel St. and 1024 feet on Park St. The land covered by buildings is 2.29 acres and the floor area of the building is 227,952 square feet. The plant is ideal for the manufacture of drop forgings, machinists' tools, wrenches, etc. The Billings & Spencer Co., which was organized in 1872, has grown steadily, and it turns out from 10,000 to 12,000 tons of steel forgings annually. It was founded by C. E. Billings and C. M. Spencer, who were the pioneer drop-forgers in Hartford. They were interested in the Roper Sporting Arms Co. of Amherst, Mass., maker of repeating shot guns, which concern was taken to Hartford in 1868. The newly acquired plant has excellent railroad facilities, a spur track from the N. Y., N. H. & H. R. R. running into the plant which will make the handling of heavy tonnage economical.

The Superintendent Found a Way to Meet Competition



Competition was sharp, prices were being cut and "the other fellow" was getting away with the business.

Then the superintendent saw an illustration in a trade paper that suggested something to him. He found that he could take a piece that had been laboriously tapered on the steam hammer, and produce it in less than a minute on

Ajax Taper Forging Rolls

(Trade Mark Registered)

He investigated this proposition at once and not only cut the cost on this important part of the product, but produced a forging free from hammer marks and defects which proved a valuable selling argument.

The cost of maintaining and repairing hammers, and the frequent delay in operations has also been done away with in this plant.

Even if you are not worried by competition it will pay you to investigate this method of producing the tapered pieces you use in your product.

If in doubt as to what can be done, consult the Ajax Engineers. Their advice is free and *they have to make good* on their estimates.

Here are some of the pieces successfully produced by this method:

Automobile Truck Axles.
Trolley Poles.
Drag Bars (for implements).
Seat Springs.
Wedges.
Brake Shoe Keys.
Tong Jaws.
Track Wrenches.
Brake Levers.
Ship Liners.
Gun Barrels.
Pliers.
Tubing.
Carriage and Wagon Axles.
Body Irons.
Bailey Body Loops.

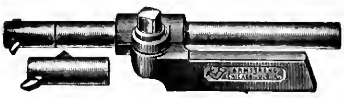
THERE'S AN

ARMSTRONG BORING TOOL

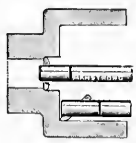
TO MEET YOUR REQUIREMENTS

Forged Boring Tools are expensive—inefficient. They are wasteful of time and tool steel and very expensive to maintain, especially if high speed steel is used—ARMSTRONG BORING TOOLS use high speed steel efficiently and economically, and are made in a range of sizes suitable for all classes of work, light or heavy.

Armstrong Boring Tools require no forging or tempering and very little grinding. They are always ready for use, are very stiff and will bore close up to a shoulder or bottom. One Armstrong Boring Tool will take the place of a dozen forged boring tools. Made in seven sizes.



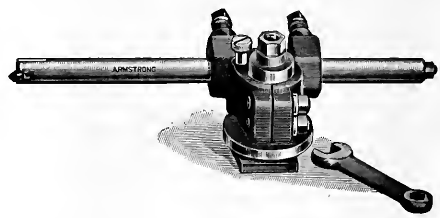
This cut shows Double Ended Cutter roughing out cored hole; also angle cutter boring and facing end.



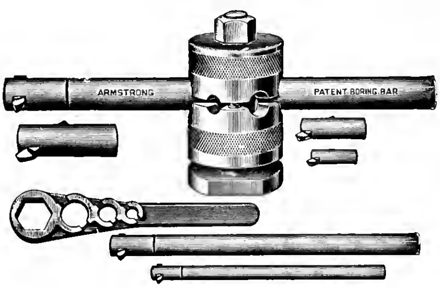
Showing Tool Cutting an internal thread

Armstrong Adjustable Boring Tool

This tool combines Convenience, Adjustability and Rigidity to a remarkable degree and is well adapted to a very wide range of work. The holder is easily adjustable to different heights and will hold bars of various diameters. The bars are made from high carbon steel seamless tubing of heavy gauge and are extremely stiff. The cutter can be adjusted and solidly fixed at various angles for Boring, Facing or Turning. Made in four sizes.



Armstrong 3-Bar Boring Tool



The many points of advantage of this lathe attachment will be appreciated by practical machinists. A slight turn of one nut releases or fastens both bar and holder. Bars can be changed as needed almost instantly, thus allowing the operator to use the stiffest bar possible for each job, with the result that speeds and feeds can be increased and time saved. Made in four sizes.

Armstrong Boring Tool Holder

This tool will be found very handy in the Tool Room or in Boring work of small internal diameter, Threading, Brass Turning, etc. The boring bars furnished are made from the best tool steel properly hardened, tempered and ground ready for use. The holder is reversible, and can be used for turning either right or left hand. Made in four sizes.

For Small, Light Boring, Threading, Etc.

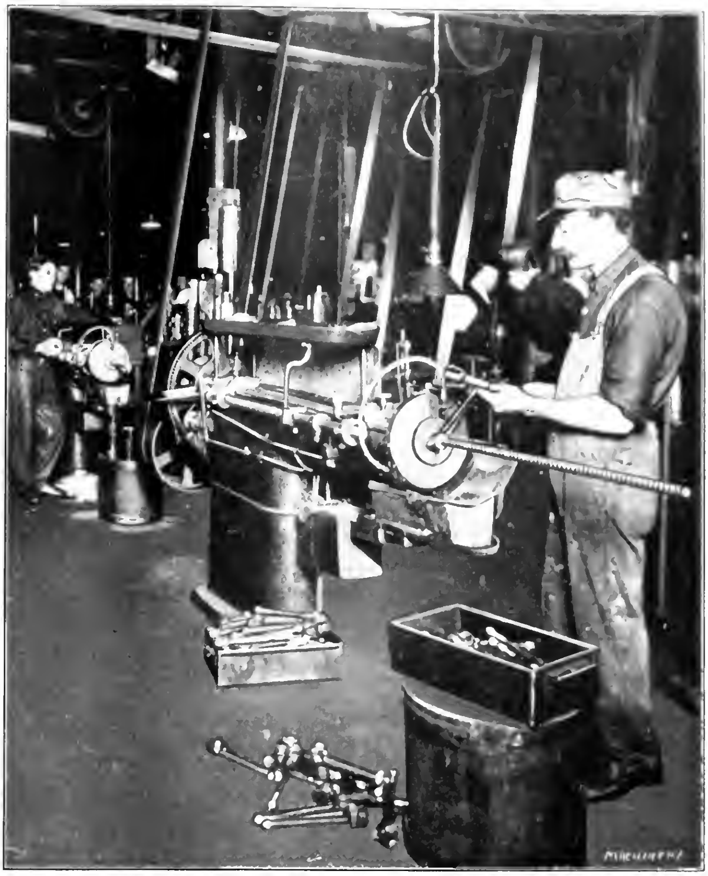
The Original Lapointe Broaching Machine and the Automobile Parts Manufacturer



A great field for the broaching machine is in the manufacture of automobile parts—and the great machine for making these parts is the Original Lapointe Broaching Machine. This is the machine which made the economical production of some automobile fittings possible—square holes, for example, in change speed gears, steering cranks, etc.

The first machine in the above illustration is in operation on steering cranks. A square hole 15-16" across the flats, 1 1-8" across the corners by 1 3-16" long is broached through this drop-forged steel crank. The machine further down the line is broaching four splines in chrome nickel steel sliding gears. These splines are 0.383" wide by 3-16" deep and 2 3-8" long.

There are many other examples; but these are sufficient to show the efficiency of the Lapointe Machine on either square, round or splined hole work. Automobile parts are broached on this machine at the rate of from 20 to 40 pieces per hour according to conditions.

Let us tell you more about the possibilities of broaching.

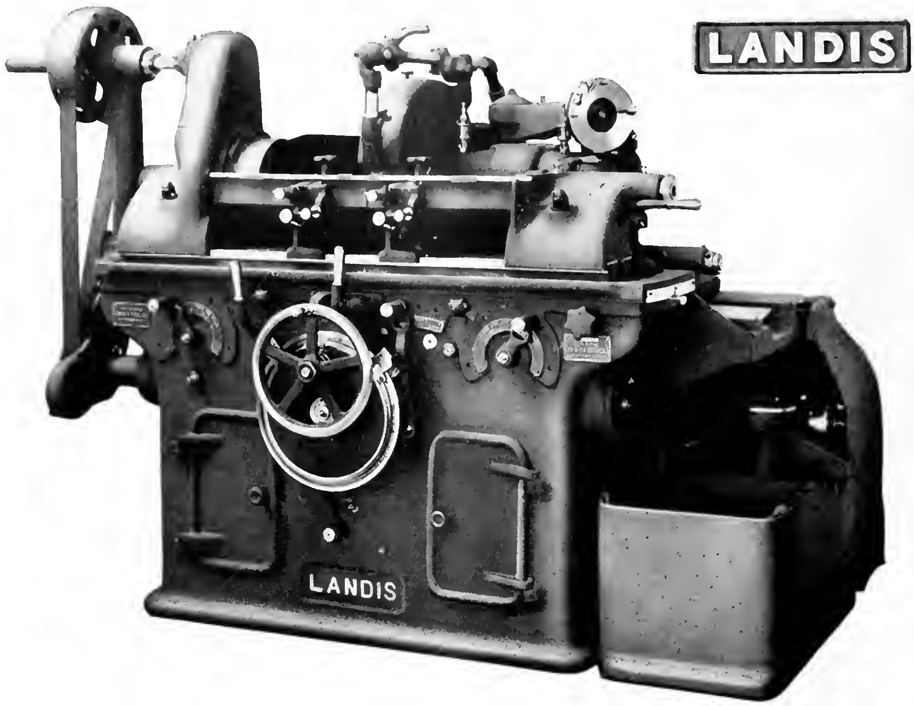
Important Development i



AN IMPROVED machine, a development, a step in advance of anything which has gone before—this is the LANDIS New Plain Grinding Machine—self-contained motor or line shaft drive, embodying the most advanced and efficient principles in cylindrical precision grinding machine design.

The general arrangement and construction are radical departures; but the original and distinguishing LANDIS feature, traversing the wheel carriage (a fixed weight), has been retained. The machine is massive in design, symmetrical in outline, convenient in arrangement of operating levers and has thorough safety protection.

Particular attention is directed to the complete belted drive for the work. Many features common to the previous types of LANDIS grinding machines are retained; i. e., the alignments are preserved by the LANDIS method of chilling such surfaces on which they are dependent; no overhanging of the work table as it is solidly clamped to the bed of the machine; all working parts or surfaces thoroughly protected from grit; centralized control, with the greatest of ease

One of Twelve

NORTON GRINDING MACHINES

in the

Willys-Garford Plant

The cam shaft in the Willys-Knight sliding sleeve motor has eight throws and three bearings, each 1 3-16″ diameter. 0.025″ is allowed for grinding, and the limit is 0.0005″. It is an accurate job first, and because it is "Norton" ground it is a profitable job, production being one completed shaft every forty minutes.

There are reasons for Norton Grinding Machine superiority. The principle of carrying the work past a fixed grinding point is right. The method of driving the wheel and the proportion and design of the carriage are carefully worked out to support this principle. Norton Grinding Machines are built with convenience of operation constantly in mind. They are accurate and convenient and rapid work producers. They carry large, heavy wheels which remove stock quickly.

These are a few of the reasons why there are twelve Norton Grinding Machines in the above plant—and why Norton machines are used by nearly all the automobile builders.

Write us concerning your grinding problems.

Look at this Combination!

A Hendey heavy pattern 24″ tool-room lathe, 8′ bed, double back gears, and equipped with type "C" relieving attachment. The lathe is built with all the care and finished with all the accuracy which are applied to and expected in every Hendey lathe.

The relieving attachment is capable of handling any work which will swing over cross slide. It will relieve either straight or spirally fluted work, formed cutters, hollow mills, right- and left-hand taps, etc.

Toolmakers are realizing more and more the value of relieved teeth in special hobs, formed cutters and taps such as they have been in the habit of making themselves, but have not been able to accomplish these results before on the larger sizes of work. This 24″ lathe meets this need in a very satisfactory manner.

Everything But the Cam At One Setting

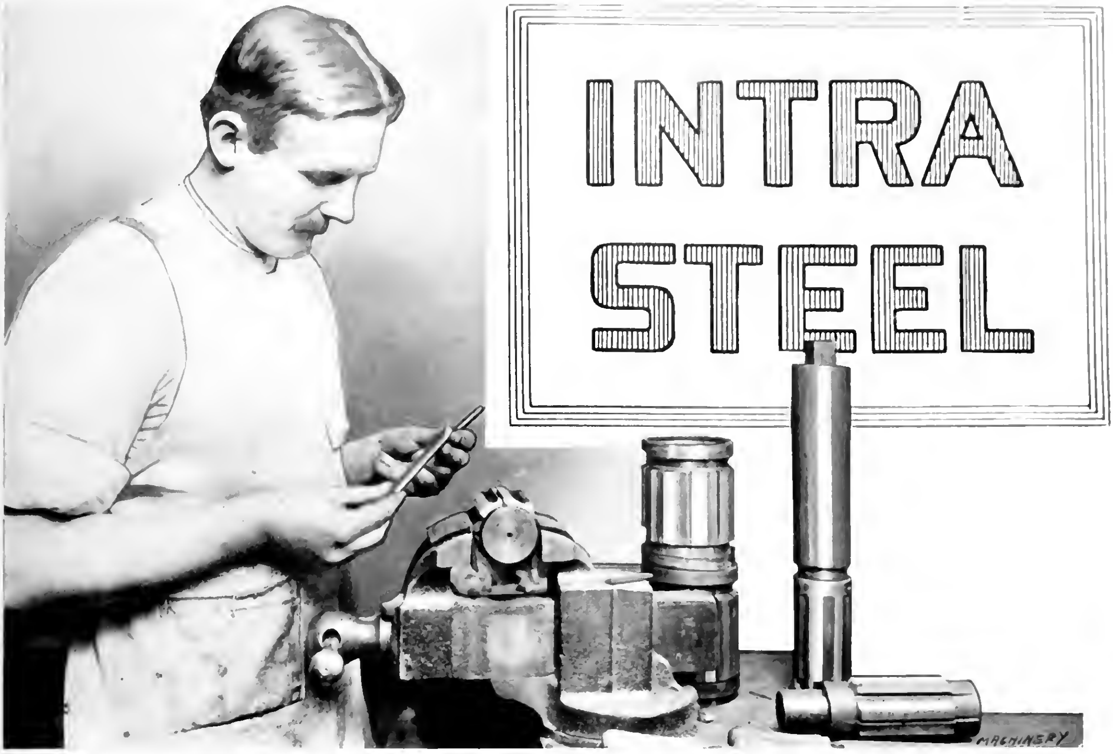
The Jackson Duplex Die Sinking Machine finishes everything but the cam on this drop forge camshaft die at a single setting of the work. You know what this means—the elimination of nearly all the bench work in die sinking and the saving of about 50 per cent in the cost of the average die. The Jackson Machine will pay for itself in most shops in a very short time. One user said: "It is a gold mine"—and he is right.

You can't afford to be without this machine. It is a big profit earner. The "cherrying" attachment enables holes to be "cherried" *below center*, and when the work leaves the machine it is finished *completely;* no hand work is necessary.

We'll gladly show you how to save 50 per cent on this work. We'll send a representative or the bulletins on request. Write us now before you forget.

JACKSON MACHINE TOOL COMPANY

JACKSON, MICHIGAN, U. S. A.



A Good Reamer is Keen Cutting, Hard, Tough

INTRA STEEL possesses every quality to make a good reamer. When soft it may be worked easily and readily. When hardened it will take the keenest kind of an edge—and hold it. It is tough and extremely hard to break, and it will withstand the most severe strains.

Isn't this the reamer you want? One which works up well and stands up well after it is hardened? The answer is obvious, *use Intra Steel.*

The manufacturer of reamers (a big, successful concern it is, too) in whose shop the above photograph was taken, says, "We can always depend upon Intra Steel from the stock to the satisfied customer."

Pass up troubles when you can, for there are many you can't. This means Intra Steel for reamers—and for many other purposes, too.

We'll send the Booklet and show you for just what uses Intra Steel is best, and why, if you'll write.

We Saved the Manufacturer Half the Cost of this Shaft

Making this little shaft for an automobile starter proved very expensive for a certain manufacturer, until Sloan & Chace were asked to take a hand. It was formerly milled from the solid—a difficult and unsatisfactory method. Our engineering staff saved practically half the cost by tooling up for two simple operations.

One was a screw machine operation which produced the plain shaft as shown; the other piece came from the punching press and was ingeniously designed so that when wrapped around the plain shaft it formed the completed starter shaft.

If your manufacturing is costing too much, let us show you a simpler method; or if you want to put more time on the selling end we have the men, machines and experience for taking over the manufacture of your entire product.

Try us on tool work. Anyway, let's get acquainted. Will you write?

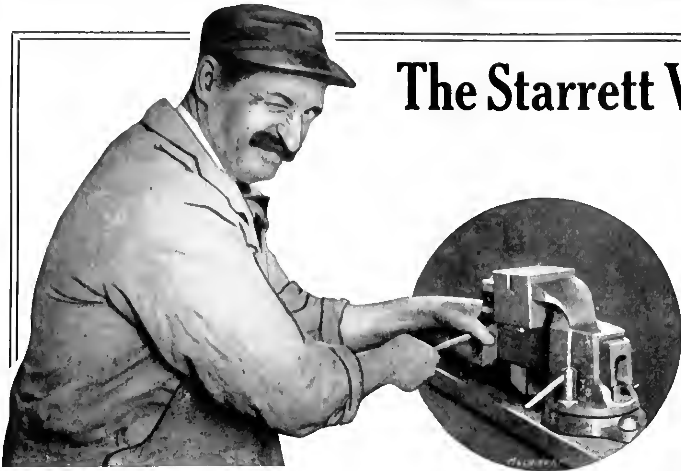
TRIMONT MANUFACTURING COMPANY

55 to 71 Amory Street **Roxbury (Boston), Mass., U. S. A.**

The Starrett Vise "Stays Put"



The new Starrett Vise with swiveled base is entirely new. Two faults are usually accredited to swivel base vises. The pin type always has backlash; the clamping bolt type has a tendency to slip. We use the clamping bolt scheme—but note the clamping bolt we use. The corrugated edges pull up in the corresponding corrugations at base of the vise; all other clamping bolts are smooth instead of corrugated.

Your strongest men cannot budge the Starrett Vise from a clamped position. Here is one of our "big fellows" trying to, but he couldn't stir it.

We make this swivel vise with that new style handle which is so popular—adjustable—any position when you need it; out of the way when you don't. *Let us send you more vise details.*

PNEUMATIC TOOLS

FOR THE

Boiler Maker—Machinist—Foundryman—Iron Worker

"Crown" Floor Rammer.

"Crown" Bench Rammer.

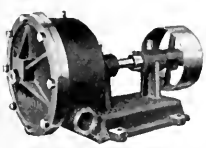
The Ingersoll-Rand pneumatic tool line is the most extensive offered the trade, and covers all the requirements of the railroad shop, the boiler shop, machine shop, foundry and iron work.

It comprises such well-known tools as the "Little David" Drills, Calkers, Riveters and Chippers, "Imperial" Hoists and "Crown" Rammers.

In the pneumatic tool field the trade names, "Little David," "Imperial" and "Crown," are recognized as representative of the very best practice. They stand for an efficiency and economy of operation unapproached by others.

In designing these tools, such factors as ease of operation, large work capacity and adaptability, low maintenance and air consumption have been so well provided for, that many plants, including some of the very largest, have standardized on them.

They are built as well as it is possible to do so. Metals of quality are used throughout; wearing parts are of hardened and ground special alloy steels, and special oil treatment of metals results in a product of exceptional lasting qualities.



"Imperial" Motor.

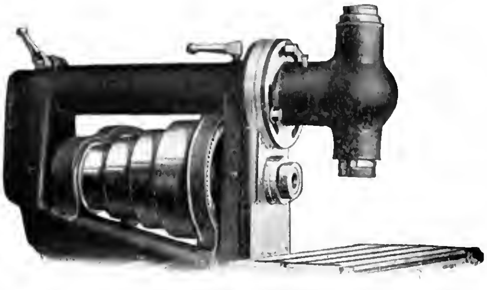
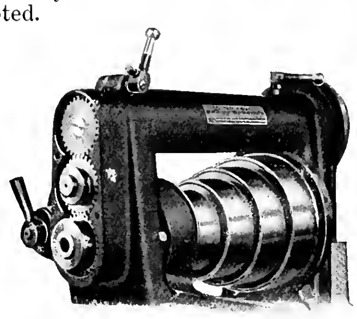
Attachments



Vertical Attachment

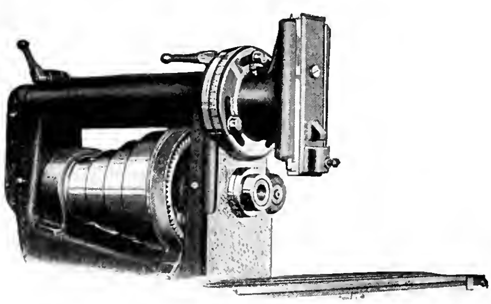
Adding a good attachment to a good machine is a step forward every time. We make *Rockford Universal Milling Machines* as good as they can be made and the attachments the same way. There is an attachment for Vertical milling that appeals where work is varied, where time is limited and where only accurate, fast machine work is accepted.



Rear view showing geared drive for attachments

There is a Slotting Attachment which widens the range, making the milling machine into a first-class Slotter in short order. With these facilities many jobs can be accomplished on the "Rockford" at one setting of the piece, which would ordinarily require several different operations.

If this outline appeals to you, send for more solid "Rockford" facts.



Slotting Attachment

Rockford Milling Machine Co.

A New Bryant Chucking Grinder—Phenomenally Fast

THIS is the new Bryant Chucking Grinder in action—a machine we furnished the Brown-Lipe-Chapin Company, Syracuse, N. Y. We have claimed it was fast—here is an example which shows just what we mean by fast.

The work is high carbon steel side bevel gears for differentials. Dimensions of hole, $1\frac{1}{4}''$ by $2''$. Production, 400 in nine hours.

Phenomenal? Yes.

If you are grinding work within the range of this new Bryant machine, we'll show you production possibilities which you probably won't believe—till we prove them. This sounds big. It is big—the biggest thing in the grinding field today.

You should know all about it. Will you write?

BRYANT CHUCKING GRINDER COMPANY

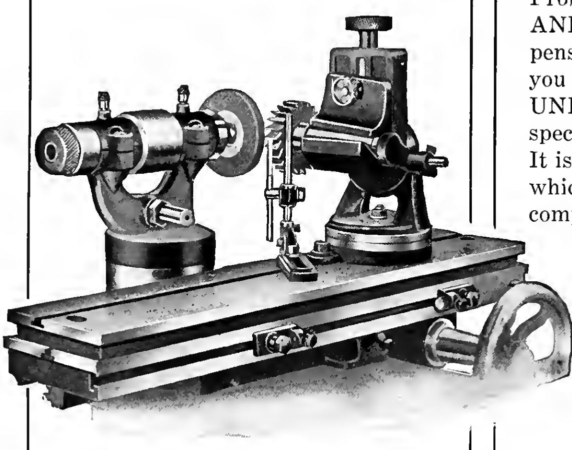
Greenfield



All Kinds of Tool Sharpening and Special Grinding.

Are You Getting Out Something New?

Probably you have a lot of SPECIAL TOOL AND JIG WORK to do. Such work is expensive, but if you have proper equipment you can keep the cost down wonderfully. OUR UNIVERSAL GRINDER handles all kinds of special grinding in a most economical fashion. It is furnished with a large line of Attachments which are simple and easy to use; there are no complicated adjustments to be made.

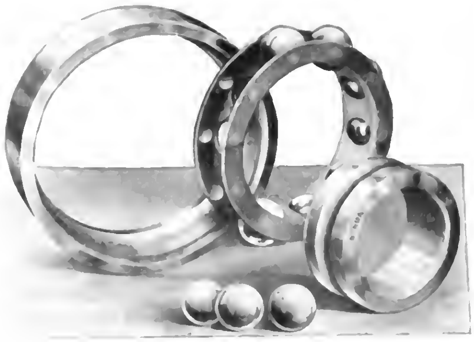
This Grinder will handle all the tool sharpening and special grinding of most shops and is very inexpensive considering its great usefulness.

We have a catalog showing each of these Attachments set up on the machine and ready for a grinding job; it might be very interesting to you; send and get it.

Greenfield Machine Co.

Greenfield, Mass., U. S. A.

The Causes and the Meaning of Noise in Ball Bearings



As you well know, Neighbor, noise in a machine is usually a danger signal. In bearings, it indicates the presence of looseness and friction that shouldn't be there. And friction, you know, means wear.

In ball bearings—which are supposed to be almost frictionless—noise is a sure sign of trouble a-brewing. Stop that noise at once—or you'll soon have to get a new bearing.

Noise results from vibration. Vibration comes—in a ball bearing—from looseness of component parts; from too much play; from imperfectly finished races; from imperfect balls; from sliding friction where rolling friction is supposed to be; from loose mounting of the bearing; and from other causes. Look out for all these—they're dangerous.

The fit of the bearing in the housing and upon the shaft is also of importance in the reduction of noise. Tight fits—rigid mounting of both races—eliminate looseness. Your question is—rigid mounting, or floating mounting?

Then, there are many types of ball retainers or cages that, in the very nature of things, are bound to create noisy conditions. Study the cage proposition and you'll know why—you'll know that a noisy bearing is a wearing, inefficient bearing.

Finally, the way a bearing is put together—the fit of the parts—their dimensional accuracy or otherwise—the way it is, or must be, mounted and assembled—the way the parts are retained (all points of design and workmanship)—determine whether that bearing is going to be noisy or to run quietly.

Consider now, Neighbor, the "**NORMA**" Ball Bearing from this standpoint of noise or silence.

In the "**NORMA**" Bearing it is almost impossible (except under misuse and abuse) to create conditions where sliding friction exists—Point One for "**NORMA**" Silence.

"**NORMA**" ball races must be rigidly mounted, outer race held tightly in the housing and inner race held without any chance of movement on the shaft. This eliminates all chance for vibration between bearing races and machine parts—Point Two for "**NORMA**" Silence.

"**NORMA**" ball cages yieldingly hold the balls at the extremities of the axis of ball rotation with a light elastic pressure and with a very small contact surface. Friction between balls and cage is minimized and vibration here absolutely prohibited—Point Three for "**NORMA**" Silence.

The parts of "**NORMA**" Bearings are uniformly made to the highest degree of dimensional precision. This means absolutely correct relations of those parts within the bearing— perfect freedom of movement without the narrow excess of freedom which permits vibration, or chattering—Point Four for "**NORMA**" Silence.

And then, the materials used in "**NORMA**" Bearings are so carefully selected in the light of bearing requirements, and so carefully treated, as to give maximum resistance to every wearing tendency which might destroy the perfect relation of parts—Point Five for "**NORMA**" Silence.

Now, Neighbor—let's get right down to brass tacks.

You want your bearings to last. They never will, if they're noisy.

You probably want them to run at high speed. They can't—for very long—if they're noisy.

You want them to run true, and keep alignment and adjustment. They can't, if they're loose—for that means they're noisy; which, in turn, means they're wearing.

What's the answer? Use "**NORMA**" Silent-Running, High-Precision Ball Bearings. Our Engineering Department is anxious to show you how.

THE NORMA COMPANY OF AMERICA

1790 Broadway New York

"NORMA"

Ball, Roller, Thrust and Combination Bearings

that Every Machine Designer Should Know

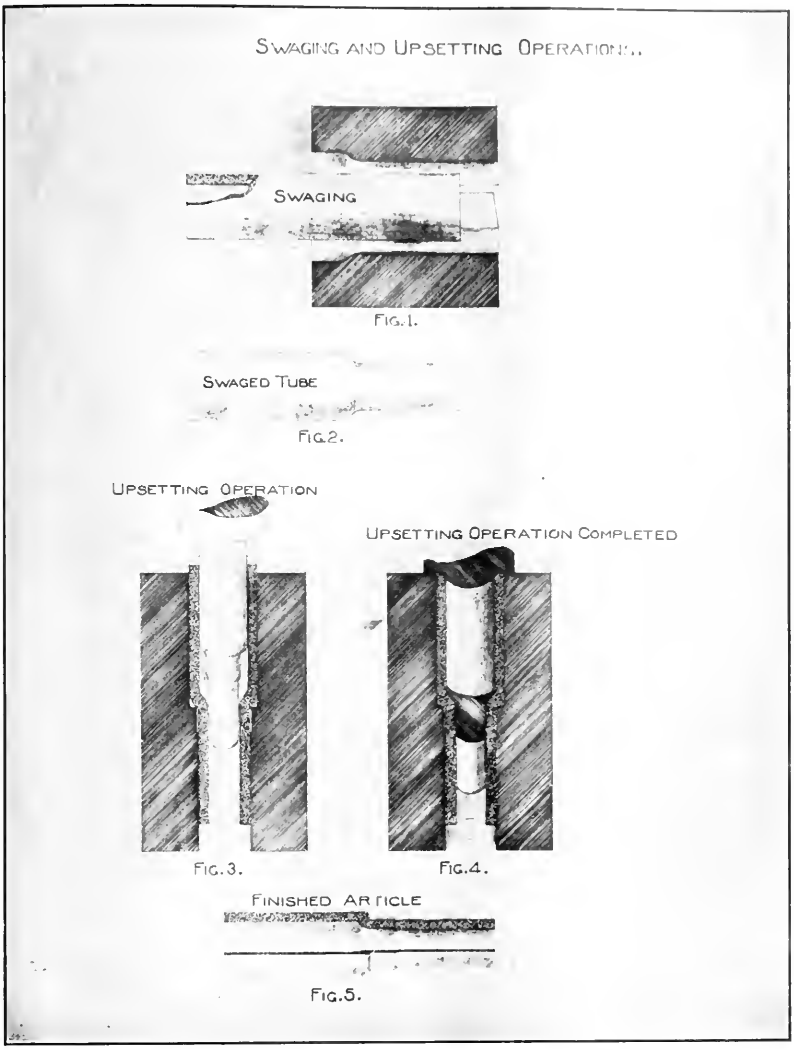


PLATE NO. 4

¶ Figure 7 (Plate 2) shows another hammering or swaging operation in a set of dies, in which the ball is rounded up so as to conform to the shape required in the finished article, figure 8 (Plate 2).

¶ Plate No. 4 shows another variation of upsetting and swaging. Here, however, the operations are reversed. The swaging, or reducing of the diameter of a portion of the tube, is done before the upsetting. The tube has three different diameters, which have to be produced with different wall thicknesses, and the most economical method of producing intricate articles is always adopted. The swaging operation, with the subsequent operation of upsetting, brings out in sharp contours the shape required in the finished article.

¶ As previously indicated, this series is designed particularly for the busy man—the illustrations suggesting (at a glance perhaps) new possibilities for Shelby Seamless Steel Tubing in machine design.

¶ Next month the operation of the spinning machine will be illustrated, and also the flow of metal during the spinning operation.

*No. 1—Facts About Shelby Seamless Steel Tubing that Every Machine Designer Should Know. (Published May, pages 152-153.)

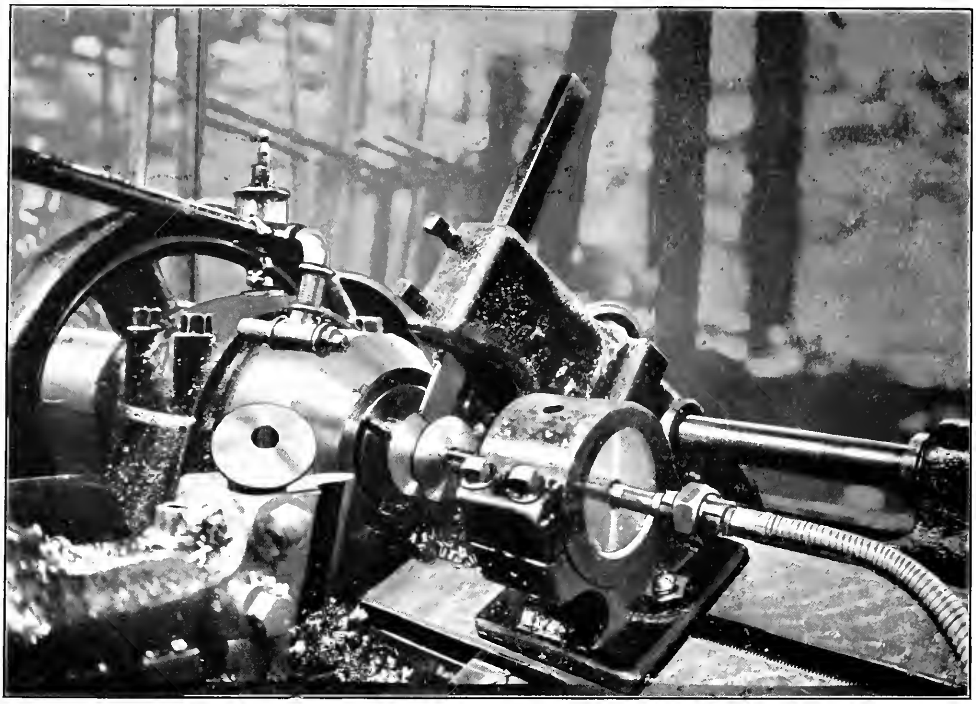
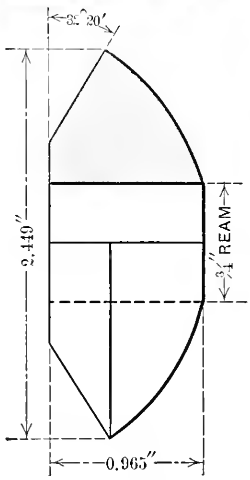
GRID AUTOM



Machining Gear Blanks on the Single Spindle Gridley Automatic



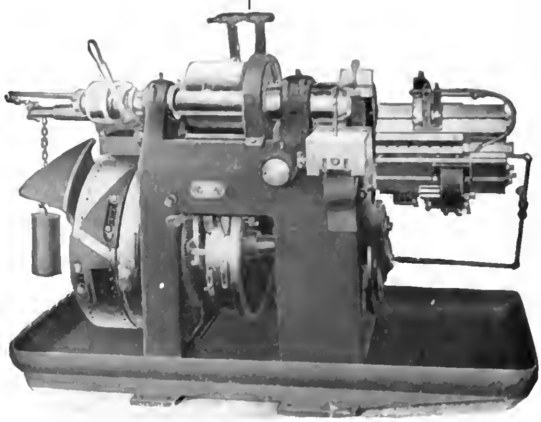
The bevel pinion shown is one of the many good jobs turned by the Warner Gear Company on Gridley Single Spindle Automatics. This gear blank is made from a 2½″ bar of 0.35 per cent carbon steel to the dimensions shown, at the rate of 157 in 10½ hours. The operations on the gear blank are as follows: Stop, spot, drill, form, ream and cut-off, and the work must be accurate in all respects. For those screw machine jobs where accuracy is absolutely necessary you need a Gridley Automatic.

WINDSOR MACHINE COMPANY,

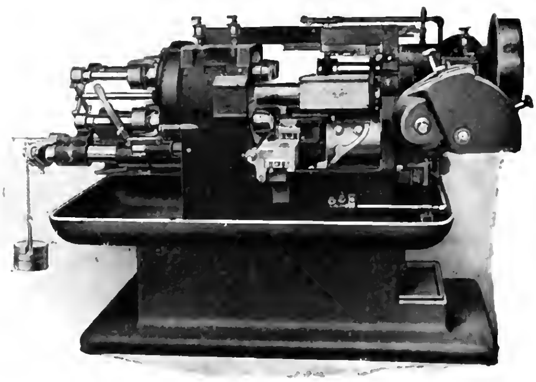
OFFICES AND REPRESENTATIVES: Western Sales Offices, 1229 McCormick Building, Chicago, Ill. Modern Machinery & Engineering Co., 1410 C. P. R. Building, Toronto, for Canada. Windsor Machinery Company, 68-Avenue de la Grande Armee, Paris, J. Ryan, Manager, for Great Britain, France, Belgium and Switzerland. Craven Bros., Ltd., Manchester, England, Great Britain and Colonies.

LEY
ATICS

The Single Spindle Gridley Automatic is built for handling a large range of work accurately. There are three sizes for handling bars up to 2¼″, 3¼″ and 4¼″ in diameter respectively. The design of the turret permits the doubling up of the tools, one behind the other, on certain work, thus affording a means for performing several operations from one turret—a great advantage where the work is long or where many different operations are to be performed. The design of this turret eliminates all overhang of the cutting tools, thus making it possible to take heavy cuts without chatter and loss of accuracy. It is adaptable to accurate work, but not at the expense of time, because the rigid machine is backed by rigidly supported tools.



Single and Multiple Spindle Gridley Automatics



The Multiple Spindle Gridley Automatic has not the range of the Single Spindle; but it is a greater producer, holding four bars of stock in the spindle carrying cylinder, which revolves step by step, bringing each spindle with its bar successively into alignment with each tool—a construction which makes for enormous outputs.

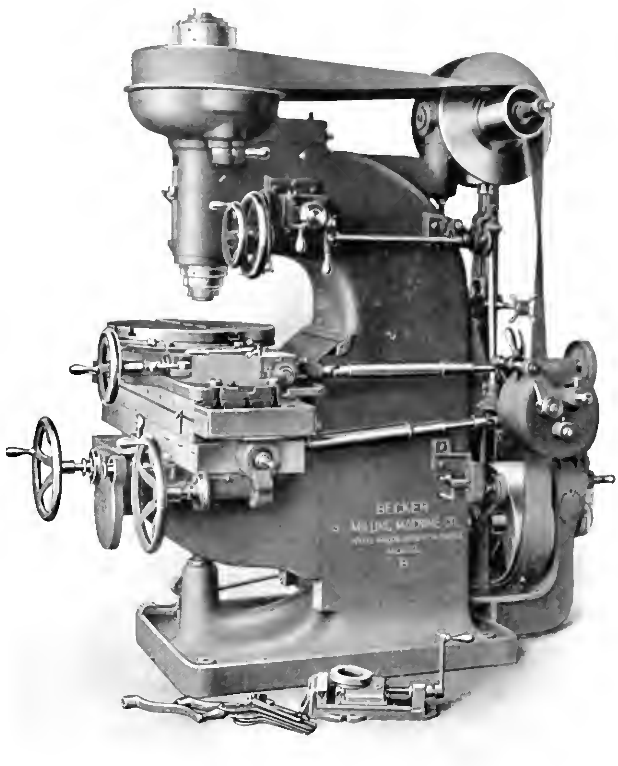
Send for complete descriptive matter on these three machines.

WINDSOR, VERMONT, U. S. A.

Chas. Churchill & Co., Ltd., London, Birmingham, Manchester and Newcastle-on-Tyne, England, and Glasgow, Scotland. M. Kretschmer & Co., Frankfurt-on-Main, Germany, for the Balkan States.

The Becker Model "B"

Made Chips Fly on This —— Job ——



THE production rate on this job is startling. It shows the great power behind the cutting tool on the Becker Milling Machine.

A Novo Superior Steel Inserted Tooth Milling Cutter was placed at a 20-degree angle, feed started at .250″ per revolution and gradually increased to .321″ at which speed the table moved at 20½″ a minute, removing 45 cubic inches of cast iron in one minute or .75″ per second. The back gear ratio was 5 to 1, the cutter diameter 6½″ with a periphery speed of 125″ and a spindle speed of 64 R. P. M. Such an arrangement produced a cut 6″ wide and ⅜″ in depth.

You, no doubt, have similar milling which could be done quicker, better and more economically on a Becker Model "B" than on any other machine. Write for full particulars.

Where Lightness and Strength Count

LIGHTNESS and strength are the essentials of good vehicle-construction. Steel gives strength, but to obtain lightness with steel construction is a more difficult matter.

So far, steel tubing has proved to be the most satisfactory material for vehicle-construction. And the most satisfactory steel tubing has proved to be

STANWELD STEEL TUBING

More Stanweld Steel Tubing is used in vehicle-construction than any other make. It is used by the world's largest manufacturer of go-carts; by the world's largest manufacturer of bicycles; by the world's largest manufacturer of motorcycles; by the world's largest manufacturer of automobiles.

Why do these people prefer Stanweld Steel Tubing? They prefer it because it combines the qualities they most require—strength and lightness. Also, Stanweld Steel Tubing has the finest finishing surface known to steel tubing.

If you are manufacturing any article that demands these qualities, investigate Stanweld Steel Tubing. We can bend it to almost any form. We can furnish it in almost any length. We can size it to the thousandth part of an inch.

You can buy it plated in almost any finish, or enameled in almost any color. You can get finished tubular parts of the most intricate design. You can get many shapes and sizes—oval tube, square tube, reinforced tube, tapered tube, in fact, almost anything you require in the steel tubing line.

Our facilities are practically unlimited, and we think you'll find our costs surprisingly low.

Send a letter or post-card today.

your screw thread work to the

Wells Self-Opening Die

adaptable to

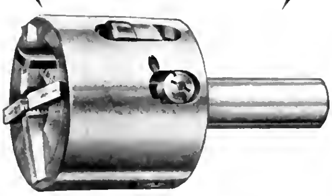
Turret Lathes, Engine Lathes,
Automatic Screw Machines,
Hand Screw Machines,
Drill Presses,
Bolt Cutters,
Etc.

SPEED

In one case thousands of screws were made by mistake with a set of carbon steel chasers at an exceptionally high speed, the machine operator believing that the chasers were of high-speed steel.

The *work* is exceedingly good. The *chasers* show no sign of the unusual strain.

The cause? The adjustment of chasers to the body part *after* they are hardened, and a support behind them directly opposite the cutting teeth.



Patented August 2, 1910

ENDURANCE

Several hundreds of thousands of small, difficult screws have already been produced with one Wells Self-Opening Die on an automatic screw machine, and the die is *still working*, turning out work as well as ever.

Several sets of chasers have been used up. Several more will be. But the Die is just as good as the day it started.

The cause? Correct design—placing the *wear* where it does not affect the accuracy or the life of the tool.

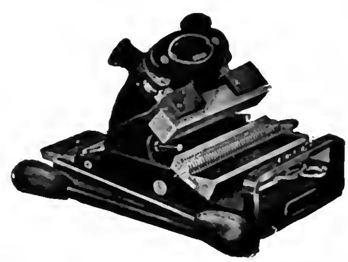
Still Worrying Along With the Old Rawhide?



If so, why? You know the time it takes to lace a belt properly by the old method. You know every minute wasted is a minute lost. You know belts must stretch —that they do break.

Why not clip the waste time with a "Clipper" Belt Lacer outfit. Over 20,000 are in use, most of them installed within the past three years.

The "Clipper" system is rapidly replacing every other method of belt fastening. The machine is light, substantial, operated successfully by any one, even the boy. The fastening is durable, flexible, low in cost and quickly made.

"Clipper"

"COES"—THE LEADING WRENCH

"Coes" Genuine Wrenches have held front place for more than seventy years—in spite of the sharpest competition and the most persistent imitation.

Stronger than other wrenches, they are more efficient—made in a wide range of sizes, they are more adaptable to requirements.

Simplest in design and construction, they stand hard usage and hold their own under all conditions.

Three Styles in "Coes"

The Knife Handle "Coes" for general utility 6″ to 21″ sizes—hard-wood handle, head and bar in one piece.

The All Steel "Coes," for extra hard service—construction, steam, water 4″ to 21″ sizes.

The Key Model "Coes," for the engine room and railroad plant—the largest of the "Coes" wrenches—28″, 36″, 48″ and 72″ sizes.

Pick your "Coes" and order by name from your dealer.

Coes Wrench Company, Worcester, Mass.

AGENTS: J. C. McCARTY & CO., 21 Murray Street, New York. 438 Market Street, San Francisco, Cal. 1515 Lorimer Street, Denver, Colo.

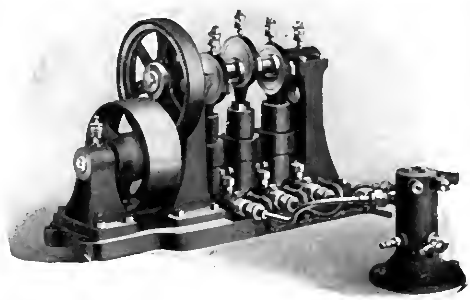
Dudgeon Appliances

Hydraulic Pumps, Jacks, Rail-benders—hydraulic machinery of all kinds bearing the name "Dudgeon" can be relied upon to give positive satisfaction.

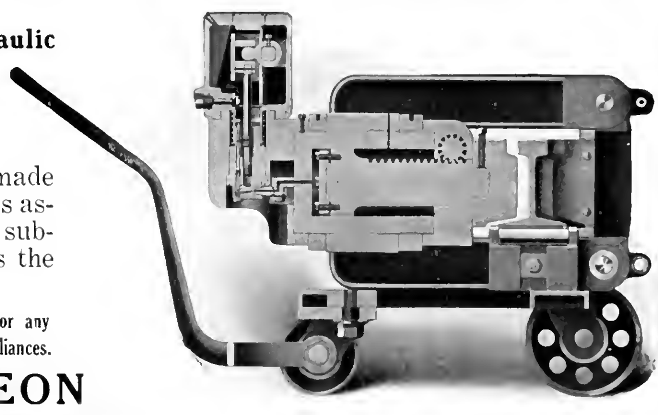
The Triple Plunger "Dudgeon" Pump for instance, has the durability to stand continuous "twenty-four-hour-a-day" service and still uphold the Dudgeon reputation for quality service.



TRIPLE PLUNGER PUMP

The "Dudgeon" Universal Hydraulic Girder and Rail-bender is so constructed that the ram can be run against the work by a rack and pinion; the first stroke is therefore made under pressure. Double pumps assure rapid operation, and a substantial clamping device holds the work firmly.

If heavy castings must be lifted, materials bent or any hydraulic force employed, use "Dudgeon" appliances.



HYDRAULIC RAIL-BENDER

RICHARD DUDGEON

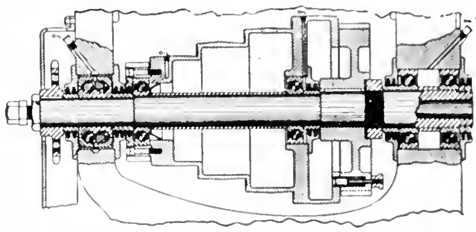
YOU WILL DO BETTER WHEN YOU ORDER

"TOLEDO CRANES"

THE TOLEDO BRIDGE & CRANE CO.

2950 Dorr Street TOLEDO, OHIO



In this application of New Departure ball bearings, the front end of the spindle is supported by two New Departure Single Row bearings of heavy series, the outer races of which float so that they take only radial loads. The rear end of the spindle is mounted on New Departure Double Row bearing so clamped that it takes all thrust on the spindle and carries the radial loads as well. The pulley cone, mounted on a Single Row ball bearing, turns with minimum friction when the back gears are thrown in on heavy cuts.

New Departure Ball Bearings

in Milling Machine Head

Ball Bearings can be as successfully applied to milling machinery as they have been to drilling appliances. The use of ball bearings in machines of this type reduces power consumption and increases production capacity. In the example shown above, New Departure Double Row or combined radial and thrust ball bearings are used to excellent advantage.

Other applications of New Departure ball bearings to machine tools are shown in data sheets which will be mailed free to manufacturers, purchasing agents, mechanical engineers, master mechanics, etc., writing on the letterhead of their firm.

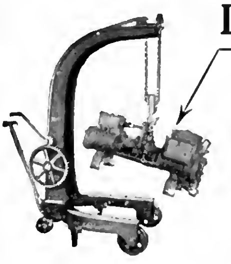
WESTERN BRANCH: 1016-17 Ford Building, Detroit, Michigan

It Would Require Six Men to Lift this Casting



Can you afford to take six men away from their regular work just to carry some heavy casting to a machine? Not when a Canton Portable Crane and one man can do the work, not an experienced, high-priced man at that.

Canton Floor Cranes are well built, simple to operate and they sure can lift. Prices are reasonable. Ask for Booklet E-10, when writing.

THE CANTON FOUNDRY & MACHINE CO.

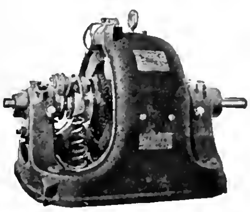
CANTON, OHIO, U. S. A.

John Has Never Scrapped a Westinghouse Motor

"IT'S OLD, BUT IT'S STILL ON THE JOB."

"JOHN," said the manager to the superintendent, "that's a pretty old motor we have there. I got it when we started business fifteen years ago."

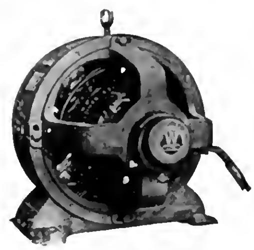
"It's old," replied John, "but it is still on the job and is good for several more years. That's what I like about Westinghouse motors. They're not only good when you get them, but they stay good. Why, as long as I've been here I've never scrapped a Westinghouse motor.



The old Westinghouse Type M Motor which has an international reputation for reliability and good service.

"And these modern Westinghouse motors we have here with their rolled steel frames and sparkless commutation are better in every way than the old types. I expect your children's children can come here and find these motors still working."

Westinghouse motors are built for long life. Every detail of the design is the result of years of experience in motor building. The use of the highest grade of materials, expert workmanship, rigid inspection and thorough tests before shipment, insure the purchaser receiving apparatus of greatest reliability.



The modern Westinghouse type SK commutating pole motor.

FOR ALL PURPOSES

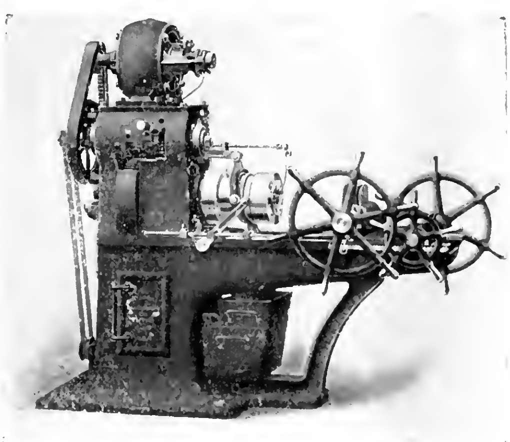
The National Bolt Cutter

always cuts perfect threads—uniform in diameter and accurate in pitch, no matter what class of threading, what quality of material, or what variation is encountered in diameter or hardness of the stock.



The National Die Head has a positive lock that makes it as rigid as a solid die, and insures the same high degree of accuracy in cutting. Once set for size, the National Die Head retains that size until changed by the operator. This eliminates constant gauging and frequent adjustments on the Head, hence eliminates this element of waste time by the operator, and insures greater output.

Leading Railways and Industrials are using National Bolt Cutters, and many shops are installing National Die Heads on other types of Threaders to secure bigger output and greater accuracy.

National Bolt Cutters are built in sizes of $\frac{3}{4}$ to 6 inch capacity, single, double, triple and quadruple spindle, belt or direct motor drive.

Ask for Bulletins Nos. 10 and 20 on National Bolt Cutters, and let us assist you in eliminating your threading difficulties.

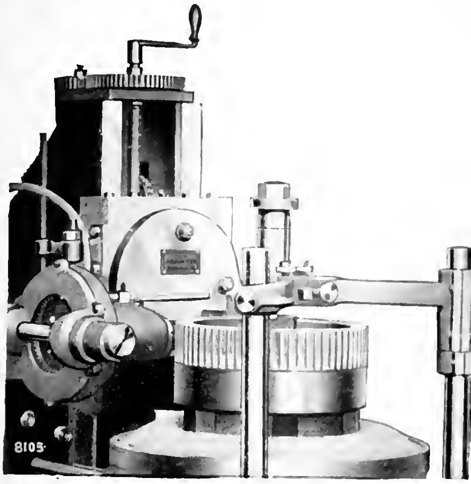
The Edgemont Machine Company
2700 National Avenue DAYTON, OHIO, U. S. A.

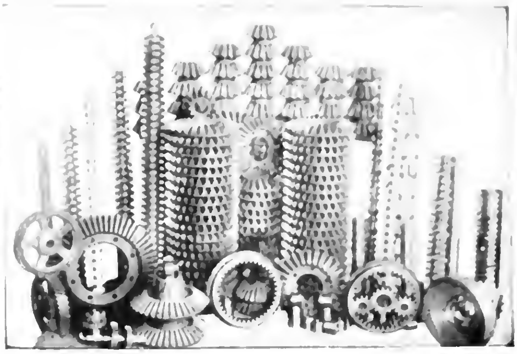


In Cutting a Sixty-Tooth Gear

on an old-style Automatic Gear Cutter the cutter head stops, backs up, the blank indexes and a new cut is started sixty times. On a Farwell Gear Hobber this happens just ONCE for each gear or arbor full of gears, no matter how many teeth there are. This is one reason for our big outputs.

Write about it today.

The Adams Co., 972 Market Street Dubuque, Ia., U. S. A.



Products of the Foote Plant

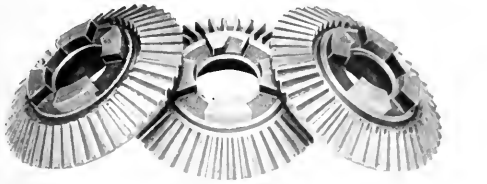
GEARISMS

Published by the Philadelphia Gear Works
1120 Vine Street, Philadelphia, Pa.

VOL. II AUGUST, 1914 No. 10

DEVOTED *to the* INTERESTS *of* GEAR USERS EVERYWHERE
Edited by the Little Gear Man



At the Top

MOUNTAIN climbing is similar to building a reputation in the business world. There are many obstacles to overcome; it takes lots of determination and there are times when it seems as though the top were as far away as when you started; but once it is reached the reward is ample for all your efforts. After years of climbing, the Philadelphia Gear Company is able to say:—"There are none above us in point of service."

Let us handle your next gear cutting order and you'll see why we are "at the top" in our particular line.

Conditions Which Govern Gear Design

The gear designer bases his choice of materials and dimensions on the considerations of strength, durability, smoothness of action, noiselessness and cost. Gearing cannot be perfect in all these respects, as some of them are mutually hostile. Cost, for example, must be sacrificed if gain is to be made in other directions. The designer must compromise—rely upon judgment and experience in determining the relative importance of various requirements. Strength, however, must be the prime consideration, for if the teeth of a gear are not strong enough to transmit the power required, they will break, and all other advantages are lost. Durability is usually sufficient if strength is sufficient, though high-speed gearing may wear out before it breaks. Smoothness of action is coincident with high efficiency and silent running, and this latter is largely a matter of selection of materials, provided the teeth are formed to the correct tooth curves.

Our Engineering Department is at your service—use it.

Wherever a Leather Belt Can be Operated to Advantage

a Gilbert Wood Split Pulley can be used successfully. Style A, illustrated, is built for extra heavy service—main drives, trip-hammers, dynamos, etc. We guarantee

STYLE A

GILBERT WOOD SPLIT PULLEYS

for the work specified—no matter how severe the requirements. Being much lighter than either solid or split iron or steel pulleys, less expensive shafting and hangers may be used with equally satisfactory results. Less weight on the bearing reduces frictional loss in power, and the hard maple wood rim assures perfect belt contact and allows the pulley to run with absolute safety, at from two to three times the speed of the best iron pulleys.

DIXON'S

Graphite Cup Grease

This line is made in a wide variety of grades—uniform as to quality, but differing in hardness for various classes of service.

Only the finest of mineral oils are used, with their lubricating qualities made more lasting and effective by the admixture of the right proportions of Dixon's fine flake graphite.

They never turn rancid or gum up—are not greatly affected by changes of temperature — the graphite veneer built up on the bearings may be depended upon to give perfect lubrication at all times and under all conditions.

Dixon's Graphite Greases need no special handling—they can be used in ordinary grease cups or in open bearings.

If you are not sure just what grade of Dixon's you need for your work, write us as to the service involved and we will recommend the proper grease—will send you a trial sample if you wish.

Send for Booklet No. 74 on "Graphite Cup Greases."

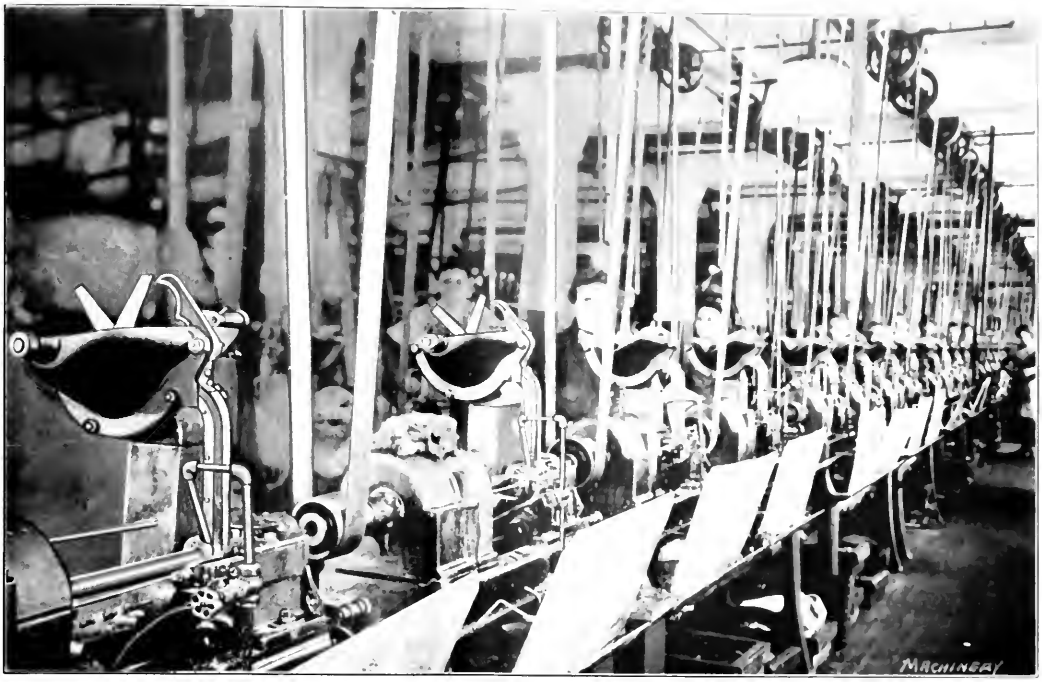
Don't Waste Time Figuring

The index table tells at a glance just the right speed to run an "Albany" High Speed Drilling Machine. The micrometer depth gauge tells when the hole has been drilled deep enough, and the special friction drive is very practical. Prominent among "Albany" features are: "Rapidity of stopping and starting the spindle; speed with which drills and chuck can be changed, and closest accuracy when drilling to the correct depth.

Latest catalogue fully describes the machine. May we mail a copy?

Albany Hardware Specialty Mfg. Co.
ALBANY, WISCONSIN, U. S. A.



A Battery of Eighty "ACME" Semi-Automatic Nut Tappers

We furnished this battery of eighty Acme Semi-Automatic Nut Tappers to a large manufacturer in the Middle West, where these machines are used for tapping nuts from 1-2" down to 3-16". The photograph shows a row of machines at work on 1-4" and 3-8" stove and carriage bolt nuts, and a production of 30,000 1-4" nuts in ten hours is secured from each machine. Each operator attends to four machines, making the labor cost less than 1 1-2 cents per thousand.

Each machine has three spindles and three taps; but only one spindle and tap is in operation at a time. The nuts are automatically fed to the revolving tap from the bottom of a hopper and when the top shank is full the turret automatically indexes, bringing the next spindle and tap into action. The operator loosens the set-screw holding the shank and unloads the tapped nuts, then replaces the tap in the spindle. When the tap in operation is filled the turret again indexes, this sequence of operations being repeated continuously.

There is no backing taps out of the nuts the spindles are non-reversing, hence good threads are produced. All the operator does is keep the hopper filled and remove the taps when they become filled.

For the cheap manufacture of nuts with good threads these machines have no equal. Let us send circulars describing them in detail.

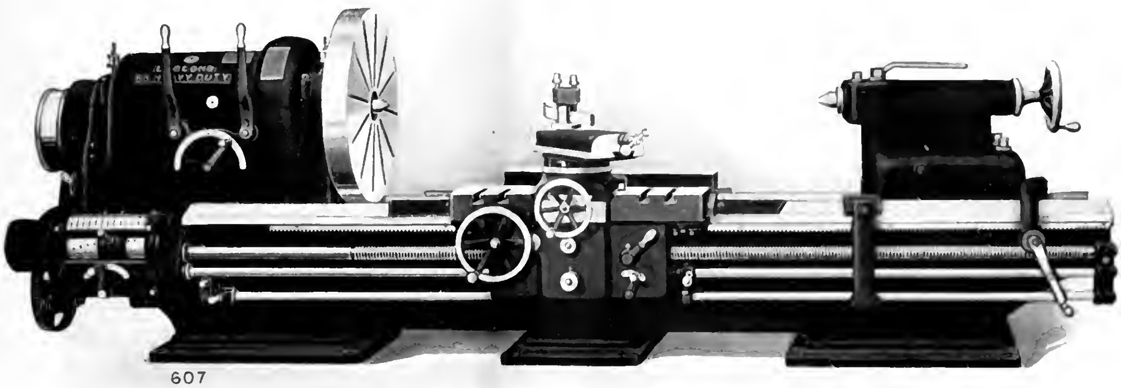
IT IS ONLY LOGICAL THAT LeBLOND HEAVY DUTY LATHES PRODUCE MORE WORK



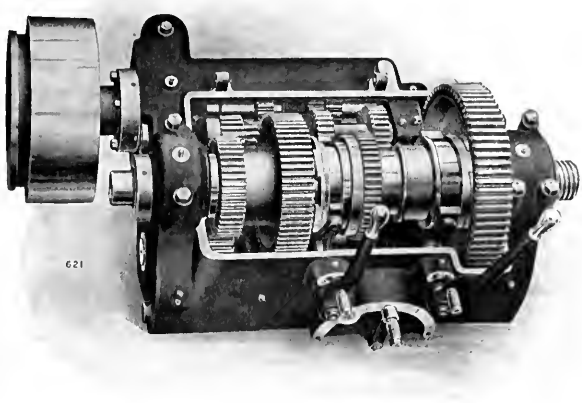
LeBLOND 30-INCH HEAVY-DUTY LATHE WITH SINGLE PULLEY DRIVE GEARED HEADSTOCK

They Produce More Work Because They Are Built For It

The powerful geared headstock, the single piece box section apron with only seven gears (all drop forged), the patent compensating vee bed section with twice the carriage bearing surface found on any other lathe of the same size, are factors—big factors—in determining production.

THE HEADSTOCK

The headstock is simply an automobile transmission in principle, carried out several steps and back geared to provide twelve changes of speed. The sliding gears and their mates, as well as the jaw clutches, are three and one-half per cent nickel steel, heat treated, with strengthened stub form teeth; in other words, practically indestructible. The shafts are short and rigidly supported, the driving power is tremendous—all that the modern tool steels can utilize. The changes are made instantly by the simple movement of three levers conveniently placed, while the spindle is started and stopped from the apron, introducing a new degree of convenience.



INTERIOR VIEW OF HEADSTOCK

If you need a Lathe at all, you can't afford to overlook the LeBlond heavy duty.

Threading Insurance
Threading screw machine work by the Acme Multiple Spindle Automatic Method is really an independent operation.
In operation one of the four spindles is held stationary and the advance of the die or tap is regulated by the lead of the thread itself and the size and hardness of the material cut. The threads are uniformly full and clean—just as a good mechanic would cut them by hand.
While the thread is being cut the other operations up to as many as 6 or 8 are also made, so that the time of one operation the longest—completes the job. When threading is the longest cut it can be shortened to the time of running on the tool by using the NAMCO Self-Opening Die.
If you are interested in good threads, more of them, and a lower cost per piece on your screw machine work, send along your samples or blue prints for Acme estimates.

Rivett High Speed Internal Grinding

High speeds—productive speeds—are possible with the Rivett Internal Grinder because of the patented spindle construction. 10,000 to 30,000 revolutions per minute are obtainable on these machines without heating up the spindles, provided, of course, they have been properly oiled and adjusted. For such work as gages, automobile bearings, rollers for sewing machines and other small, accurate work these machines are without an equal.

In the Ford (Detroit) plant, Rivett Internal Grinders are used throughout the various departments. These machines fill an important place, especially in the tool-room. The photographs show one No. 3 and one No. 4 Rivett Internal Grinder, one being used on internal work and the other on tapered external work.

We guarantee Rivett Internal Grinders to grind a hole 0.010" in diameter as true and as easily as a larger hole can be ground. It matters not whether you want production or accuracy; Rivett Internal Grinders will give you both. Let us get together on your requirements.
